ACKNOWLEDGMENTS

North Pacific Research Board expresses deep appreciation for the enthusiastic cooperation and unwavering commitment of BOEM staff to partnership with NPRB on the Arctic Integrated Ecosystem Research Program. In particular, NPRB expresses thanks to the following individuals who were BOEM staff in the early stages of development of this partnership and/or participated actively throughout 2016-2021: Dee Williams, Cathy Coon, James Kendall, Rodney Cluck, Walter Cruikshank, Guillermo Auad, Rick Raymond, Sean Burril, Lorena Edenfield, Heather Crowley, and Paula Barksdale.

Contents

List of Abbreviations and Acronyms

Arctic IES	Arctic Integrated Ecosystem Survey

RFP	Request for Proposals
SOAR	Synthesis of Arctic Research
SSC	Science Steering Committee
UAF	University of Alaska Fairbanks
USFWS	U.S. Fish & Wildlife Service

1 Introduction

North Pacific Research Board (NPRB) and the Bureau of Ocean Energy Management (BOEM) entered into this Cooperative Agreement to support the Arctic Integrated Ecosystem Research Program (Arctic IERP, www.nprb.org/arctic) in partnership during 2016-2022. NPRB provided administration of the research program under this Cooperative Agreement as detailed in this report.

The Arctic IERP involved the integration of multiple streams of marine data, from physical forcing factors to the processes driving marine ecology, human dimensions and ecosystem services. The geographic scope of the program included the northern Bering Sea, Bering Strait, Chukchi Sea and the adjacent Beaufort Sea. Research from this multilateral collaboration supported mutually-identified information needs on the physical, biological and social processes in the Arctic marine environment to improve BOEM's scientific understanding of large marine ecosystem dynamics.

The Arctic IERP was led by NPRB and included partnership with BOEM, the North Slope Borough/Shell Baseline Studies Program, and the Office of Naval Research (ONR) Marine Mammals & Biology Program. The proposals funded under the Arctic IERP brought generous in-kind support from the National Oceanic & Atmospheric Administration (NOAA), University of Alaska Fairbanks (UAF), U.S. Fish & Wildlife Service (USFWS), and National Science Foundation (NSF). The program was developed in coordination with the Interagency Arctic Research Policy Committee (IARPC) and the U.S. Arctic Research Commission (USARC).

Since 1974, the BOEM Alaska OCS Region has produced a collection of studies in the Arctic to conduct interim baseline research and monitoring in fields of interest that include: meteorology, ice dynamics and basic oceanography, benthic fauna and sedimentation, marine mammals (including whales, walrus, seals, and polar bear), fish, birds, and social systems. Most of the projects have exhibited complex, multilateral collaborations with explicit inter-disciplinary linkages between the physical and biological sciences. These types of studies have pursued multi-year data collection efforts on a regional scale, with careful attention to inter-annual variability and ecosystem processes.

NPRB staff discussed the IERP model with BOEM staff at the Alaska Region and Headquarters and expressed interest in establishing a partnership to address mutual needs for information. These conversations are described in more detail in section 2 of this report that provides a brief history of the development of the partnership that enabled this Cooperative Agreement.

BOEM and NPRB built upon synthesis projects such as the "Synthesis of Arctic Research (SOAR)" and the "Pacific Marine Arctic Regional Synthesis (PacMARS)" to examine areas where collaborative studies could enhance informed decision-making on the sustainable use of marine resources. The multiple tasks of this collaborative effort included several individual study proposal topics of high interest to BOEM, such as: the influence of sea ice dynamics and advection on biotic phenology, magnitude and location of primary and secondary production; distribution and life history of upper trophic predators in response to availability of lower trophic prey resources; and quantification of rates of consumption, growth, and reproduction of benthic and pelagic organisms.

A representative of BOEM was invited to participate in the NPRB Science Panel and Advisory Panel review of proposals that NPRB received in response to a request for proposals (RFP). The BOEM representative shared the perspectives of the agency with NPRB during NPRB's discussion of the proposals and NPRB took that information into account when making funding decisions.

The overarching research question addressed by the Arctic IERP was the following:

"How will reductions in Arctic sea ice and the associated changes in the physical environment influence the flow of energy through the ecosystem in the Chukchi Sea?"

The Arctic IERP provided funding for the following scientific research projects:

- Arctic Shelf Growth, Advection, Respiration, and Deposition Rate Experiments (ASGARD)
- Arctic Shelf Growth, Advection, Respiration, and Deposition Rate Experiments (ASGARD): Marine Mammals
- Arctic Integrated Ecosystem Study (IES): Oceanography & Lower Trophic Levels
- Arctic Integrated Ecosystem Study (IES): Upper Trophic Levels
- Chukchi Coastal Communities' Understanding of and Responses to Environmental Change

This report on the Cooperative Agreement between BOEM and NPRB for the administration of the Arctic IERP includes reports on the scientific research projects identified above as appendices.

The Arctic IERP represented a direct investment of >$18.6 million to support the five scientific research projects above. The Arctic IERP also served as a nexus to support broader collaboration during 2016-2022 and several other Arctic research projects participated, many of which were supported by BOEM. These collaborations are described in the science reports, and the significant results of some of these collaborations are published in individual chapters in the science reports or in peer-reviewed manuscripts in a series of special issue publications in *Deep-Sea Research II* organized by NPRB.

2 Partnership Development

NPRB strives to fund IERP research in partnership with other agencies and institutions. Integrated multi-disciplinary marine science programs conducted in Alaska waters are expensive and require several million dollars to support. NPRB seeks to ensure that research programs of this scale address the needs of other agencies and organizations. To facilitate partnerships and ensure that these programs reflect the insights and interests of co-funding agencies, NPRB welcomes direct engagement in establishing research priorities and in developing the RFP, the implementation plan, and outreach activities. This is intended to leverage the valuable perspectives of other institutions and ensure that the research remains relevant to the missions of other agencies and organizations.

NPRB approached partnerships with engagement from the outset. Well in advance of the research program launch, NPRB staff began discussing research priorities with a wide range of relevant agencies, regional entities, and other potential partners, including BOEM. Discussions between NPRB staff and BOEM staff were initiated in 2011, more than five years in advance of the Arctic IERP launch in 2016. NPRB staff initiated a series of meetings with BOEM staff in both the Alaska Regional Office in Anchorage and at BOEM Headquarters in Washington, D.C. NPRB staff traveled to meet in person with colleagues at BOEM Headquarters on multiple occasions and met with BOEM staff in Anchorage regularly during the five years prior to the initiation of the Arctic IERP and this Cooperative Agreement. This high level of interaction was designed to ensure that those making budget decisions at every level of the agency understood the unique value of the NPRB IERP model and how the outcomes would provide information necessary to meet the BOEM mission.

Ultimately, this collaboration led to the development of a profile for "Collaboration with North Pacific Research Board (NPRB) Arctic Marine Research Program" that was incorporated into the FY15 BOEM Alaska Annual Studies Plan. NPRB responded to this profile with the proposal that was funded under this Cooperative Agreement.

As stated in the profile objectives, NPRB successfully "buil[t] upon existing working relationships with NPRB, NOAA, USGS, AOOS, industry and others by establishing financial cooperation, coordinated Request for Proposals, data sharing agreements, and logistical support agreements"... to establish a "new collaboration [that] involve[d] established funding partners and existing research implementation strategies (e.g., IARPC, Arctic Council, Distributed Biological Observatories) to form interdependent but linked studies to examine physical, biological, and social processes".

This high level of engagement with BOEM was maintained throughout the collaboration. Prior to the solicitation of research proposals, NPRB staff shared drafts of the Request for Proposals (RFP) for the Arctic IERP with BOEM staff and welcomed input. Prior to decisions on funding, NPRB also invited a BOEM Representative to observe the proposal review discussions at the NPRB Science and Advisory Panels. A BOEM representative was also invited to join the May 2016 NPRB Board meeting and used that opportunity to comment on proposals and express the BOEM perspective about the value and relevance of the proposed research to the BOEM mission. While BOEM did not vote on funding decisions, the NPRB Board seriously considered all comments voiced by BOEM prior to determining funding. BOEM Alaska Region staff actively participated throughout the Arctic IERP 2016-2021, participating in Principal Investigator meetings, and coordinating regularly with NPRB staff to stay apprised of progress and significant emerging results.

NPRB greatly appreciates the enthusiastic cooperation and unwavering commitment of BOEM staff at all levels throughout the development and implementation of the Arctic IERP.

3 Coordination Meetings

NPRB hosted coordination meetings throughout the Arctic IERP 2016-2022 to ensure coordination among all participants. Meetings included a kickoff meeting to begin coordination among the scientists; logistics meetings prior to each field season (2017-2019); hub meetings to facilitate communication with Alaska communities; annual Principal Investigator (PI) meetings; monthly Science Steering Committee (SSC) meetings; monthly PI calls/virtual meetings; Communications Working Group meetings; and funding partner coordination meetings. More detail about each of these coordination meetings is provided below. The agendas for some of these meetings are available on the Events & Meetings section of the Arctic IERP website.

3.1 Kickoff Meeting

NPRB hosted a kickoff meeting in June 2016 shortly after announcing funding decisions to facilitate coordination among the research projects. Each of the Lead Principal Investigators (PIs) discussed the hypotheses and objectives described in their respective proposals and they worked together to identify the following overarching question that the Arctic IERP would address:

> "How will reductions in Arctic sea ice and the associated changes in the physical environment influence the flow of energy through the ecosystem in the Chukchi Sea?"

An Integrated Work Plan (Appendix A; https://www.nprb.org/assets/uploads/files/Arctic/Arctic_IERP_Integrated_Work_Plan_FINAL.pdf) was developed to articulate in a cohesive manner how each of the scientific research projects would contribute to addressing the overarching question and the broad objectives of the Arctic IERP.

Representatives of research projects not funded directly under the Arctic IERP but listed in Appendix A of the NPRB request for proposals ("Appendix A projects") were invited to share information about their research and express interest in collaboration.

Discussion was invited about gaps in the funded research program and as a result, NPRB funded some smaller-scale projects to address critical gaps. These projects included:

- Microzooplankton biomass and grazing rates
- Phytoplankton-related measurements on spring cruises (2017-2018)
- ASGARD: Productivity fractionation
- ASGARD: Fish
- Seasonal distribution and energetics of Arctic fishes in the Chukchi Sea

The results of these smaller-scale projects were included in the final reports of the five main science projects funded under the Arctic IERP.

During the kickoff meeting, NPRB staff led discussions about the roles and responsibilities of all participants to set expectations. A Science Steering Committee (SSC) was established comprised of the Lead PIs of each of the five main science projects. NPRB staff formalized plans for monthly meetings with the SSC and monthly PI meetings in which all scientists funded under the Arctic IERP were expected to participate. Conversations were also hosted about plans for outreach activities.

Staff of Axiom Data Science were invited to share information about plans for data management and the services they planned to provide under a contract established by NPRB. These services included establishing a secure Research Workspace, advising scientists on authoring metadata, archiving final datasets in national repositories (e.g., DataONE), and creating a public portal for Arctic IERP data at the conclusion of the research program.

3.2 Logistics Meetings

NPRB hosted logistics meetings to facilitate communication and coordination prior to each field season in 2017, 2018, and 2019. These meetings were hosted in person over two days in October or November. NPRB staff worked in cooperation with the SSC to organize the agendas.

During these logistics meetings, scientists discussed plans for chartering vessels for the upcoming field season, the allocation of berths, the expected dates of the vessel charters, division of the cruises into legs and identifying the Chief Scientist for each leg, ports for crew changes, needs for gear and plans for shipment of gear, chain of custody for samples and allocation of samples, and standardizing data collection protocols.

NPRB staff stressed the importance of discussing how sampling plans would be adjusted in the event that the sampling could not be carried out as planned (e.g., weather delays). Scientists were encouraged to discuss, for example, the ramifications of cutting some types of sampling versus increasing the spacing between stations and how that might affect the ability to meet the broad objectives of the Arctic IERP.

Scientists also discussed plans for communicating with coastal communities about sampling plans during the research cruises. For example, during field operations, emails were sent daily to a broad distribution list to describe where the vessel was located, where it planned to be operating in the coming 24 hours, and the types of sampling planned. The Chief Scientist also announced this information over the VHF radio at least twice daily. Scientists would change the sampling plans if notified that operations would interfere with subsistence activities.

3.3 Hub Meetings

NPRB organized meetings in the "hub" communities of Nome, Kotzebue, and Utqiagvik to engage members of Alaska communities in the Bering Strait, Northwest Arctic, and North Slope regions of Alaska in conversation about Arctic IERP research plans. NPRB cooperated with Kawerak, Inc., the Northwest Arctic Borough, and the North Slope Borough to host these meetings. Every tribal council in each region was invited to nominate a representative to participate and NPRB covered their travel expenses.

Hub meetings were held in late 2016 and early 2017 prior to Arctic IERP field operations. NPRB planned to repeat these meetings periodically throughout the five-year research program and/or at the conclusion of the program, however, challenges that included the COVID-19 pandemic prevented such meetings at later stages of the Arctic IERP.

During the hub meetings, NPRB staff and Lead PIs of the science projects introduced the research plans and welcomed dialogue with meeting participants. Community members were encouraged to share concerns about any potential conflicts of research operations with subsistence harvests. During the meeting in the Bering Strait region, concerns were raised about the potential for the ASGARD cruise planned in May to conflict with walrus harvests. As a result, the cruise was shifted to June.

Participants were also asked about any environmental concerns they might have that Arctic IERP research cruises might be able to address. Participants reaffirmed that their primary concerns centered around food security. Much of the Arctic IERP research planned was relevant to addressing food security, and Arctic IERP scientists added sampling for harmful algal blooms to their research plans to further strengthen the relevance of the science to people living in the Arctic.

3.4 Principal Investigator Meetings

NPRB organized annual PI meetings in coordination with the SSC to convene all Arctic IERP participants over a period of approximately three days to share their research findings and integrate their results. These meetings are a hallmark of NPRB's IERPs. They provide important opportunities to share information across disciplines and discuss the mechanistic linkages from physics and chemistry to biology at all trophic levels. The agendas for these meetings are available on the Events & Meetings section of the Arctic IERP website.

The social science project brought members of eight Alaska communities to the annual PI meetings to share their perspectives on the science and discuss how the environmental research was relevant to their communities. They also shared their insights about the relevance of environmental versus socio-economic factors to food security for their communities.

Scientists shared plans for manuscripts they planned to submit a series of special issues in *Deep-Sea Research II* or to other peer-reviewed journals. This coordination opportunity allowed the development of papers that were broad in scope, complementary, and interdisciplinary.

PI meetings provided opportunities for the discussion of plans for outreach that were led by the NPRB Communications and Outreach Director. Scientists were encouraged to engage in outreach activities with an emphasis on communicating about the goals and scope of the broader Arctic IERP rather than one scientist's narrow field of research.

Staff of Axiom Data Science led discussions about data management and data standardization. They were available to provide assistance to scientists in authoring metadata and formatting data to meet the standards of national data repositories.

3.5 Monthly Steering Committee Meetings

NPRB staff met monthly via Zoom with SSC members to coordinate all aspects of the research program and discuss any challenges as they arose. Conversations included developing the agendas for monthly PI calls/virtual meetings and annual in-person PI meetings.

NPRB maintained a "contingency fund" in reserve to allow flexibility to respond to challenges. Staff typically discussed the application of contingency funds with the SSC, and while staff and the NPRB Executive Committee retained decision-making power, the input of the SSC was valued.

The SSC served as the Guest Editors for the series of special issues in *Deep-Sea Research II* and the SSC meetings provided an opportunity to coordinate those publications.

3.6 Monthly Principal Investigator Calls/Virtual Meetings

NPRB staff and the SSC Chair hosted monthly calls/virtual meetings in which all Arctic IERP scientists were expected to participate. Collaborating projects listed in Appendix A of the RFP were also invited to participate, as were representatives of funding partners.

Monthly meetings provided an important opportunity to facilitate regular communication among Arctic IERP scientists between the annual in-person meetings. Monthly meetings included brief updates from each participant that allowed the sharing of information about preliminary results and planned publications, for example.

NPRB staff used these meetings as opportunities to share information related to project administration (e.g., reminders about biannual progress report deadlines) and to seek input from the scientists in the development of outreach products.

3.7 Communications Working Group Meetings

The NPRB Communications and Outreach Director organized a working group comprised of communications and outreach specialists from some participating institutions including NOAA and UAF and a selection of Arctic IERP scientists who expressed interest. The working group discussed plans for developing outreach products, including a brochure highlighting the significant results of the research, a series of brief videos, lesson plans for K-12 educators updated with information about current Arctic marine science, and a museum exhibit capable of sending remote modules to Arctic communities.

3.8 Funding Partner Coordination Meetings

NPRB staff met regularly with representatives of funding partner organizations throughout the Arctic IERP to keep them apprised of the program's progress and highlight exciting preliminary results. Staff of the BOEM Alaska Region participated in monthly PI meetings and the Chief of the Alaska Environmental Studies Program met one-on-one with the NPRB Senior Program Manager for the Arctic IERP at regular intervals.

4 Award Administration

4.1 Request for Proposals and Proposal Review

NPRB drafted a request for pre-proposals (RFP) and shared it with BOEM Alaska Region staff prior to releasing it in May 2015. After the RFP was released, NPRB staff held an informational teleconference and 127 callers participated. An audio recording of the event was made available via the NPRB website. This teleconference was hosted to ensure equal access to information and to allow participants to see who else might be interested in the opportunity to help scientists identify potential collaborators.

The Arctic IERP website provided "Resources for Investigators" to help interested parties find relevant information that NPRB and funding partners hoped would be considered as proposals were developed. Resources included reports such as the Arctic IERP Implementation Plan; the Pacific Marine Arctic Regional Synthesis final report; the IARPC Arctic Research Plan 2013-2017; a report entitled "Developing a Conceptual Model of the Arctic Marine Ecosystem" that resulted from a workshop that NPRB co-sponsored in 2013; an IARPC report on "Framing Arctic Marine Research Initiatives"; and a report on the BOEM-funded Hanna Shoal research project. The website also provided links to data archives and map servers, including the Alaska Ocean Observing System's Arctic Portal; Distributed Biological Observatory; Chukchi Sea Environmental Studies Program industry-funded data; National Science Foundation Arctic Data Center; North Slope Science Initiative Data Catalog; and the Pacific Marine Arctic Regional Synthesis Data Archive and Map Server.

Eighty pre-proposals were received in response to the RFP. Following review by the NPRB Science and Advisory Panels and the Board, a selection of the applicants was invited to submit full proposals for funding consideration.

Twenty-three full proposals underwent review by peer reviewers, the NPRB Science and Advisory Panels, the Board, and representatives of funding partner organizations. Representatives of funding partners were invited to listen to the discussion of the NPRB Science and Advisory Panels and were invited to share their perspectives during the Board meeting prior to the Board's vote to fund proposals in May 2016.

4.2 Subawards, Budgets, and Grant Compliance

Scientists were notified of funding decisions in May 2016 and NPRB staff formulated a plan to allocate the funds from various sources (three NPRB Prime Awards from NOAA, BOEM Cooperative Agreement, and North Slope Borough/Shell Baseline Studies Program) to support the institutions funded under the umbrella of the Arctic IERP.

NPRB staff worked with grants administrators at the Alaska Sea Life Center (ASLC), NPRB's fiscal agent, to establish subawards. Throughout the course of the Arctic IERP, a total of 44 subawards were issued and administered by NPRB/ASLC.

ASLC assisted NPRB in ensuring that all subawards complied with applicable federal guidelines. NPRB awards were reviewed during annual audits and no issues of concern were identified.

4.3 Review of Biannual Progress Reports from Science Projects

NPRB reviewed progress reports from each of the science projects funded under the umbrella of the Arctic IERP twice per year. Progress reports provided an opportunity for the scientists to share

preliminary results of their scientific analyses, notify NPRB of any needs for no-cost extension or rebudget of their subaward, inform NPRB of any challenges with respect to their own progress or the delay of analyses that relied on collaborators, and to document progress on their provision of data.

NPRB shared progress reports from the science projects with BOEM Alaska Region program officers. These were shared as attachments to the quarterly progress reports that NPRB provided to BOEM under this Cooperative Agreement in the quarter following NPRB's receipt of the reports.

4.4 Provision of Quarterly Progress Reports to BOEM

NPRB provided quarterly progress reports to BOEM under this Cooperative Agreement. Reports included information on administrative and outreach/engagement activities undertaken during the reporting period and progress reports from the science projects were attached twice per year.

4.5 Review of Final Reports from Science Projects

The NPRB IERP Senior Program Manager and the Science Director reviewed the final reports for each of the science projects funded under the umbrella of the Arctic IERP and shared them with staff of the BOEM Alaska Region for review during winter 2022. The reports restated the hypotheses and objectives of each project and documented progress towards addressing them. Manuscripts that were accepted or submitted for publication in peer-reviewed journals were included. The full reports are attached as appendices.

The SSC, in collaboration with NPRB staff, authored a preamble that was included in each final report that provided an overview of the Arctic IERP to acknowledge the full breadth and scope of the program. This included a summary of the field operations undertaken 2017-2019 and the goals of the social science project. It also included an introduction to the history of the development of the Arctic IERP using input from previous synthesis efforts and input from Alaska communities.

5 Publication of Special Issues

NPRB has facilitated the publication of the peer-reviewed scientific research papers that result from IERPs in special issues to showcase the results of these programs in a cohesive manner. All the IERPs to date have published Special Issue volumes in the journal *Deep-Sea Research II*. The NPRB Science Director served as the Managing Guest Editor and the members of the SSC served as the Guest Editors for the Arctic IERP special issues.

The first volume of the special issue in *Deep-Sea Research II* dedicated to the Arctic IERP was published in May 2020, with 14 manuscripts (see Baker et al., 2020 for overview). All manuscripts are available online here. Twenty-six manuscripts were submitted to the second special issue volume in early 2022, including five manuscripts from Russian scientists working in collaboration with the Arctic IERP, which complement research in U.S. waters and characterize dynamics in the western Bering and Chukchi Seas. The manuscripts cover a variety of research areas, including oceanography and plankton, benthic structure and invertebrate communities, stock structure and distribution for groundfishes and pelagic fishes, shifts in distribution of pollock and cod and marine mammal distributions.

NPRB plans to support a third volume of the Arctic IERP special issue in the future to welcome manuscripts resulting from the Arctic IERP synthesis and those that were still in development when the second volume closed for submissions in early 2022.

Additional manuscripts associated with Arctic IERP data and collaborative research have been published in other journals, including PLOS One, Progress in Oceanography, Conservation Physiology, Nature Climate Change, Polar Biology, and the Proceedings of the National Academy of Sciences.

6 Administration of Contingency Funds

NPRB established a $1M Contingency Fund for the Arctic IERP, the intent of which was to provide NPRB the ability to respond to needs as they arose to ensure the integrity of the overall research program and protect the investments of NPRB and funding partners. Staff suggested the creation of such a fund based on experience during past IERPs.

NPRB staff and the Executive Committee of the Board reviewed requests for the application of the contingency funds as they arose. Examples of applications of the funds include cost-sharing contracts for the recovery of lost moored instruments and vessel repairs when gear was tangled in the propeller of a research vessel in the Chukchi Sea during field operations. Contingency funds were also applied to support the addition of sampling to address critical gaps identified during the Arctic IERP kickoff meeting in June 2016.

7 Data Management

NPRB established a contract with Axiom Data Science, Inc. to provide data management services for the Arctic IERP. Axiom provided a password-protected Research Workspace to allow scientists to share their data and derived products throughout the course of the research program 2016-2021. At the conclusion of the Arctic IERP, finalized datasets were archived in national data repositories (e.g., DataONE).

Axiom staff attended monthly PI virtual meetings and annual in-person meetings and regularly interacted with PIs about data organization, data standardization, and metadata authorship. Axiom staff offered one-on-one assistance to PIs in authoring metadata and ensured that all datasets were ready for archive at the conclusion of the Arctic IERP.

Axiom coordinated with NPRB staff to develop a public Arctic IERP data portal at the conclusion of the research program that is accessible via the Arctic IERP website. NPRB pointed to this data portal when the request for proposals for the synthesis phase of the Arctic IERP was advertised in fall 2021.

NPRB staff met regularly with Axiom staff throughout the course of the Arctic IERP to discuss the organization of the Research Workspace, provide feedback on the development of updated tools (e.g., metadata editor), and to discuss possibilities for Axiom to produce visualizations of Arctic IERP data to facilitate interdisciplinary data exploration and/or analysis.

8 Outreach and Engagement

8.1 Hub Meetings

As discussed in more detail in section 2.3 above, NPRB organized meetings in the “hub” communities of Nome, Kotzebue, and Utqiagvik to engage members of Alaska communities in the Bering Strait, Northwest Arctic, and North Slope regions of Alaska in conversation about Arctic IERP research. NPRB cooperated with Kawerak, Inc., the Northwest Arctic Borough, and the North Slope Borough to host these

meetings. Every tribal council in each region was invited to nominate a representative to participate and NPRB covered their travel expenses.

These meetings were organized based on a model used by the Pacific Marine Arctic Regional Synthesis (PacMARS) project that served as an assessment phase for the Arctic IERP and informed NPRB's development of the Arctic IERP. During those meetings in 2013, participants expressed appreciation for the opportunity those meetings provided to share information among rural Alaska communities in each region.

During the hub meetings, NPRB staff and Lead PIs of the science projects introduced research plans and welcomed dialogue with meeting participants. Discussion included the relevance of the research to addressing issues of interest to communities and how best to avoid any potential conflict of research with subsistence activities.

8.2 Reports at Meetings of Alaska Native Organizations, National, and International Venues

8.2.1 Arctic Waterways Safety Committee

The Arctic Waterways Safety Committee was active during the period that the Arctic IERP engaged in field data collection and the NPRB Senior Program Manager for the Arctic IERP and lead PIs of the field research projects participated in these meetings regularly. Prior to each field season, draft research plans were shared with the Committee, and this provided an opportunity for the scientists to learn of concerns about the potential for conflict with Alaska Native subsistence harvests. Following each field season, the scientists shared presentations about their preliminary results.

8.2.2 Alaska Native Co-Management Organizations and Inuit Circumpolar Council-Alaska

The NPRB Senior Program Manager for the Arctic IERP, and often also the Lead PIs of the science projects that involved field operations, provided reports to Alaska Native Co-Management Organizations throughout the course of the Arctic IERP. Presentations were offered both before and after field operations in 2017, 2018, and 2019 to share information about research plans and allow dialogue about how best to avoid potential conflict with subsistence activities and to share preliminary results after the field season.

Presentations were welcomed at regular intervals by the Alaska Eskimo Whaling Commission, the Indigenous People's Council for Marine Mammals (IPCoMM, a statewide umbrella organization in which many Arctic marine mammal co-management organizations participate) and occasionally the Ice Seal Committee and Alaska Beluga Whale Committee. Although other co-management organizations could not offer us time on their agendas, they did receive the information during IPCoMM meetings. Vera Metcalf of the Eskimo Walrus Commission was a member of the NPRB Advisory Panel and heard updates on the research program twice per year in that forum.

NPRB staff also communicated with staff of the Inuit Circumpolar Council-Alaska during the early stages of the Arctic IERP to discuss synergies among our respective activities, especially with respect to a food security project led by ICC-Alaska.

8.2.3 North Slope Borough Fish & Game Management Committee

The NPRB Senior Program Manager for the Arctic IERP and the SSC Chair provided a lengthy presentation to the North Slope Borough Fish and Game Management Committee and staff of the North

Slope Borough Department of Wildlife Management in Utqiagvik when it became impossible to repeat hub meetings in the North Slope Region at later stages of the research program. Participants voiced their appreciation for the opportunity for engagement in September 2018. NPRB planned to return to present the final research results of the program in later years, however, the COVID-19 pandemic prevented travel. Instead, print materials were distributed to members of the Committee by mail in fall 2021.

8.2.4 Interagency Arctic Research Policy Committee and U.S. Arctic Research Commission

The NPRB Senior Program Manager for the Arctic IERP, Danielle Dickson, served as a Co-Lead of the Marine Ecosystems Collaboration Team (MECT) for the Interagency Arctic Research Policy Committee (IARPC) throughout the course of the Arctic IERP. (Cathy Coon of the BOEM Alaska Region also served as a Co-Lead of the MECT.) MECT's >400 members include a wide range of individuals representing federal agencies and non-federal organizations and academic scientists affiliated with universities nationwide. Regular communications were provided to the MECT to share updates on the progress of Arctic IERP research and opportunities for collaboration. Plans for research cruises were shared prior to each field season and at times scientists funded by other agencies (e.g., National Science Foundation) were able to secure berths on vessels chartered for Arctic IERP research or to secure samples collected by Arctic IERP scientists.

Arctic IERP scientists were invited to share presentations about their research results during meetings of the IARPC MECT, which typically hosted monthly webinars. Personal invitations were sent to members of the research community to notify them of discussion topics that they might find particularly relevant to their interests.

The U.S. Arctic Research Commission (USARC) holds a seat on the NPRB Board and NPRB staff occasionally provided updates during Commission meetings.

8.2.5 BIA Provider's Conference and Alaska Forum on the Environment

The NPRB Senior Program Manager for the Arctic IERP and Lead PIs of the science projects provided presentations regularly at the Bureau of Indian Affairs Provider's Conference and the Alaska Forum on the Environment in which environmental scientists from rural Alaska communities statewide participated. Presentations were offered to share the results of preliminary analyses. The COVID-19 pandemic prevented opportunities to share final results at the conclusion of the Arctic IERP as planned.

8.2.6 Arctic Icebreaker Coordinating Committee

The NPRB Senior Program Manager for the Arctic IERP regularly participated in meetings of the Arctic Icebreaker Coordinating Committee to share information about plans for Arctic IERP research, particularly for the ASGARD cruises in 2017 & 2018 that were conducted aboard the R/V *Sikuliaq*. NPRB shared plans for communication with Alaska coastal communities and Alaska Native Organizations (e.g., Alaska Eskimo Whaling Commission) during research operations.

8.2.7 International Pacific Arctic Group and Pacific Marine Science Organization (PICES)

The NPRB Senior Program Manager for the Arctic IERP regularly participated in meetings of the Pacific Arctic Group (PAG), an international body that includes participation by the U.S. Canada, Japan, South Korea, China, and Russia. The PAG is organized under the International Arctic Science Committee (IASC) and its mission is to serve as a Pacific Arctic regional partnership to plan, coordinate, and collaborate on science activities of mutual interest, including the Distributed Biological Observatory (DBO). The DBO supports the collection of time series data at a set of standardized stations in the

Northern Bering, Chukchi and Beaufort Seas. Arctic IERP scientists contributed data to the DBO. PAG meetings were typically hosted twice per year in spring and fall and during these meetings NPRB staff reported the plans for the upcoming field season and the preliminary results of the previous field season. NPRB staff also advertised the expected IERP synthesis opportunity that would follow the Arctic IERP field program beginning in 2022.

The NPRB Science Director regularly participated in meetings of the International Pacific Marine Science Organization (PICES) to facilitate coordination with international scientists. Of particular interest to NPRB was attracting the collaboration of Russian scientists who could share information about the marine ecosystem on the Russian side of the Chukchi Sea where U.S. scientists were not able to gather data. Consecutive workshops were led and facilitated by the NPRB Science Director at PICES Annual Science Meetings in San Diego in 2016 and Vladivostok in 2017 in collaboration with NOAA and Russian Federal Fisheries Research Institute (VNIRO) colleagues to explore means to promote data sharing and exchange in the eastern and western Bering Sea and eastern and western Chukchi Sea. Those discussions led to longstanding international collaborations where Russian scientists participated in Arctic IES surveys in 2017 and 2019. These collaborations resulted in five manuscripts that integrated data from Russian waters and either engaged Russian scientists in collaborative data analysis or were led by Russian scientists.

More recently, international collaborations have been suspended related to complications from the COVID-19 pandemic and the current geopolitical situation.

8.2.8 Scientific Conferences

NPRB staff and Arctic IERP scientists shared the exciting results of the Arctic IERP as they emerged at a variety of science conferences, including the annual Alaska Marine Science Symposium, the biennial Ocean Sciences conference, the Society for Marine Mammalogy biennial conference, meetings of the American Fisheries Society, the Gordon Research Conference on Polar Marine Science, Arctic Science Summit Week, Arctic Observing Network meetings, and others.

During the period that the Arctic IERP was ongoing, the Nansen Legacy program was established on the Atlantic side of the Arctic and NPRB staff seized opportunities to communicate with leaders of that effort to discuss opportunities for synergy. Individual Arctic IERP scientists formed collaborations with colleagues associated with that research program.

8.3 Outreach Products

8.3.1 Website, Blog, and Social Media

NPRB created a website (www.nprb.org/arctic-program) for the Arctic IERP where information about the program was shared publicly. NPRB expects that this website will remain publicly available in perpetuity as long as NPRB exists. The website recognizes all funding partners.

The website provides a history of the funding of the Arctic IERP, including access to the RFP and the "Resources for Investigators" page that was created to help interested parties find relevant information that NPRB and funding partners hoped would be considered as proposals were developed. Resources included reports (e.g., Arctic IERP Implementation Plan, the Pacific Marine Arctic Regional Synthesis final report, the IARPC Arctic Research Plan 2013-2017, a report entitled "Developing a Conceptual Model of the Arctic Marine Ecosystem" that resulted from a workshop that NPRB co-sponsored in 2013, an IARPC report on "Framing Arctic Marine Research Initiatives", a report on the BOEM-funded Hanna Shoal research project) and links to data archives and map servers (e.g., Alaska Ocean Observing System's Arctic Portal, Distributed Biological Observatory, Chukchi Sea Environmental Studies

Program, National Science Foundation Arctic Data Center, Pacific Marine Arctic Regional Synthesis Data Archive and Map Server).

The website also provides the Integrated Work Plan established for the Arctic IERP following the kickoff meeting in June 2016 that guided the research 2016-2021. The Events & Meetings page provides the agendas for the annual PI meetings and the logistics meetings.

During the field seasons in 2017, 2018, & 2019, a field blog and social media presence were maintained to share information in near-real time about what was happening aboard the research vessels. Some of the blogs were written by Alaska Native and early career scientists who participated in the research.

8.3.2 Brochure Highlighting Significant Results

NPRB staff and Arctic IERP scientists cooperated to author an outreach brochure highlighting the significant results of the Arctic IERP. NPRB contracted a graphic designer to assist with the layout of the brochure. The brochure is available in electronic form on the Arctic IERP website.

Hard copies were mailed to a distribution list of approximately 115 tribes and Alaska Native Organizations in the Bering Strait, Northwest Arctic, and North Slope regions of Alaska. The brochure was accompanied by a cover letter expressing regret that the COVID-19 pandemic prevented travel to rural communities to share the results in person.

8.3.3 Videos

NPRB contracted a video production team to create a series of brief videos about the Arctic IERP. NPRB staff (the Communications & Outreach Director and the Senior Program Manager for the Arctic IERP) worked closely with the production team to shape the messages that these videos will convey.

NPRB hopes the videos will appeal to a broad range of audiences, including Alaska communities, the interested public nationwide and internationally, youth, the science community, and potential funding partners of future IERP research. The videos will be available via the Arctic IERP website (in late summer or fall 2022) and they will be showcased in an exhibit at the Anchorage Museum expected in 2024.

The videos provide an introduction to the scope and goals of the Arctic IERP and the value of an integrated, multidisciplinary approach to studying a marine ecosystem. The videos feature interviews with a variety of Arctic IERP scientists and include footage filmed aboard the research vessels and discussion of results filmed at the conclusion of the research program.

The videos also feature interviews with Alaska Native participants in the research, including Billy Adams, a leader from the North Slope Borough who was a member of the social science team; Harmony Wayner, a student in the Alaska Native Science and Engineering Program at the University of Alaska who worked as a summer fellow for NOAA aboard the Arctic IES surveys in 2017; and Opik Ahkinga, a community leader from Little Diomede who participated in the ASGARD cruises in 2017 & 2018 and who is conducting science in her community to monitor for harmful algal blooms. The comments shared in these interviews highlight the relevance of Arctic IERP research to Alaska communities and the value of working with communities to conduct the research.

8.3.4 K-12 Lesson Plans

NPRB issued a contract to the Arctic Research Consortium of the U.S. (ARCUS) to update Arctic marine lesson plans for K-12 educators originally created in 2013 using updated information that resulted from the Arctic IERP. NPRB co-sponsored a workshop in Barrow, Alaska (now Utqiagvik) in 2013 to create

the original lesson plans in cooperation with the Alaska Ocean Observing System, ARCUS, and the Center for Ocean Science Education Excellence Alaska. The workshop brought K-12 educators, informal education specialists, and scientists working on Alaska research projects together to cooperate to develop the lesson plans using real data collected in Alaska waters. Staff of the North Slope Borough Department of Wildlife Management and local experts also participated.

8.3.5 Museum Exhibit with Traveling Modules for Rural Communities

NPRB is pursuing an exhibit at the Anchorage Museum to showcase the Arctic IERP. The exhibit, if realized, would be on display beginning in 2024. NPRB intends to develop smaller-scale modules that could travel to rural Alaska communities and potentially use technology like virtual reality goggles to simulate research activities. The exhibit will be co-produced with Alaska Native partners and NPRB is in the early stages of discussion with the North Slope Borough Department of Wildlife Management about their interest and capacity. BOEM communications experts will be invited to participate in the design and execution of the exhibit.

9 Conclusions

NPRB greatly appreciates the partnership provided by BOEM for the Arctic IERP under this Cooperative Agreement. BOEM partnership and the involvement of BOEM staff throughout the research program helped to ensure that Arctic IERP research was relevant to meeting the applied needs of this resource management agency and others (e.g., NOAA, USFWS).

The science conducted under the umbrella of the Arctic IERP resulted in significant results that are relevant to BOEM-Alaska. The research documented significant changes in water temperature, large shifts in the distributions of species that represent important nodes in the Arctic marine food web (e.g., Arctic cod), and changes in the distribution, abundance, and timing of subarctic species presence in the Chukchi sea (e.g., Pacific cod, walleye pollock, subarctic marine mammals). All these results are relevant to updating environmental assessments for permitting activities in the Alaska OCS region.

This Cooperative Agreement allowed BOEM to leverage NPRB's experience in administering IERPs to achieve integrated, multi-disciplinary research that provides updated information about the mechanistic processes governing how the marine ecosystem in the Chukchi Sea is structured under a changing climate. NPRB is a respected leader in facilitating integrated ecosystem research and attracted highly qualified scientists affiliated with a wide range of federal and non-federal institutions and the active participation of Alaska Native and industry partners. NPRB staff applied lessons learned through previous IERPs to strengthen the Arctic IERP, for example, requiring logistics coordination meetings prior to each field season and maintaining a contingency fund to respond nimbly to challenges as they arose.

NPRB welcomes the partnership of BOEM on future Integrated Ecosystem Research Programs and looks forward to future opportunities to cooperate. NPRB intends the next IERP to continue integrated research in the Bering and Chukchi Seas, centered on the Northern Bering Sea. Areas of interest include how shifts in environmental conditions and processes may influence species of commercial, ecological and subsistence importance, and implications for state and federal fisheries management and communities that depend on these resources.

Arctic Integrated Ecosystem Research Program

Integrated Work Plan

As a changing climate and sea-ice retreat progressively expose the Chukchi Sea to a longer open water season, society will confront new resource management issues. These include the future of the cultures and subsistence lifestyles of local indigenous communities, potential impacts of industrial activities (e.g. commercial fishing, oil and gas extraction), potential changes to regional ocean carrying capacity, and resilience of the arctic marine ecosystem (NRC, 2014).

To address these issues, the North Pacific Research Board in cooperation with other organizations[1] has funded integrated ecosystem research, the Arctic Integrated Ecosystem Research Program (Arctic IERP), with the goal to better understand the mechanisms and processes that structure the ecosystem and influence the distribution, life history, and interactions of biological communities in the Chukchi Sea. The overarching question that the Arctic IERP study will address is:

How will reductions in Arctic sea ice and the associated changes in the physical environmental influence the flow of energy through the ecosystem in the Chukchi Sea? Specifically, we will examine:

- Transport, seasonal composition, distribution, and production of phytoplankton, particulate matter, zooplankton, fishes, benthic invertebrates, seabirds, and marine mammals
- Timing, magnitude and fate of the primary and secondary productivity
- Partitioning/flux of energy between pelagic and benthic realms

[1] Funding for this $16 million program is provided by the North Pacific Research Board, Collaborative Alaskan Arctic Studies Program (formerly the North Slope Borough/Shell Baseline Studies Program), Bureau of Ocean and Energy Management, and the Office of Naval Research Marine Mammals and Biology Program. Additional in kind support has been contributed by the National Oceanic and Atmospheric Administration and the University of Alaska Fairbanks.

- Distribution, condition, and standing stocks of large crustacean zooplankton that serve as the prey base for upper trophic level fishes and seabirds
- Assemblages, distributions, abundances, and condition of larval and early juvenile fishes that influence the recruitment success of later life stages
- Density of marine mammals and seabirds
- Human use of, and interaction with, the marine environment

To address the goals and overarching question, Arctic IERP scientists and scientists with collaborating projects (see Appendix A) plan a diverse set of investigations, including seasonal integrated ecosystem surveys that will sample hydrography, pelagic fishes, benthic communities, observations of seabird and mammal distributions, year-round measurements from fixed autonomous samplers, and documentation of traditional knowledge of the Chukchi Sea ecosystem and the changes it is undergoing. The Arctic IERP individual project hypotheses and objectives are listed in Appendix B. The individual project timelines are listed in Appendix C.

Background

The northern Bering and Chukchi sea continental shelves that constitute a portion of the Pacific Arctic Region (PAR; Grebmeier and Maslowski 2014) annually transmit freshwater, heat, nutrients, and carbon (dissolved, particulate, and planktonic) from the North Pacific into the Arctic (Woodgate et al., 2005; Carmack & Wassmann, 2006). Previous work during the 1982-1988 Inner Shelf Transfer and Recycling (ISHTAR) program (with field work primarily in July and August) showed that the Chukchi inflow is an important source of new nitrogen for western Arctic productivity and the Arctic carbon budget as a whole (Walsh et al., 1989). Recent estimates of net community production (NCP) by Codispoti et al. (2013) on the order of 70-100 g C m^{-2} identify the northern Bering and Chukchi shelves as the singular most productive region across the entire Arctic marine system, exceeding the NCP of the Nordic seas by a factor of 2-3 and exceeding other Arctic shelf and basin systems by factors of 6-100.

An extraordinary feature of the northern Bering and Chukchi shelves that fundamentally shape the regional ecosystem is the year-round delivery of substantial nutrient concentrations (NO_3 > 10 μM) that lies many hundreds of kilometers from the nearest continental slope (Sambrotto et al., 1984; Kinder et al., 1986; Walsh et al., 1989). Nutrient delivery to the Chirikov Basin

euphotic zone is maintained at consistently high levels by the nutrient rich Anadyr Water (AW) carried by the Anadyr Current (Figure 1) where production is estimated at 250–300 g C m^{-2} y 1988; Walsh et al., 1989). Bering Strait transport can vary by nearly a factor of two inter-annually (Woodgate et al., 2012) and nutrient concentrations vary year-to-year (Danielson et al., 2016) but nutrient flux variations into the Chukchi remain unquantified.

Primary production begins initially in early spring, leading to rich sympagic communities (Gradinger 2009). Phytoplankton growth accelerates in late spring once ice retreat and snow melt permit sufficient light penetration into the water column (Hill et al., 2005; Mundy et al., 2005). Production quickly outpaces consumption by grazers, leading to the spring bloom. With an overall thinning of sea-ice, substantial under-ice blooms may also occur (Arrigo et al. 2012, Zhang et al. 2015). As the bloom wanes, ungrazed cells age and tend to settle quickly to the shallow (< 60 m) shelf, but the degree to which sinking particles are remineralized or repackaged in the pelagic zone is unknown. Nonetheless, a large fraction of the organic matter makes it to the seafloor where it sustains a thriving benthic community (Highsmith & Coyle, 1990; Feder et al., 2007; Grebmeier & Maslowski, 2014, and references therein) that supports benthic-feeding fish and marine mammals. However, during this critical period of ice retreat, the magnitude and spatial extent of the spring bloom, phyto-and zooplankton growth rates, planktonic grazing rates, and benthic deposition rates are all poorly known, thus precluding construction of a robust carbon budget. Even later in the season when zooplankton communities support rich seabird communities (Day et al., 2013; Gall et al. submitted), rate measurements of primary and secondary production remain scarce (Nelson et al., 2014).

Historically, the food web of the Chukchi ecosystem has been based on primary production driven by under-ice algal communities. However, rising Arctic temperatures have contributed to reduction in the percentage of thick, multi-year ice and a shift to thinner, first-year ice (Comiso et al. 2008). This shift has contributed to earlier seasonal sea-ice retreat which favors open water phytoplankton primary production and benefits a pelagic ecosystem (Grebmeier et al., 2006; 2015; Moore and Stabeno, 2015). The increase in water column primary production occurs in shallower water where light levels are adequate, as long as sufficient nutrients are available. During late summer, due to nutrient exhaustion in the upper mixed layer, phytoplankton in the northeastern Chukchi are typically found below the pycnocline (subsurface; Martini et al. 2016).

Thus changes in stratification will impact primary production through the inverse relationship of light availability from the surface and nutrient availability from depth.

Restructuring in the Chukchi ecosystem is not limited to a change from a benthic to a pelagic dominated system. Physical changes (e.g., increased stratification) are expected to influence nutritional quality of the prey base via a shift in the phytoplankton community to a greater fraction of small cells (Ardyna et al. 2011, Arrigo et al. 2014, Li et al. 2009). This nutritional shift is expected to re-shape zooplankton assemblage composition (Ershova et al. 2015a, 2015b, Pinchuk and Eisner in review) and energy content, increase food chain length, and decrease the trophic transfer efficiency among food web constituents. When sea-ice structures the system, waters are nutrient-rich, prolific blooms of under-ice algae are supported, and the zooplankton community is dominated by large copepods and euphausiids that provide a lipid-rich source of energy to upper trophic levels. This food web is short and efficient, supporting large numbers of seasonally abundant fish, birds, and mammals. In contrast, under warm, stratified conditions, near-surface waters contain fewer nutrients, the phytoplankton community is dominated by picoplankton and the zooplankton community is dominated by small, lipid-poor copepods. This food web is longer, less efficient, and of relatively poor nutritional quality (Richardson 2008). These food web changes will manifest as shifts in upper trophic level species distributions, changes in species assemblages at all trophic levels, seasonal changes in timing of life-cycle events (Beaugrand et al. 2002, 2003), less efficient feeding interactions (Berchok et al. 2015, Norcross et al. 2013, Logerwell et al. 2015, Sigler et al. in review), and overall reductions in biomass.

Arctic fishes such as Arctic cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*) are key components of the PAR food web (Lowry and Frost 1981, Welch et al. 1992) and contribute to supporting large numbers of seabirds (Matley et al. 2012) and marine mammals (Bradstreet et al. 1986; Holst et al. 2001) which migrate to the Arctic to take advantage of high seasonal production. Arctic cod are particularly abundant in the PAR (Moore et al. 2014) and along with snow crab and saffron cod, are recognized as potential target species for new fisheries in this region (Arctic Fishery Management Plan 2009). Continued loss of sea ice and warming in the PAR may restructure the food web by negatively impacting Arctic cod growth and survival (Laurel et al. 2015). For instance, age-0 Arctic cod have a low thermal tolerance (< 7°C) for

growth and survival; whereas saffron cod have a much wider tolerance and are expected to thrive at higher temperatures (Laurel et al. 2015). Age-0 Arctic cod have 2.7 times more lipid per unit body mass than Age-0 saffron cod (Ron Heintz, personal communication). Therefore continued warming along the Chukchi Sea shelf may reduce the abundance of lipid-rich prey (Arctic cod) with negative consequences to other fishes and post-breeding seabirds, similar to that experienced by walleye pollock (Heintz et al. 2013) and Pacific cod (Farley et al. 2014) in the southeastern Bering Sea during a recent warming event (see Coyle et al. 2011).

In addition, continued warming of surface temperatures could increase salmon production in the Arctic. During 2007, summer sea temperatures in the Chukchi Sea were anomalously warm (Eisner et al. 2013). Integrated ecosystem surveys conducted in the Arctic during 2007 documented relatively high abundances of juvenile pink and chum salmon in the Chukchi Sea (Moss et al. 2009b). The abundant juvenile salmon returned as adults to the coastal regions of the PAR in relatively high numbers during 2008 (pink salmon) and 2009/10 (chum salmon) as reported by subsistence users in coastal communities (Carothers et al. 2013; Taquilik Hepa, personal communication). These events (anomalously warm summer sea temperatures, historic summer sea ice minima, and highly abundant juvenile pink and chum salmon in the Chukchi Sea) were all "surprises" in that they were large variations from predicted anthropogenic effects on temperatures and sea ice loss from climate models (Overland 2011). These "surprises" could become the norm in the not too distant future and while the presence of maturing salmon in Arctic waters north of known salmon producing drainages likely reflects straying and not colonization (Stephenson 2006), continued warming in marine, terrestrial and riverine environments may make it possible for these salmon to become permanently established in the Arctic.

It is also highly likely that climate warming in the Arctic will impact the abundance and distribution of seabird species. Seabird distribution is often influenced by oceanographic characteristics that promote productivity and concentrate prey (Piatt et al. 1991; Gall et al. 2013). In the Chukchi Sea, 'hotspots' of seabird abundance varied among foraging guilds (i.e., surface or diving foragers) and between summer (breeding season) and fall (post-breeding and migration), but were often associated with persistent topographic features such as shelf breaks and underwater canyons (Kuletz et al. 2015). During 2012 and 2013 northern Bering and

Chukchi Sea surveys, the distribution of planktivorous and piscivorous seabirds reflected the distribution of their prey at broad spatial scales (see reports from the Arctic Ecosystem Integrated Survey (Arctic Eis) at: https://web.sfos.uaf.edu/wordpress/arcticeis/). Gall et al. (2016) have also shown a decadal-scale shift from a predominantly piscivorous seabird community to one dominated by planktivores. If warming seas lead to longer ice-free conditions and generally higher productivity, this trend could continue. However, an alternative hypothesis is that these conditions lead to smaller zooplankton and thus less suitable prey to support high densities of planktivorous seabirds, resulting in a shift back towards a predominantly piscivorous seabird community. Furthermore, lack of high-lipid prey (Arctic cod) near breeding colonies could result in low reproductive success and high nutritional stress (see Paredes et al. 2014).

Furthermore, a "reorganization," from benthic- to pelagic-based in the PAR, might negatively impact marine mammal species that rely on sea ice for habitat (e.g., ice seals, walrus, bowhead whales) and/or benthic infauna for food (e.g., walrus, gray whales, some ice seals) via a reduction in habitat and prey abundance (Grebmeier et al. 2006). Other species, however, such as sub-Arctic "summer whales" may benefit from increased access to northern habitat and pelagic prey species (Clarke et al. 2013). One means of assessing changes in marine ecosystems (the physical environment can be measured directly) is to examine the distribution of fauna that are directly influenced by such changes (Moore et al. 2014). As the top of short Arctic food webs, marine mammals can be considered sentinels of environmental change (Moore 2008; et al. 2014). Changes in cetacean abundance and distribution have been shown in conjunction with short and long time scale climate events in the north Pacific (Benson et al. 2002; Fiedler 2002; Croll et al. 2005) and Bering Sea (Stafford et al. 2010).

Lastly, understanding the relationships between coastal residents and the marine environment is an essential contribution to the effective management of Arctic marine resources and activities that affect those communities and resources (e.g., BOEM 2014). Year-to-year variability in subsistence harvests of many species is high (e.g., ADF&G, N.D., Noongwook et al. 2007, Huntington et al. 2013c). Much of the variability can be attributed to changes in physical conditions (e.g., Ashjian et al. 2010, Kapsch et al. 2010), affecting access as well as distribution of the species being sought. When longer term variability has been documented, it has reflected factors such as the shift from dog teams to snowmachines (Burch 1985), the imposition of the

International Whaling Commission's quota for bowhead whales (Huntington 1992), access to financial resources stemming from oil development at Prudhoe Bay (Huntington 1992), and changing tastes, for example in fur seals on St. Paul Island (Lestenkof et al. 2011, Fall et al. 2013).

Gross indicators of well-being in Arctic communities suggest improvements in recent decades (e.g., AHDR 2004, 2014). In the Chukchi region, subsistence harvests overall appear to be robust (ADF&G, N.D.), with some prominent exceptions such as poor walrus hunting years on St. Lawrence Island (due in part to sea ice conditions) or high variability in bowhead whale harvests in many communities (personal communications from community residents). These variations are likely related to environmental variability, but distinct from long-term trends. There are many assertions of negative impacts from climate change and other forms of environmental change, but few unambiguous demonstrations that the impacts are indeed negative and widespread.

Project design

Shipboard Surveys

Arctic Shelf Growth Advection Respiration Deposition Rate (ASGARD) – Spring 2017 and 2018

Berth Space: Contact the PI for berth availability discussions.

The R/V Sikuliaq, a newly-constructed ice-capable research vessel engineered to be acoustically quiet, will be used to survey the northern Bering and southern Chukchi shelf (Figure 1). The survey will consist of water-column and benthic work in open-water and in/near the ice-edge, in late May and early June 2017 and 2018. The research surveys will work south to north, occupying ten "process" stations (yellow squares in Figure 1), setting up growth rate experiments that require extended (~ 10 day) incubation times and collecting our broad suite of standard measurements (Table 1). Moorings that record year-round time-series will be serviced when the ship stops for process stations. Once all process-station experiments are running, the ship would transition to a "survey" mode of operation, rapidly working north-to-south along multi-station transects and re-occupying the process stations with a more limited sampling suite to provide information about short-term (~days) changes to the water-column and continued trawl and benthic samplings. Throughout the cruise we will collect continuous underway navigational, ocean surface, ocean profile, and meteorological data to provide additional environmental

context for subsequent analyses. In addition, measurements of microzooplankton carbon biomass and grazing rates will be conducted throughout the spring survey as well as phytoplankton-related measurements to compliment those planned on the late summer surveys. Collection of fishes will occur as part of the spring-season ASGARD expeditions on the *R/V Sikuliaq* within the northern Bering and southern Chukchi seas. Sampling will take place in open water, at the ice edge, and in the pack ice in late May through early June in 2017 and 2018. The fish stations (n = 20) will include all process stations, equidistant sampling along the Arctic Marine Biodiversity Observing Network (AMBON) and Distributed Biological Observatory (DBO) lines, the Alaska side of the Bering Strait, and across Chirikov Basin. Demersal fishes will be sampled using a 3-m plumb staff beam trawl, allowing for direct comparison with collections with past Arctic research programs and with the late summer Arctic IES cruise. Sub samples of fishes collected during the survey will be preserved on board the vessel and processed at the UAF Oceanography Laboratory following a systematic protocol that includes length, weight, removal of otoliths, stomachs, and tissues (for stable isotopes and seasonal energetics).

Arctic Integrated Ecosystem Survey (Arctic IES) – Summer 2017 and 2019

Berth Space: Contact the PI for berth availability discussions.

An integrated ecosystem survey of the Chukchi and western Beaufort seas (Figure 2) will occur during August through early October in 2017 and 2019. Operations performed at each grid station are listed in Table 2. The survey will follow the protocols developed for Arctic Eis (Arctic Ecosystem Integrated Survey 2014) and Bering Aleutian Salmon International Survey (BASIS) (Farley et al. 2005). Sampling of oceanography and lower trophic levels (LTL) and upper trophic levels (UTL) will be conducted on one vessel capable of deploying bio/physical oceanographic gear, fish trawls (pelagic/surface/midwater) and demersal trawls (3-m plumb-staff beam trawl). Acoustic measurements along survey transects (gridded regions from east to west) along with modified Marinovich midwater trawl samples targeting water column backscatter will be used to estimate the distribution and abundance of midwater young-of-the-year cods and other forage fishes in the survey area. Surface trawls (Cantrawl 400/600) will be conducted at nearshore stations to assess juvenile salmon. Demersal trawls (3-m plumb-staff beam trawl (PSBT) will be utilized along gridded stations to assess older age classes of Arctic cod and crab.

Similar to the spring survey, subsamples of fishes and jellyfish from surface, midwater, and bottom will be collected for diet, otoliths, isotopes and seasonal energetics.

Oceanography and plankton sampling will be coordinated with the Arctic Integrated Ecosystem Survey Phase II Lower Trophic Level (LTL) team. Four transects on the Chukchi shelf have been occupied previously by the Ecosystems and Fisheries Oceanography Coordinated Investigations Program (EcoFOCI) and others, and three transects sample across the Chukchi slope. Three transects across the Beaufort Slope will investigate connections between the Chukchi and Beaufort ecosystems. The Barrow Canyon transect corresponds to DBO-5; the Icy Cape and Cape Lisburne lines have been occupied annually since 2010 by EcoFOCI; the Pt. Hope line is the U.S. portion of DBO-3. Shipboard activities will include: CTD casts, paired bongo tows for zooplankton tows; and deployment of towed vehicle (Sea Sciences Inc. Acrobat). High-resolution measurements from the Acrobat will include pressure, temperature (T), salinity (S), chlorophyll a (Chla) fluorescence, oxygen, nitrate and photosynthetically active radiation. In addition measurements of microzooplankton community composition, abundance, and biomass will be conducted throughout the late summer survey and phytoplankton-related measurements to complement those collected during the spring survey.

Seabird surveys will be conducted using visual observations and standardized strip transects (Tasker et al. 1984, Kuletz et al. 2008), with adjustments used for previous Alaska surveys (USFWS 2008). Surveys will be conducted during daylight hours while transiting between sample stations. The observer records all marine bird and mammal sightings within 300m and a 90° arc forward from the 'center line' (line of travel). Standard transect width will be 300m, with individual sightings recorded in distance bins (0-50m, 50-100m, 100-200m, 200-300m, >300m), and angle from the observer in 5 degree increments. Birds in the water or actively foraging are recorded continuously, while flying birds are recorded during quick 'scans' of the transect window at intervals of approximately 1• min-1 (depending on vessel speed) to avoid overestimating. The observer records observations directly into a laptop computer using survey software DLog3 (A.G. Ford, Inc., Portland, OR), recording species, number of individuals, behavior (on water, in air, on ice, foraging), distance bin, and angle. Environmental variables such as sea state (Beaufort scale), glare, weather, and sea ice cover (proportion in tenths) are recorded at first entry and automatically thereafter unless updated as necessary.

Moorings

ASGARD

The *ASGARD* mooring array consists of three biophysical moorings south of Bering Strait, two moorings in the southern Chukchi Sea plus the NPRB Long-Term Monitoring Program NE Chukchi Sea Ecosystem Mooring located on the southern flank of Hanna Shoal near Barrow Canyon. Together, these six moorings will collect bio/physical oceanographic data to examine cross-shelf differences between the Anadyr Water (AW) and Alaska Current Water (ACW) regimes and physical and biogeochemical changes imparted as the waters flow across the shelf into the Arctic. These instruments will record year-round to reveal time histories of: a) Nutrient and phytoplankton concentrations and fluxes; b) The bifurcation of flow to either side of St. Lawrence Island and the influence of regional winds on the upstream structure and partitioning of water masses feeding Bering Strait; c) Conditions in Anadyr Strait, in the nexus of the most important zone at which subsurface nutrients are mixed to the surface as they arrive at Chirikov Basin and Bering Strait; d) AW and ACW properties and advection rates; e) Phytoplankton blooms, sinking organic matter fluxes and their relationship to advective supply, light, ice thickness and the retreating ice edge; and f) Bottom sediment resuspension with respect to water and ice motion.

In addition, data will be collected on the occurrence of vocal marine mammals as upper trophic level consumers at the top of a complex Arctic ecosystem. To do so, hydrophone packages will be added onto three proposed oceanographic moorings as part of the ASGARD program to improve our understanding of the northern Bering and Chukchi Sea ecosystem and its constituent parts, structure and functioning by examining productivity drivers, energy pathways and turnover rates, migratory and distribution patterns, and human dimensions. The hydrophone data will be used to 1) document the inter-seasonal and inter-annual presence of vocal marine mammals (Arctic and sub-Arctic) in the Bering Strait; 2) Integrate presence with co-located oceanographic data to better understand how the physical environment influences the biological inhabitants of that environment; 3) Provide data on ambient noise levels in the region to assess the impact of commercial shipping; 4) Report to local communities on the health of the ecosystem including information on new species, and residency times of Arctic species. The combination of passive acoustic and physical and biological oceanographic data sets will provide urgently required

information on how species presence varies seasonally with changes in benthic and water column prey, sea ice, currents, ocean water temperatures and freshwater flow. The proposed effort in collaboration with other ASGARD PIs will provide data on interannual variability and the bio-physical drivers of this variability. Co-located ecosystem measurements from "wind to whales" will allow for the testing of scientific hypotheses such as: how do oceanographic conditions dictate the residency of different marine mammal species? Are temperate species "invading" the Arctic and what will their influence be on Arctic species and Arctic food security?

Arctic IES

Subsurface moorings would be deployed at sites provided in Figure 2. These moorings measure current speed and direction (ADCP; RCM-9), near-bottom T and S, oxygen, nitrate, Chla fluorescence, PAR, bottom pressure and turbidity. C2 also measures ice thickness. C1, C2 and C4 moorings are presently in the water and will be redeployed in 2016 by PMEL/RUSALCA. All four moorings will be recovered and re-deployed in 2017 and in 2018 on RUSALCA or another cruise, and recovered in 2019. Data from these moorings thus constitute a valuable long-term record that allows examination of interannual variability. Also at C2, a summer, surface mooring will measure radiation (shortwave, longwave, direct/diffuse), meteorological parameters (wind speed/direction, atmospheric pressure, air temperature, relative humidity, sky camera) and oceanographic parameters (T, S, Chla fluorescence, oxygen, nitrate, PAR) at multiple depths throughout the water column. The radiometer suite will include a new-generation radiometer (SPN-1 from Delta-T Devices) that distinguishes between direct and diffuse light. Three of the moorings (C1, C4, C11) will be instrumented from 2017 to 2019 with next generation upward-looking active acoustic instrumentation (i.e., Simrad wideband autonomous transceiver; WBAT) to collect 70 kHz and/or 38/200kHz data continuously to describe abundance, distribution, and movement patterns of the dominant fish backscattering (e.g., Arctic cod) throughout the water column at different spatio-temporal scales (vertical and geographic scales over hourly to interannual periods).

<u>Autonomous Platforms</u>

Numerous new sensors and platforms are being developed at PMEL through the Innovative Technology for Arctic Exploration (ITAE) program http://www.pmel.noaa.gov/itae/technologies).

Profiling Floats: To sample ice-covered waters in spring, two types of profiling floats are under development: a pop-up float, and an ice-reinforced ARGO-like float. In collaboration with this proposal, ITAE will deploy both types of floats in spring 2017, and results from these early missions will steer future development and help guide 2019 deployment strategy. Pop-up floats reside on the bottom until scheduled release when they rise toward the surface profiling the water column. Upon reaching the ice, they continue to sample directly under the ice until it melts, at which time they transmit all data back to PMEL. A series of pop-up floats will be anchored (near C2) and programmed to sequentially release under the ice in spring, recording the evolution of water properties throughout the water column and the environment directly under the ice as it melts. Planned sensors include pressure, tilt, T, S, PAR or multi-channel irradiance, and Chla fluorescence.

Once free of ice, data from the float will be returned via satellite. Current development is for profile data to also be transmitted to a moored data recorder that would be recovered in summer/fall. These floats acquire otherwise difficult-to-obtain profiles and time series of light, Chla, warming and freshening directly under the ice. ITAE is working with MRV Systems LLC to develop ice-reinforced biogeochemical ARGO floats (Air- Launched Autonomous Micro-Observer [ALAMO]) designed for use in shallow waters. In collaboration with this proposal, ITAE plans to deploy 6 biogeochemical ALAMO floats from aircraft and/or ships of opportunity. In spring 2016, two ALAMO floats with a CTD will be deployed from a Twin Otter aircraft in open waters of the Chukchi Sea as part of a heat flux experiment. These floats are expected to provide ~100 profiles of the water column shortly after ice retreat. The development plan is to incorporate oxygen, Chla fluorescence and PAR or multi-channel irradiance sensors into ALAMO floats equipped with ice algorithms and hardened crowns for protection when encountering ice. These floats will provide numerous profiles of the water column before and after ice retreat, with potential to observe the release of ice-algae and determine sinking rates of algal mats. For more Eulerian like time series, ALAMO floats can

park on the bottom between scheduled profiles. Thus, profiles can be closely linked to other moored time series.

Profiling Gliders: In 2017, PMEL will provide a Slocum glider for measuring CTD, oxygen and nitrate through the water column. The Slocum will be deployed from the USCGC Healy during Arctic Shield (or other ship of opportunity), and recovered during the fall survey. In addition, ITAE and NOAA-OAR are currently building two variable-speed coastal gliders. This glider is designed to rapidly change buoyancy to avoid bottom, and has maximum speed of ~2 kts to allow the glider to punch through buoyant layers or escape strong coastal currents. The gliders will measure pressure, T, S, oxygen, Chla fluorescence, colored dissolved organic matter (CDOM) fluorescence, red-light backscatter (to estimate organic particle concentration), and irradiance (either PAR or multi-channel irradiance).

In addition, one glider will be equipped with a multi-wavelength Light Detection and Ranging (LIDAR) sensor. This sensor is being developed by Dalgleish and Twardowski (Harbor Branch Oceanographic Institute) with funding from NOAA-OAR. LIDAR will be used to quantify particle size and distinguish between diffuse phytoplankton blooms and sinking algal clumps associated with the ice. The second glider will be equipped with a holographic zooplankton Video Plankton Recorder (VPR). This system is currently being developed by Hare (NMFS) and Davis (Woods Hole Oceanographic Institution) in collaboration with SeaSCAN Inc. and ITAE. The system will have two prongs extending in front of the glider nose-cone that encase the camera and laser light source. The holographic camera brings into focus all particles >60 μm that pass between the prongs. An onboard classification system is designed to identify and quantify zooplankton and ichthyoplankton.

Field testing of gliders and LIDAR are planned in spring and summer 2016; the initial field program is planned for Gulf of Mexico in 2017. Incorporation of the VPR into the glider should be complete by fall 2017. In spring 2018 and 2019, ITAE will deploy these two gliders in the Chukchi Sea in collaboration with this proposal with the goal to quantify particle size, identify and quantify species of zooplankton and ichthyoplankton, distinguish between phytoplankton and ice-derived algal clumps, explore the light field, patch size, sinking rate, and duration of sinking ice-algae, and determine whether events are widespread or localized to hotspots.

Profiling Mooring: The Profiling Crawler (PRAWLER) is a programmable autonomous platform attached to the radiation buoy's mooring line. This platform uses wave energy to crawl up the mooring line, and can either crawl or free-fall back down the mooring line. Operation is controlled from shore with options for profiling frequency (~5 min per round trip) or holding at fixed depth. The instrument package includes CTD, oxygen sensor, and Chla fluorometer. Data from the PRAWLER, together with other instruments at the site, can be used to investigate internal waves and mixing processes, determine heat flux of the upper water column, and provide high-resolution sampling of oxygen and Chla biomass in the two-layer system. In summer 2015, the PRAWLER, sampled between 5 and 25 m, completing ~30,000 profiles.

Saildrone: The Saildrone is an autonomous vehicle that utilizes wind for propulsion and solar panels to power on-board systems. The Saildrone derives its speed from a 4-m wing. In heavy seas, outrigger hulls provide stability and the wing can be eased to reduce power and heeling. The payload capacity (~100 kg) is distributed among several payload bays along the 5.8-m hull. The drones autonomously sail to a series of remotely provided waypoints. Data (returned in real time) include position, atmospheric parameters (sunlight, barometric pressure, wind, air temperature and relative humidity) and oceanic parameters (T, S, Chla and CDOM fluorescence, oxygen, nitrate, red-light backscatter). ITAE will plan an oceanographic and acoustic survey in 2019 to augment the Lower Trophic Level (LTL) - Upper Trophic Level (UTL) field program in the Chukchi Sea. (In 2017, the Saildrones are obligated to a CO2 survey in the Chukchi Sea). Active acoustics will be the same instrument to be used in the UTL moorings (as described in the linked UTL proposal), either a 70 kHz splitbeam, or 38/200 kHz (38/200 split/single beam).

Arctic Communities

Literature & Archive Review: Using the results of a PI survey circulated in summer 2016 as well as the hypotheses and work plans of other Arctic IERP components, a survey of publications on LTK and subsistence harvests will be carried out, supplemented by reviewing archival materials from the Kawerak Eskimo Heritage Program, University of Alaska Fairbanks Oral History Program and Project Jukebox, and other sources. The intent is to find relevant material that has already been documented so that this existing information can be used by Arctic IERP and associated researchers to address their hypotheses and find connections between their work and LTK. This work will proceed iteratively. A first review will be done prior to the March 2017 PI

meeting, so that results can be shared at that time with other researchers. The resulting conversations, in person at the PI meeting and subsequently by email and teleconference, will point to areas where further details are desired, which will guide further review of the literature and archives. This process will continue in FY18 and FY19.

Annual Team Meetings: The LTK team, consisting of the four PIs/co-PIs, and nine residents of coastal communities in the Arctic IERP region (one each from Savoonga, Diomede, Buckland, Kotzebue, Kivalina, Point Hope, Point Lay, Wainwright, Barrow; participants will be selected for experience with scientific-LTK collaborations as well as the depth of their own LTK) will meet in conjunction with the annual PI meeting in FY17, FY18, and FY19. The group will consider the results of the literature and archive review and analyze these and other information, including personal experience and LTK, to address the hypotheses of this component of the Arctic IERP. The group will also consider the areas of focus and interest of other Arctic IERP components and associated projects and review the available information to prepare for interactions with the other Arctic IERP researchers. In FY20 and FY21, the effort will shift to writing and synthesis, and the team will be reduced to the four researchers plus one coastal resident from each of the three regions (Bering Strait, Northwest Arctic, North Slope).

The approach will be structured as follows. Prior to the annual LTK team meetings, the core research team will review the compiled information and assemble the evidence for and against each of our hypotheses. This information will be shared with our community partners prior to the meeting. At the meeting, we will review the evidence, discuss additional sources of information including the community partners' own experience and observations, and assess the hypothesis in question. This stage is the central piece of our approach, having community residents help in the analysis of available evidence rather than just serving as sources of information for others to analyze later and elsewhere. We expect the discussions to provide far greater depth and context than will be apparent from the written and recorded sources we have reviewed, few if any of which will have been targeted to our specific hypotheses. The assessment will include an appraisal of what other information would help determine whether the hypothesis is true or false, and/or help increase the confidence we have in our conclusion. We will then develop a plan for further research, with published and archival materials as well as with the personal experiences and community connections of our community research partners. The additional research will be

carried out for the following annual meeting, at which time we will repeat the compilation of evidence, discussion, and assessment. It is likely that the outcome will be a more sophisticated revision of the hypothesis statement rather than a simple true/false determination, as these topics are complex and likely to vary greatly from one community to the next.

Annual PI Meetings: The LTK team (four researchers, nine community members) will participate in the annual PI meetings in FY17, FY18, and FY19. The intent is to interact as much as possible with other researchers, to share the LTK we have gathered, to get new direction for further LTK inquiry, and to find opportunities to collaborate on analysis (teasing apart the pieces of the system that make it work) and synthesis (developing a conception of the system as a whole based on our understanding of the pieces). In FY20 and FY21, as noted above, the LTK team will be reduced from 13 to seven members, and will focus at the PI meetings on collaborative papers and other products involving other AIERP researchers.

The approach here will be similar to that for our own research team's meetings. For topics of interest to other researchers, we will lay out the findings from LTK and from scientific studies side by side and compare and contrast them in collaboration with the other PIs, looking for complementarity seeking insight into differences, and drawing greater confidence from similarities. These initial insights will be the basis for further exploration of the topic in question, which if sufficiently insightful will be developed into a collaborative paper.

During these interactions and discussions, we will apply the principles of LTK research that have proven successful. For example, we will let the coastal residents take the discussions in directions they find interesting and important, allowing them to establish chains of thought that might not occur to other researchers. We will emphasize discussion over formal presentations, and find ways to encourage informal conversations, e.g., during meals and breaks. We will recognize different communication styles, such as comfort with silence and different ways of expressing dissent, to make sure all perspectives are heard and no participants are left out.

Table 1. Survey Station measurements on ASGARD surveys. All measurements listed here will also be made at all Process Stations. Underway samples (Table 4) will also be collected at all stations. Abbreviations include: T=temperature, S = Salinity, Chla = cholorophyll a , ChlaF = chlorophyll a fluorescence, DO = Dissolved Oxygen, PAR = photosynthetically available radiation, CTD = conductivity temperature depth datalogger.

Measurement	Instrument	Temporal/Spatial resolution
T,S,P, ChlaF, DO, PAR, Beam Transmittance	SeaBird SBE 911 CTD	1-m ave. profiles all survey stations
Photosystem-II efficiency Photosystem-II quantum yield	CDT-mounted Chelsea FRRF	5-m ave. profiles all survey stations
NO_3, NO_2, NH_4, PO_4, SiO_4, Total size-fractioned Chla	CTD Rosette	5-10 depths per station. All survey stations
Quantity & quality of sediment organic matter, and modeled degradation rates within sediments (labile protein, chloropigments, TOC, $d^{13}C$)	Multicore	20-30 survey stations
Sediment grain size	Multicore	20-30 survey stations
Bacterial biomass in sediments (ATP)	Multicore	20-30 survey stations
Abundance, biomass and functional group analysis of benthic meio-and macro-infauna with $d^{13}C$ and $d^{14}N$ of select species	Multicore	20-30 survey stations
Metazooplankton composition, abundance, biomass	Plankton nets (150 and 505µm)	20-30 survey stations
Microzooplankton composition, abundance, biomass	CTD Rosette	20-30 survey stations
Particle size distribution (65 µm – 2.5 cm)	Underwater Vision Profiler 5	5 m depth bins All survey stations

Particle size distribution (2.5 – 500 µm)	Sequoia LISST	5 m depth bins All survey stations
Mesozooplankton abundance	Underwater Vision Profiler 5	All survey stations
Phytoplankton primary production (total and size fractionated) and taxonomic identification	CTD Rosette	6 depths per station at a subset of stations
Fatty acid analysis of seston and zooplankton	CTD Rosette Plankton nets	At a subset of stations

Table 2. Station measurements taken on the Arctic Integrated Ecosystem Survey. Abbreviations include: T=temperature, S = Salinity, Chla = cholorophyll a , ChlaF = chlorophyll a fluorescence, DO = Dissolved Oxygen, PAR = photosynthetically available radiation, CTD = conductivity temperature depth datalogger.

Measurement	Instrument	Temporal/Spatial resolution
T,S,P, ChlaF, DO, PAR, Beam Transmittance	SeaBird SBE 911 CTD	1-m ave. profiles all survey stations
NO_3, NO_2, NH_4, PO_4, SiO_4, Total size-fractioned Chla	CTD Rosette	5-10 depths per station. All survey stations
Metazooplankton and ichthyoplankton composition, abundance, biomass	Plankton nets (150 and 505µm)	All grid survey stations
Microzooplankton composition, abundance, biomass	CTD Rosette	All grid survey stations
Abundance, biomass, composition of benthic community	3 m plumb staff beam trawl	All grid survey stations

Abundance, biomass, composition of pelagic community	Acoustic – modified marinovich trawl	Continuous collection of acoustic data with trawl sampling as needed to verify acoustic targets
Abundance, biomass, composition of epi-pelagic community	Cantrawl rope trawl	All nearshore grid stations (red triangles)
Phytoplankton primary production (total and size fractionated) and taxonomic identification	CTD Rosette	6 depths per station at a subset of stations
Fatty acid analysis of seston and zooplankton	CTD Rosette Plankton nets	At a subset of stations

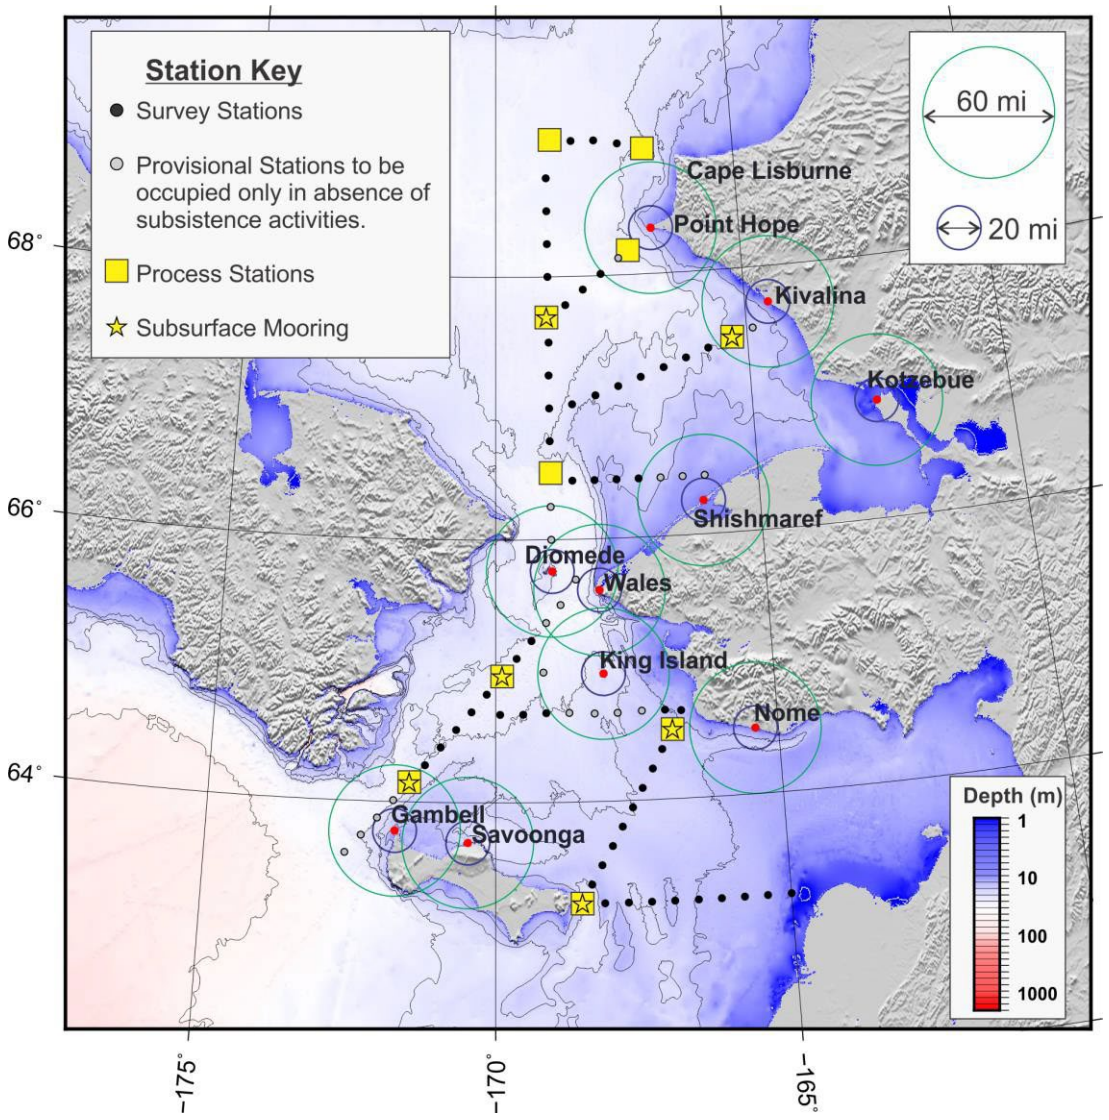

Figure 1. Proposed station and mooring locations for ASGARD during May and June 2017 and 2019. Process stations would be occupied first (from south to north), then survey stations would be occupied from north to south. Microphone icons denote locations of companion marine mammal recorders.

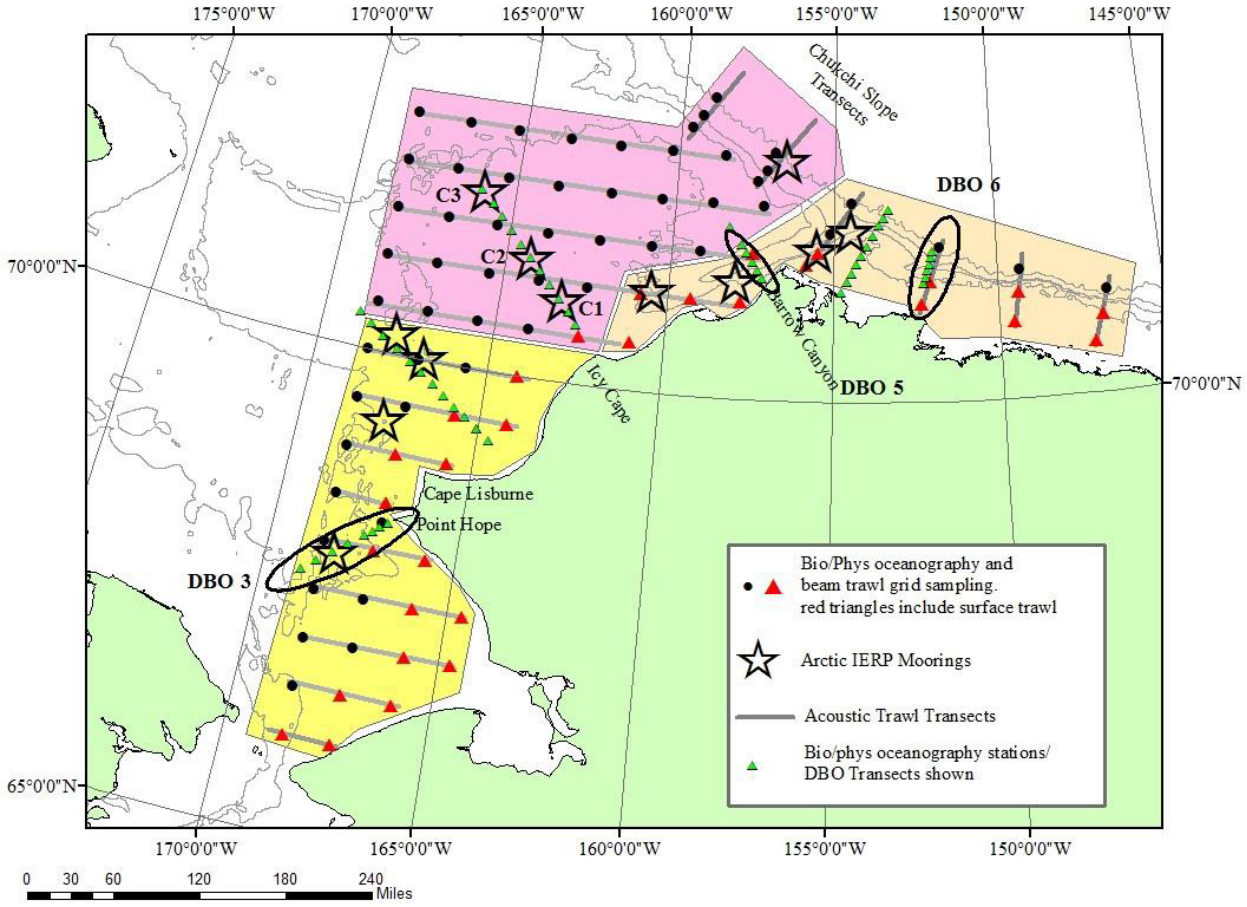

Figure 2. Proposed station (black dots, green and red triangles), mooring (black stars) locations, and acoustic trawl transects (grey lines) during Arctic Integrated Ecosystem Surveys, August to October 2017 and 2019.

Integration and Plans for Synthesis

Integration of analyses will occur throughout the Arctic IERP, and will involve collaborating Appendix A projects when feasible. To the extent that collaborating investigators are interested, joint manuscripts will be prepared that draw on data collected directly by this program and by other relevant projects. NPRB plans to organize a series of special issue publications to publish the results of this program, and papers that involve collaboration with other projects are encouraged.

Lead Principal Investigators (PIs) of other ongoing projects may elect to commit to collaboration and join the list of Appendix A collaborators at any point. The Arctic IERP expects such projects to commit to sending a representative to annual Arctic IERP PI meetings (travel expenses and salary will not be reimbursed) and to share data within a password-protected portal established for the Arctic IERP. In turn, collaborators will gain access to the Arctic IERP data and will be invited to join collaborative discussions throughout. If interested, contact the NPRB Senior Program Manager, Danielle Dickson (Danielle.Dickson@nprb.org).

NPRB intends to issue a call for proposals for a synthesis that will begin shortly after the main Arctic IERP field program concludes in fall 2021. Ideally the synthesis will include some investigators who have participated throughout and some new participants. The synthesis may emphasize modeling projects that would integrate the data collected by the field program.

Appendix A−Collaborating Projects

North Pacific Research Board is cooperating with other funding organizations to formally include the existing projects listed here in the Arctic ecosystem program. These projects will collaborate with projects funded through this call for proposals; the lead Principal Investigators will participate in annual PI meetings, share preliminary data with collaborators, and contribute intellectually to addressing the core hypotheses of the funded research program. Proposers are encouraged to describe how their research would use the data and expertise provided by existing projects. Existing projects are not intended to constrain the direction of the new research projects proposed.

Bering Strait mooring program

Funding provided by National Science Foundation

A physical oceanographic year-round mooring program has been maintained in the Bering Strait since 1990, with measurements for other disciplines being incorporated in recent years. For an overview of this prior mooring and accompanying section work, please see Woodgate, Stafford and Prahl (submitted) http://psc.apl.washington.edu/HLD/Bstrait/BStraitMooringSynthesis2015.html. Under National Science Foundation Arctic Observing Network (NSF-AON) funding, a set of 3 Bering Strait moorings will be maintained in the strait from summer 2014 to recovery in summer 2018, with annual mooring turn-around cruises, which (as time and weather allow) run accompanying CTD sections (no water samples) in the strait.

Lying all in US waters, the three mooring

- A2 (center of US channel);
- A4 (east side of US channel, measuring the Alaskan Coastal Current); and
- A3 (central to the strait about ~ 35km north of the Diomede Islands, at a site found to give a useful average of the flow through the Russian and US channels of the strait).

The data from the 3 moorings sites (combined with some satellite data) allow hourly quantification of the volume, heat and freshwater fluxes through the strait and an estimate of the physical water properties of the mean flow, of the waters in the US and Russian channels, and of

the Alaskan Coastal Current. These data are being combined with modeling results (Heimbach and Nguyen, MIT) and traditional knowledge (Raymond-Yakoubian, Kawerak, Inc) to yield a fuller understanding of the properties of the throughflow.

Each mooring carries lower level (~45m) and upper level (~17m) temperature and salinity sensors and an upward looking ADCP measuring water velocity in 2m bins to the surface, and some measure of ice thickness and ice velocity. (All instruments are internally recording, thus data are only available after recovery, and data calibration.) All calibrated data and data products are available via our website (psc.apl.washington.edu/BeringStrait.html), ACADIS and NODC. See e.g., the 2014 cruise report for full details, including mooring locations, cruise maps, and preliminary results (Woodgate et al., 2014, Bering Strait Norseman II 2014 Mooring Cruise Report, 73 pp, available at http://psc.apl.washington.edu/BeringStrait.html).
For further details (e.g., re data collaborations or possible additions to the moorings), contact Rebecca Woodgate.

Rebecca Woodgate, University of Washington, (206) 221-3268, woodgate@apl.washington.edu, psc.apl.washington.edu/BeringStrait.html

Arctic Marine Biodiversity Observing Network (AMBON)

Funding provided by Bureau of Ocean Energy Management, National Oceanic and Atmospheric Administration, and Shell

This study will build on emerging distributed biological observatories (DBOs) by developing a prototype ecosystem-based marine biodiversity network over offshore oil and gas lease areas in the Chukchi Sea, monitoring multiple trophic levels and species, and informed by historical data and past modeling efforts. Such a network will: expand upon planned and recently-launched observing sites, systems, and programs; employ innovative techniques for data discovery and methods that dynamically interrelate data sets and add value to existing monitoring data; collaborate with the U. S. Integrated Ocean Observing System (U.S. IOOS) participants and funding agencies to optimize data management and modeling capabilities.

Katrin Iken, University of Alaska Fairbanks, (907) 474-5192, kbiken@alaska.edu, https://www.sfos.uaf.edu/

Aerial Survey Arctic Marine Mammals (ASAMM)

Funding provided by Bureau of Ocean Energy Management

Bowhead whales, gray whales, beluga whales, Pacific walrus, polar bears, bearded seals, and other species of ice seals are known to seasonally occupy the Chukchi Sea. All of these species are subject to changes in environmental variables such as oceanographic currents, sea temperature, sea ice cover, prey availability, and anthropogenic impacts. Having a good understanding of the seasonal distribution, relative abundance, and habitat use of marine mammals in the Chukchi Sea is fundamentally important to evaluating the potential environmental impacts associated with oil and gas exploration and development and other anthropogenic activities. Aerial surveys of marine mammals are an efficient tool because they offer quick coverage of large marine areas. Past surveys are available for comparison with new data to assess whether changes in distribution or abundance have occurred since the earlier surveys were completed.

Megan Ferguson, National Oceanic and Atmospheric Administration, (206) 526-6274, Megan.Ferguson@noaa.gov, http://www.nmfs.noaa.gov/

Chukchi Acoustic, Oceanography and Zooplankton Study (CHAOZ)

Funding provided by Bureau of Ocean Energy Management

Baleen whales are subject to changes in environmental variables such as oceanographic currents, sea temperature, sea ice cover, prey availability, and anthropogenic impacts. Extreme ice-retreat and climate warming in the western Arctic over the last decade is anticipated to lead to changes in species composition and distribution, evidenced already through local knowledge and opportunistic observations. Hanna Shoal in the northeast Chukchi Sea is an area of special biological concern bordering the boundary between Chukchi and Arctic Ocean waters and its importance bowhead, gray and other whales, as well as walruses and ice seals, is not well known. The shallower waters of the shoal have long been known as traps for grounding of sea ice, and the creation of reoccurring polynyas. In most recent years, floating pack ice in summer persists in this area longer than elsewhere in the Chukchi, often surrounded by open water even to the north. Biological “hot spots” in the Chukchi Sea are thought to be related to coupled pelagic and benthic productivity.

Catherine Berchok, National Oceanic and Atmospheric Administration, (206) 526-6331, Catherine.Berchok@noaa.gov, http://www.nmfs.noaa.gov/

Characterization of the Circulation on the Continental Shelf Areas of the Northeast Chukchi and Western Beaufort Seas

Funding provided by Bureau of Ocean Energy Management

This study is a continuation and expansion of the existing surface circulation study within the northeast Chukchi Sea. Prior to 2009, surface current observations on the Chukchi shelf were extremely limited. Through a joint Industry/BOEM supported study, the University of Alaska Fairbanks (UAF), Coastal Marine Institute began measuring surface currents during the open water period on the Chukchi shelf beginning in September 2009 with the deployment of long range, High Frequency (HF) radar systems located at the villages of Barrow and Wainwright. In 2010, coverage was expanded to the southwest to include additional offshore lease areas. The surface current data was supplemented by water column profile data collected by Slocum Gliders. Acoustic Doppler current profilers (ADCPs) were also deployed across the Alaska Coastal Current at the head of Barrow Canyon to assess the annual flow regime, the connectivity between surface and subsurface currents during the open water season, and the changes in subsurface currents beneath the mobile pack ice and lead system during the winter months. This study will expand present efforts to improve understanding of the flow regime and shelf dynamics between the inner and outer Chukchi shelf, the exchange of waters between the Chukchi Sea and western Beaufort shelf through Barrow Canyon, and the upwelling of Atlantic Waters.

Thomas Weingartner, University of Alaska Fairbanks, (907) 474-7993, tjweingartner@alaska.edu, https://www.sfos.uaf.edu/

Distribution of Fish, Crab and Lower Trophic Communities in the Chukchi Sea Lease Area

Funding provided by Bureau of Ocean Energy Management

This study proposes to develop a broader understanding of abundance and distribution of demersal and pelagic fish, crab, and lower trophic communities needed to evaluate and mitigate the effects of offshore oil and gas development. Formerly, several BOEM funded studies have

identified temporal, seasonal, and spatial gaps in data on fish in the Chukchi Sea near the lease areas. This study is designed specifically to fill these information needs. It will build upon recent information on invertebrate communities in the Chukchi offshore lease area obtained by the 2009 study "Chukchi Sea Offshore Monitoring in Drilling Area (COMIDA): Chemistry and Benthos (CAB)." It will create a similar survey design such that data sets are compatible, comparable, and extend the time series and contribute to further knowledge of pelagic fishes in the northeast Chukchi Sea.

Franz Mueter, University of Alaska Fairbanks, (907) 796-5448, fmueter@alaska.edu, https://www.sfos.uaf.edu/

Marine Arctic Ecosystem Study (MARES)

Funding provided by Bureau of Ocean Energy Management, Office of Naval Research, Shell, U.S. Arctic Research Commission, U.S. Coast Guard, and ArcticNet

This project intends to collect additional comprehensive and integrated information in the Arctic on the spatio-temporal distribution of fundamental physical, biological and chemical variables, their associated interactions and regulating mechanisms, as well as the distribution of cultural and subsistence resources which sustain local communities. This information will be used to better understand and assess arctic ecosystem sensitivities and vulnerabilities as a function of space and time to aid decision-makers in minimizing the impact of the oil and gas industry on the Outer Continental Shelf. The resulting information will support NEPA analyses, environmental impact assessments, in validating models, as well as in Oil-Spill Risk Analysis. Additionally, these observations and improved description and understanding of biogeochemical and physical interactions will aid to improve the accuracy of model simulations and forecasts. Coordinated observational and modeling efforts will produce information that will be analyzed from different perspectives: a) ecosystem understanding and environmental protection, b) climate change and monitoring, and c) Oil-Spill Risk Analysis.

Francis Weise, Stantec Consulting, (907) 343-5276, francis.wiese@stantec.com, http://www.stantec.com/

Hanna Shoal Project

Funding provided by Bureau of Ocean Energy Management

The Hanna Shoal Project complements the earlier BOEM-supported COMIDA CAB project. Field work for the Hanna Shoal Project is complete and the PIs are synthesizing the results. Hanna Shoal is a shallow topographic feature of the northeastern Chukchi Sea that lies about 100 mi northwest of Barrow, Alaska at latitude 72° N. Water depths on various parts of the Shoal are as shallow as 20 m (60 ft), compared to 55 to 60 m (180 ft) on the surrounding seabed. The deeper flanks of the shoal are biologically rich, as reflected in the historically high concentration of walruses there in the summer that actively feed on the abundance of molluscs, crustaceans, polychaete worms, and other benthic fauna. 5

Oceanographers attribute the high productivity of Hanna Shoal, and the northeastern Chukchi Sea shelf in general, to the unique physics that steer highly productive water masses into the region, the relatively shallow average depth (42 m on the northeastern Chukchi Shelf), and weak grazing pressure from low zooplankton abundance during spring. These factors facilitate the deposition of a large proportion of pelagic primary production to the seabed, thus providing a major carbon subsidy to the benthic food web. The result is an extraordinary high diversity and biomass of benthic fauna that coincides with high water column chlorophyll a in localized "hotspots" of the Chukchi Sea. Benthic grabs revealed chlorophyll a concentrations among the highest ever reported in marine sediments (up to 665 mg m-2) and levels varied depending on the overlying water mass type. Estimates of epibenthic and infaunal organisms around Hanna Shoal, collected using plumb staff beam trawls and van Veen grabs (respectively), were enormous. Epibenthic assemblages ranged to 500 g m-2 (and thousands of individuals m-2); infaunal biomass and abundances approached 820 g m-2 and 5,500 individuals m-2, respectively. In both sampling years, the greatest biomass was not on the Shoal itself, but on its northwest and southeast flanks (or both), which receive Bering Sea water that originates in the North Pacific.

Ken Dunton, University of Texas at Austin, (361) 749-6744, ken.dunton@utexas.edu

NE Chukchi Sea Moored Ecosystem Observatory

Funding provided by Alaska Ocean Observing System, North Pacific Research Board, Olgoonik-Fairweather, University of Alaska Fairbanks, Université Laval, and University of Washington

A multi-institutional, multi-investigator partnership operates and maintains a subsurface moored observatory on the NE Chukchi shelf near 71.6N, 161.5W. The first deployment occurred in September 2014 and the mooring will be re-deployed annually through at least 2018.

The instruments record with high temporal resolution throughout the year, including the under-sampled and poorly understood seasons when sea ice typically inhibits ship-based sampling. Measurements include ice, ocean physics, nutrient and carbonate chemistry, particulate matter, phytoplankton, zooplankton, fisheries, and marine mammal datasets, thereby providing multifaceted views into the inter-trophic co-variability of the Chukchi shelf ecosystem. The scientific objectives of this monitoring effort are to:

1. Quantify hourly, daily, seasonal, annual, and inter-annual variations in selected physical, chemical, and biological measurement parameters on the shallow Chukchi Sea continental shelf.
2. Relate the timing and magnitude of fluctuations in nutrient and carbonate chemistry, particulate, and fish/zooplankton parameters to the current field and the physical hydrography, wind, light, and ice environment.

3. Provide researchers and resource managers with a broad-spectrum and multi-year set of reference observations that can be applied to evaluating and improving regional and global-scale biogeochemical, ice-ocean circulation, ecosystem, and stock-assessment models.

The observatory consortium welcomes new partners, new applications of the data already being collected, and new instrumentation that can further enhance the value of the existing efforts.

In accordance with the NPRB data policy, all data collected on this mooring are publicly available. There will be two data releases associated with each dataset. The first will come immediately after the recovery cruise and will include raw, unprocessed, data for users with time-sensitive applications. The second release includes fully processed data following requisite calibrations, application of calibration coefficients, and editing, typically within ~6 months of mooring recovery. Additional details about the mooring configuration, data policy, and the observatory consortium are available online at: http://mather.sfos.uaf.edu/~seth/CEO.

Seth Danielson, University of Alaska Fairbanks, (907) 474-7834, sldanielson@alaska.edu, http://www.sfos.uaf.edu/directory/faculty/danielson/

Northern Bering Sea bottom trawl survey

Funding provided by National Oceanic and Atmospheric Administration

Biennial northern Bering Sea (NBS) shelf surveys will start in 2017. This survey will provide long-term monitoring of bottom fishes, crabs, and other demersal macrofauna to help provide a better understanding of how biota and the ecosystem are responding to climate change and loss of sea ice. The ultimate goal is a long time-series of standardized data collections that will provide quantitative indices of abundance for determining how climate change is affecting population trends and community structure. The expanded survey data collections from the NBS will also augment those from the eastern Bering Sea (EBS) shelf and provide new insight into the spatial and temporal response of bottom fish and crab populations to highly variable interannual ice cover and summer bottom temperatures across the entire eastern Bering Sea shelf. Digital data are available online (http://www.afsc.noaa.gov/RACE/groundfish/survey_data/data.htm).

Bob Lauth, National Oceanic and Atmospheric Administration, (206) 526-4121
Bob.Lauth@noaa.gov

Northern Bering Sea BASIS (Bering-Arctic Subarctic Integrated Survey)

Funding provided by National Oceanic and Atmospheric Administration

The northern Bering Sea BASIS survey will continue in 2016 and 2018. These surveys will assess the relative abundance, size, and energetic status of late summer/early fall fish species such as western Alaska juvenile Chinook and chum salmon, capelin, herring, juvenile pollock, and saffron cod. Bio/physical oceanographic data will also be collected to assess the impact of climate change and variability on the ecosystem. When combined with the southeastern Bering Sea BASIS survey, the resulting survey effort will cover much of the eastern Bering Sea shelf. Digital data are available from the program leader Ed Farley.

Ed Farley, National Oceanic and Atmospheric Administration, (907) 789-6085,
Ed.Farley@noaa.gov

Chukchi Ecology and Seal Survey (CHESS)

Funding provided by National Oceanic and Atmospheric Administration

A comprehensive survey for the abundance and distribution of bearded and ringed seals in the Chukchi Sea will be conducted in 2016. In collaboration with the U.S. Fish and Wildlife Service, the objectives may be expanded to include polar bears. The survey will be based on coupled infrared and color imagers. Animals will be detected by infrared video and the species will be identified from high-resolution color photographs, a method demonstrated to be highly effective in recent surveys of the Bering Sea pack ice zone. Because large portions of the bearded and ringed seal populations use the Russian waters of the western Chukchi Sea, the survey will require collaboration with the Russian Federation. The Chukchi survey will complement the results of the Bering Sea survey, leaving only the Beaufort Sea as a gap in complete estimates of the breeding populations of ice seals in the seas surrounding Alaska.

Peter Boveng, National Oceanic and Atmospheric Administration, (206) 526-4244, peter.boveng@noaa.gov

Influence of sea ice on ecosystem shifts in Arctic seas

Funding provided by U.S. Geological Survey Changing Arctic Ecosystems Initiative

The decline of Arctic sea ice is predicted to promote an ecosystem shift from benthic-dominated to pelagic-dominated communities on Arctic shelves, raising concern for species like walrus and eiders that feed on benthic organisms. Sea ice dynamics are thought to support a rich benthic ecosystem by promoting the export of surface primary production to the ocean floor. As sea ice extent diminishes, more prolonged open-water phytoplankton blooms and increased zooplankton grazing may increasingly route surface primary production to pelagic consumers. The pace of declining benthic production has been difficult to quantify, leaving resource managers with much uncertainty. We propose to relate annually resolved growth increments in benthic bivalves with satellite derived sea ice records to develop a predictive relationship between sea ice and benthic production. Bivalves are a key prey item for both walrus and eiders. The relative contributions of sea ice algae and phytoplankton, the two major sources of surface primary production, will also be described for bivalves using stable isotope analysis. Changes in bivalve size will be converted to differences in caloric content available to predators. Combining these products with model projections of future sea ice cover will allow us to predict the pace of shifts in benthic

production, clarify the underlying mechanism, and enhance forecasts of the population response of Department of Interior managed species to a changing Arctic environment. (Funded FY2014-FY2019)

Regional Arctic System Model (RASM)

Funding provided by U.S. Office of Naval Research

The Regional Arctic System Model (RASM) has been developed to advance capability in simulating critical physical processes, feedbacks and their impact on the Arctic climate system and to reduce uncertainty in its prediction. RASM is a limited-area, fully coupled ice-ocean-atmosphere-land model that uses the Community Earth System Model (CESM) framework. It includes the Weather Research and Forecasting (WRF) model, the LANL Parallel Ocean Program (POP) and Community Ice Model (CICE) and the Variable Infiltration Capacity (VIC) land hydrology model. In addition, a streamflow routing (RVIC) model was recently implemented in RASM to transport the freshwater flux from the land surface to the Arctic Ocean. Finally, marine biogeochemistry components are currently being implemented in the ocean and sea ice components to expand RASM capability into Arctic ecosystem studies. The model domain is configured at horizontal resolution of 1/12° (or ~9km) for the ice-ocean and 50 km for the atmosphere-land model components. It covers the entire Northern Hemisphere marine cryosphere, terrestrial drainage to the Arctic Ocean and its major inflow and outflow pathways, with optimal extension into the North Pacific / Atlantic to model the passage of cyclones into the Arctic. All RASM components are coupled at high frequency to realistically represent interactions among model components at inertial and longer time scales.

Arctic Coastal Ecosystem Survey (ACES)

Funding provided by North Pacific Research Board (project 1229), Bureau of Ocean Energy Management, National Oceanic and Atmospheric Administration, and North Slope Borough/Shell Baseline Studies Program

In response to a rapidly changing Arctic, we developed a multi-faceted approach to examine variation in community structure and trophodynamics of nearshore arctic nekton during the ice-free season of 2013 and 2014. Fish samples were collected weekly via beach seine at 12 stations surrounding Pt. Barrow in three water bodies (Chukchi, Beaufort, Elson Lagoon) from ice breakup (early July) until late August in 2013 and 2014 (also planned for 2015). Juvenile and larval stages (98%) comprise the majority of catch data suggesting nearshore areas might serve as nursery habitat similar to those in similar lower latitude systems. The Elson Lagoon is dominated by euryhaline and amphidromous species, whereas the Beaufort and Chukchi Sea stations were dominated by marine species. Several species of sculpin are common but rarely abundant throughout all sites; catch data from 2007-2009 and 2012-2014 show that availability of high quality forage species (capelin and Pacific sand lance) in the nearshore is linked to fluctuations in temperature, salinity and turbulence. A laboratory study has examined the temporal scale of tissue turnover for nitrogen and carbon stable isotopes, using Arctic sculpin. Results will offer insight into the rates of change in tissue and how landfast ice breakup alter foodweb structure. These different approaches will offer a better understanding of important drivers of spatiotemporal variability in nearshore foodwebs and improve the ability to predict how these systems may shift in the face of Arctic climate change.

Coincident with biological collections was a series of meteorological and oceanographic observations within Elson Lagoon and at the interface between the lagoon and the Beaufort Sea. The primary rationale for these observations was to link the meteorological and hydrodynamic conditions to changes in the biological community. To examine temporal patterns, an ADCP was moored in the inlet between Elson Lagoon and the Beaufort Sea during ice free periods of both 2013 and 2014 (also planned for 2015). Additionally, several mobile ADCP surveys were conducted within this inlet as well as the inlet between Elson Lagoon and North Salt Lagoon near Barrow to characterize flow dynamics between adjacent water bodies. These measurements

were linked to a nearby meteorological station to examine coupling from atmospheric and oceanographic processes at local scales. Based on preliminary analyses, responses in the biological community are likely mediated by the strong dependence of physical controls, both meteorological and hydrodynamic, and suggest variation in the temporal and spatial patterns. For more information about the project, see http://boswelllab.wix.com/boswelllab#!aces-project-summary/ce65.

Tracing sea ice algae in Arctic benthic food webs using the sea ice diatom biomarker IP25

Funding provided by North Pacific Research Board (project 1503)

Sea ice cover over the Chukchi Sea shelf is continually decreasing with a warming climate and the effects on primary production regimes, especially sea ice algal production and subsequently benthic food webs are still uncertain. Here we propose to use IP25 as an ice-algal specific tracer to reliably track sea ice algal sources in the Chukchi Sea benthic food web and to distinguish ice algae from other production sources such as pelagic phytoplankton. We will combine the IP25 tracer use with the sterol brassicasterol as a biomarker for phytoplankton to identify the relative proportions of sea ice algae (IP25) and phytoplankton (brassicasterol) in consumer diets (PIP25 ratio). Benthic bivalves and polychaetes are used as representatives of benthic food web consumers for their prominence in benthic communities and their wide variety of feeding types. We will use stable carbon isotope composition of dissolved inorganic carbon and of IP25 in sea ice algae, surface sediments and benthic consumers to ground-truth the sea ice origin of IP25 and its specificity for ice algae. This work can significantly advance our ability to project changes in the primary production regime to subsequent lower and higher trophic levels. Many of these higher trophic levels such as walrus and spectacled eiders are of subsistence interest to Alaska Native peoples, and knowledge gleaned from this project can enhance our understanding how these subsistence resources may be affected with continued climate warming.

Assessing the role of oceanic heat fluxes on ice ablation on the Chukchi Sea Shelf

Funding provided by North Pacific Research Board (project 1504)

This proposal seeks to understand the role of oceanic heat flux convergences in the summertime retreat of sea ice over the central Chukchi Sea. It is motivated by observations and preliminary numerical model results indicating that eddies generated along the marginal ice zone front carry substantial quantities of heat laterally beneath the ice. The lateral eddy heat flux is via intrusions of warm water into the pycnocline separating cold, dilute surface meltwaters and near-freezing, salty bottom waters. This process is potentially important in heating the underside of the ice and thus enhancing summer ice melt and retreat. In addition, the mean summer currents in the Central Channel may be thermodynamically important in the summertime retreat of sea ice directly and, indirectly, as a source of the eddies to other portions of the shelf. This project will support one graduate student and use an ocean-ice circulation model to: 1) determine the proportion of ice melt due to the vertical heat flux from the ocean with that due to the net air-sea heat flux at the ice surface; 2) evaluate the role of intra-pycnocline eddies versus the mean flow in providing this sub-surface heat flux; and 3) evaluate the role of winds in modifying the subsurface heat flux to the ice. Outreach consists of developing digital model animations (and explanations) for use in schools and communities to explain how the ocean affects sea ice melt in the Chukchi Sea. The content will be directed at junior high and high school audiences. Weingartner's role on the North Slope Borough-Shell Baseline Studies Science Steering Committee (SSC) will assist in outreach. The SSC includes representatives from six NSB villages and meets four times/year. He will use these meetings to inform the village representatives and present to the communities.

Thomas Weingartner, University of Alaska Fairbanks, (907) 474-7993, tjweingartner@alaska.edu, https://www.sfos.uaf.edu/directory/faculty/weingartner/

Growth and dispersal of early life history stages of Arctic cod and saffron cod under variable climate forcing

Funding provided by North Pacific Research Board (project 1508)

We propose to develop a biophysical transport model to simulate the dispersal of early life history stages of the two most abundant fish species, Arctic cod (*Boregadus saida*) and saffron

cod (*Eleginus gracilis*), in the Chukchi Sea and Beaufort Sea. These species form a crucial link from lower trophic levels to seabirds, marine mammals, and humans and have been recognized as potential target species for new fisheries in the Arctic. We combine observations of late larval and early juvenile stages of both species during the summer of 2012 and 2013 with laboratory-derived estimates of their temperature-dependent growth to parameterize an individual particle tracking model (TRACMASS) that includes growth and vertical movement. The model will be linked to a recently developed pan-arctic ocean circulation model (PAROMS) to test hypotheses about the origin and fate of young-of-the-year Arctic and saffron cod. Specifically, we aim to (1) identify likely spawning locations by tracking particles backward in time from known summer aggregations in the Chukchi Sea and (2) simulate pathways of dispersal from these aggregations to downstream nursery areas, which may include areas in the Beaufort Sea. Improved understanding of the growth, distribution, and movements of early life history stages of Arctic cod and saffron cod in the region, and of the connectivity between the Chukchi Sea and Beaufort Sea, has several immediate and long-term benefits. It directly addresses research priorities identified in the Arctic Fisheries Management Plan, enhances required descriptions of Essential Fish Habitat for two key prey species, and provides benchmarks against which to assess future changes to the Arctic marine ecosystem that may result from new development in the Arctic and from anthropogenic climate change.

Franz Mueter, University of Alaska Fairbanks, (907) 796-5448, fmueter@alaska.edu, https://www.sfos.uaf.edu/directory/faculty/mueter/

Glider based real-time monitoring of marine mammals in the Arctic

Funding provided by North Pacific Research Board (project 1515)

Shipboard observations of marine mammal distribution and habitat are expensive and logistically challenging to collect in Arctic waters. Port facilities are minimal and access to appropriate vessels for spending extended periods of time at sea is extremely limited. Autonomous platforms like gliders provide the capability to collect both oceanographic and passive acoustic data for far longer periods of time (weeks to months) and at significantly reduced costs than traditional shipboard or aerial surveys. We have developed a system to record, detect, classify, and remotely report Arctic and sub-Arctic marine mammal calls in real time from Slocum ocean gliders based on the digital acoustic monitoring (DMON) instrument and the low-frequency detection and

classification system (LFDCS). The system has been used several times in the northwest Atlantic Ocean and was successfully demonstrated for Arctic research during two pilot studies in the Chukchi Sea during September 2013 and 2014. Deployments to date have been short (1-3 weeks), but the capability exists for much longer missions. Our objective is to conduct an 8-10 week survey of the northeastern Chukchi Sea using a G2 Slocum glider to (1) examine the distribution, occurrence, and habitat of marine mammals using in-situ passive acoustic and oceanographic data collected by the glider, and (2) demonstrate the near real-time detection and reporting capability of the system. We hypothesize that some Arctic species associate with a front separating Bering Sea water and Alaska Coastal Current water to take advantage of aggregations of either pelagic or benthic prey. We further hypothesize that marine mammal community composition will change predictably with the strong spatial variability in oceanographic properties found in this region. We anticipate that these predictions will improve efforts to (1) mitigate impacts on marine mammals by human activities and (2) forecast changes in species distributions caused by climate change.

Peter Winsor, University of Alaska Fairbanks, (907) 474-7740, pwinsor@alaska.edu, https://www.sfos.uaf.edu/directory/faculty/winsor/

Northern Alaska Sea Ice Project Jukebox, Phase II

Funding provided by North Pacific Research Board (project 1521)

The project examines the complex interrelationship between people and their environment as it relates to nearshore and shorefast sea ice and humans having to continually adapt responses to changes in ice conditions. Also addressed is how climate change is affecting the ecosystems, which in turn affect the local people. This project tells the story of the changing Arctic through those who live within it daily.

Building upon the Northern Alaska Sea Ice Project Jukebox website (www.jukebox.uaf.edu/seaice) researchers can listen to recordings made in 1978, 2008, 2009, and 2013 with local experts in Barrow and other northern Alaska communities talking about their local traditional knowledge about and observations of changing sea ice. Conducting interviews in 2015 in Barrow will provide continuity in documentation of changing nearshore sea ice conditions and of "unusual" years. This expanding record is useful to researchers trying to

understand the ice environment as well as social scientists studying human adaptation, decision making, and risk taking behavior. Conducting similar interviews in Kotzebue will begin documentation of traditional knowledge of nearshore and shorefast sea ice there. This will serve as both a comparative dataset for a location with vastly different ice conditions than Barrow, and as the start of another longitudinal research plan in that area.

Leslie Joan McCartney, University of Alaska Fairbanks, (907) 474-7737, lmccartney@alaska.edu

NOAA Office of Exploration and Research

In FY15, NOAA Office of Exploration and Research will be supporting exploration projects in the Chukchi Borderlands. Three two-year projects are presently considered for funding. The field work for these projects is expected to take place in the August-September 2016 time frame.

For more information please contact John McDonough at john.mcdonough@noaa.gov, Jeremy Potter at jeremy.potter@noaa.gov or Nathalie Valette-Silver at Nathalie.Valette-Silver@noaa.gov.

'Pacification' of the Arctic: Climate change impacts on the eggs and larvae of Alaskan gadids

Funding provided by North Pacific Research Board (project 1403)

Both Arctic cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis)* play a crucial role in the Arctic by channeling energy between plankton and higher level marine mammals and seabird in a moderately simple pelagic, ice-dominated food web. Both cod species have physiology adapted for their cold-water environment, but may not be able to compete with other gadids invading northward i.e., Pacific cod, *Gadus macrocephalus* and walleye pollock, *Gadus chalcogramma*. For example, earlier experimental work from NPRB project #1228 indicated dramatic differences in the thermal optima within and among gadids from each region during the juvenile stage. However, the thermal sensitivity of dispersive egg and larval stages is unknown, yet could be the key component governing current and future biogeography of gadids in Alaskan waters. This project uses the multi-species broodstock program at the Alaska Fisheries Science Center's 20,000 sq. ft. cold-water laboratory at the Hatfield Marine Science Center. Gadids include

mature individuals from collections of juvenile Arctic and saffron cod (2012, 2013, 2014) and Pacific cod and walleye pollock (2005 – present). The first successful mass-scale spawning and larviculture of Arctic cod was completed during the spring of 2015. Current experiments are examining how variability in temperature and food availability influences growth, development, lipid storage and survival at these early, critical life stages in all four gadid species. Data from these common garden experiments will be used to predict future effects of warming on fish distribution and energetic impacts on food webs in the Arctic. Temperature-dependent growth and development data from these experiments are also being used to parameterize the individual particle tracking model (TRACMASS) for NPRB project #1508.

Benjamin Laurel, National Oceanic and Atmospheric Administration, (541) 867-0197, ben.laurel@noaa.gov

Sustainability of critical areas for eiders and subsistence hunters in an industrializing nearshore zone

Funding provided by National Science Foundation ArcSEES Program

Throughout the Arctic, indigenous people are faced with difficult choices between the economic benefits of industrialization versus associated threats to subsistence hunting. Evaluating alternatives is especially challenging when climate change is likely to shift the location and quality of habitats, as well as the ice conditions that govern access to those habitats by both animals and hunters. In the Chukchi Sea, anticipated infrastructure to support offshore oil wells, including a major pipeline, will be placed in a nearshore corridor used by most marine birds and mammals that migrate to the western Arctic. Such industrial development can provide employment for local residents and tax revenue for local governments, but should minimize potential impacts on subsistence species. In this research, we are modeling habitat requirements and mapping viable prey densities for commonly hunted sea ducks in the Chukchi nearshore corridor (10 to 40 m depth), and assessing long-term variations in accessibility of those feeding areas through the ice. We are supplementing these habitat maps with long-term delineations of the landfast ice edge along which much of the eider hunting occurs. In parallel with this representative study of potential shifts in habitat and hunter accessibility, we are conducting workshops based on methods of structured decision analysis in the village of Wainwright. These workshops will help create a local vision for sustainability, in terms of potential risks to

subsistence hunting and related lifestyles versus economic benefits of different development scenarios.

Appendix B. Arctic Integrated Ecosystem Research Program, individual project hypotheses and objectives.

Hypotheses and Objectives:

Communities (Huntington):

H-1: To date, the primary drivers of short-term variability in subsistence harvests have been environmental, whereas the primary drivers of long-term trends have been economic, cultural, regulatory, and technological.

H-2: Environmental variability affects food security in the short-term, but lack of economic well-being is the main long-term threat to food security.

H-3: Trends in the Chukchi marine environment (in contrast to short-term variability) have not demonstrably affected communities' overall well-being.

H-4: Chukchi coastal communities have a variety of response mechanisms for coping with marine environmental variability and shifts.

O-1:.Analyze existing information about subsistence harvests and traditional knowledge

O-2.Determine with other PIs how existing and new LTK information can inform their research & findings

O-3.Document additional information through community workshops

O- 4.Analyze existing and additional information to develop (a) summary of the Chukchi ecosystem as seen by coastal residents and (b) collaborations to connect local understanding with the results of other project components

Arctic IES: LTL (Ladd):

H-1. The source of heat to the Chukchi Sea comprises relatively even contributions from advected heat from the northern Bering Sea and local atmospheric heat fluxes. The contribution of local atmospheric fluxes is expected to increase with future reduction in sea ice.

H-2. Earlier ice retreat/melt will result in stronger stratification. The contribution of temperature to stratification is expected to increase, while the contribution of salinity to stratification is expected to decrease or remain unchanged.

H-3. In the southern Chukchi Sea, the primary source of nutrients is from Bering Strait; while in the northern Chukchi, nutrient supply is a combination of Bering Strait and upwelled Arctic basin water. Remineralization of organic matter provides a local source of ammonium, and will decrease with earlier ice retreat/melt.

H-4. Earlier ice retreat/melt will further shift the balance of spring primary production from ice-associated algae to pelagic phytoplankton, thereby reducing organic matter export to the benthos and increasing organic matter flow to pelagic zooplankton grazers early in the season.

H-5. Warming ocean temperatures will increase upper-ocean stratification and reduce vertical nutrient inputs to the mixed layer resulting in the formation of more spatially and temporally extensive subsurface phytoplankton blooms and productivity maxima.

H-6. Increased stratification will shift the phytoplankton community to a greater fraction of small cells, thus diverting more energy flow through the microzooplankton community.

H-7. Nutritional quality of phytoplankton and their zooplankton grazers will decrease with increased warming (due to increases in stratification and reductions in nutrients).

H-8. Summer zooplankton community will shift due to a) increases in the presence of Bering-Pacific fauna and a poleward retraction of arctic species, and b) changes in size structure of the copepod community to smaller-bodied microzooplankton and mesozooplankton as a consequence of the shift in size structure of phytoplankton.

H-9. Ichthyoplankton community composition will shift due to a) species-specific responses to temperature changes, and b) changes in species composition and size structure of zooplankton prey base.

O-1. Stratification (H1, H2) Quantify the strength of stratification, its temporal evolution, and the relative contribution of temperature and salinity throughout the spring ice melt/retreat. (Stabeno, Ladd, McCabe)

O-2. Circulation (H3) Quantify transport in Herald Canyon (RUSALCA) and the eastern Chukchi shelf. Identify pathways of flow and their respective heat, salt, and nutrient concentrations. (Stabeno, Ladd, McCabe, Mordy)

O-3. Heat Flux (H1, H2, H3) Estimate surface heat fluxes (summer) and compare to estimates of advective heat fluxes. (Stabeno, Ladd, McCabe)

O-4. Ice and Phytoplankton (H4) Examine the relationship among ice thickness, ice retreat, and the timing and magnitude of near-bottom chlorophyll that fuels benthic-pelagic coupling. (Stabeno, Mordy, Eisner, Lomas)

O-5. Phytoplankton Abundance (H4, H5) Quantify the relative abundance of pelagic phytoplankton species compared to sinking ice-associated algae. (Eisner, Lomas, Mordy)

O-6. Primary Production (H5, H6) Quantify spatial patterns in rates of total and new production, and phytoplankton community size structure as a function of water column physics and chemistry (nitrate and ammonium). (Eisner, Lomas, Mordy, Ladd, Stabeno)

O-7. Primary Production Model (H4, H5) Use new primary production data to validate and constrain a model of ocean primary productivity and fate (Liu et al., in press) in regions where subsurface productivity maxima are important. (Lomas)

O-8. Secondary Production (H8, H9) Quantify the distribution, size, abundance, and species composition of zooplankton and ichthyoplankton throughout the US shelf waters of the Chukchi Sea. Compare data to relative oceanographic conditions and to historical estimates as derived from AFSC sampling 2003- present. (Duffy-Anderson, Kimmel, Spear, Eisner, Stabeno)

O-9. Trophic Interactions – Hot Spots (H4, H5) Use primary production data to understand spatial variability in net community production and identify 'hot spots' of trophic connections between LTL and UTL, and how these might change in relation to other on-going projects in the region focused on detecting change (e.g., Distributed Biological Observatory [DBO]). (Lomas, Eisner, Mordy)

O-10. Trophic Interactions – Nutrition (H6, H7, H8, H9) Determine spatial and temporal relationship between phytoplankton, zooplankton and ichthyoplankton. Link observations to UTL-derived data to provide mechanistic understanding of trophic relationships. Compare fatty acid profiles of seston (primarily phytoplankton) and zooplankton to relate carbon sources to nutritional condition of key forage fish (e.g. Arctic cod). (Eisner, Lomas, Kimmel, Duffy-Anderson, Heintz (UTL))

O-11. Ecosystem Connectivity (H8, H9) Examine connectivity and exchange of lower trophic biota (zooplankton, ichthyoplankton, juvenile fish) between ecosystems (northern Bering Sea, Chukchi, Beaufort) to determine if each region acts as a source or a sink of ichthyo- and zooplankton stocks. (Duffy-Anderson, Kimmel, Spear, Eisner, Farley (UTL))

O-12. Arctic Cod and Saffron Cod (H9) Further resolve spawning and connectivity of Arctic cod and saffron cod adults, larvae and juveniles by providing new field data on late-stage larvae in summer that will be used to ground truth results from biophysical transport model efforts. (links to NPRB project 1508; Duffy-Anderson collaborator, postdoctoral co-advisor; Farley (UTL))

O-13. US/Russian Chukchi (H8, H9) Connect US Chukchi Sea IERP surveys to those planned in the Russian exclusive economic zone (EEZ; 2017, 2019; Melnikov, TINRO; Afanasyev, VNIRO). (Duffy-Anderson, Farley (UTL))

ASGARD: LTL (Danielson):

H-1. The structure (timing, magnitude and direction) of the wind field is the primary regulator of: a) variations in the partitioning of flow to either side of St. Lawrence Island, b) variations in advective pathways, sediment resuspension and sediment deposition events, c) two-way coupling of nutrient-poor coastal water masses with nutrient-rich mid-shelf water masses, d) temporally

variable advective contributions to the pre-bloom nutrient concentrations throughout the water column and to near-bottom nutrient concentrations year-round.

H-2. Near-surface stratification during the period of ice retreat regulates macronutrient availability, the depth, location, and magnitude of primary productivity, and the type (small vs. large) of phytoplankton community that subsequently dominates.

H-3. Fluxes and quality of particulate matter supplied to the benthos are tightly coupled to the phenology of sea-ice retreat and primary production. Beginning with under-ice phytoplankton blooms in the late spring and continuing through the summertime open-water season, sinking fluxes of fresh planktonic-derived organic matter provide a sustained food supply. In other times of year, supply of organic matter is small and less labile, coming primarily from resuspended, reprocessed and advective sources further south.

H-4. Although zooplankton are unable to contain the phytoplankton bloom, they are nonetheless important in both transferring some portion of this production into the metazoan planktonic food-web and efficient at repackaging material into fecal pellets for accelerated export to the benthos. The composition of the zooplankton community, and the temperatures at which they are operating, determine the efficiency of energy transfer into the zooplankton (i.e. losses to respiration versus growth and reproduction) and the rates of fecal flux. Some of these rates are consistent with emerging empirical global relationships (i.e. respiration), while others (i.e. growth rate) deviate significantly because polar data is currently underrepresented in such syntheses.

H-5. Benthic respiration, carbon biomass, production, macrofaunal community structure, functional group composition, and community-level production all vary with oceanic advection, water mass characteristics, and pelagic production regimes.

O-1. Quantify ice, water volume, heat, salt, nutrient, carbon, and planktonic fluxes at under-sampled locations and times in the northern Bering and Chukchi seas.

O-2. Assess particulate organic matter sinking and deposition rates and lower trophic level growth and respiration rates in locations and times that currently lack data.

O-3. Better quantify synoptic, seasonal, and inter-annual changes in the regional biological carbon pump dynamics and kinematics.

O-4. Collect physical, chemical, biogeochemical, and biological process rate data needed to constrain and evaluate biophysical and ecosystem models.

O-5. Help develop educational and outreach materials to communicate compelling narratives about our research to indigenous and non-indigenous local, regional, national and international audiences.

O-6. Contribute to the education and research programs of at least 6 M.S. and Ph.D. graduate students.

O-7. Support additional NPRB Arctic Program research projects with moored and ship-based measurement platforms.

O-8. Form coordinated data collection and analysis collaborations with national and international partners.

O-9. Enhance the Distributed Biological Observatory (DBO) program by occupying DBO stations at a time of year in which few samples have been collected previously.

Arctic IES: UTL (Farley):

H-1. Cods in the Arctic - Winners and Losers: Loss of sea ice and continued warming of sea temperatures during summer in the Chukchi Sea will restructure the food web, decreasing the amount of fat available to higher trophic level predators.

H-2. Cod habitat in the Arctic: The northern Chukchi serves as a nursery area for young-of- the-year Arctic cod, supplying juveniles to other areas of the Arctic.

H-3. Salmon expansion into a warming Arctic: Summer surface waters in the northeastern Bering Sea will continue to warm and be a source of heat advected to the Pacific Arctic Region, providing new marine habitat for juvenile salmon.

H-4. Seabird community structure and seabird-prey dynamics: The current predominance of planktivorous seabirds in the Arctic may shift back towards piscivorous seabirds, if warming sea temperatures restructure the food web.

O-1. (H1) Quantify the distribution, abundance, and condition of demersal fishes and shellfishes throughout the US shelf waters of the Chukchi and western Beaufort Sea.

O-2. (H1, H2, H3) Quantify the distribution, abundance, and condition of pelagic marine fishes, in particular young-of-the year Arctic gadids and other forage fishes, throughout the US shelf waters of the Chukchi and western Beaufort Sea (BOEM). Link observations with those derived from LTL component (physics, primary, secondary production) to provide mechanistic understanding of trophic relationships.

O-3. (H1, H2, H3) Combine results from previous (2003, 2007 - BASIS, 2012, 2013 - Arctic Ecosystem Integrated Survey (Arctic Eis)) and planned surveys (2017, 2019) to assess variability in pelagic and demersal fish ecology over time and relative to oceanographic conditions.

O-4. (H3) Establish the relative abundance, size, and condition of juvenile salmonids that utilize the coastal regions of the Northern Bering (NBS project), Chukchi, and western Beaufort Sea (BOEM) and determine their likely origin.

O-5. (H2) Further resolve early life history characteristics of Arctic cod and saffron cod and their behavior and connectivity between the Chukchi Sea and western Beaufort Sea using new survey results and the continuous observations from moored echosounders.

O-6. (H4) Quantify the distribution, abundance, and prey association (as a proxy for diet) of seabirds in the US shelf waters of the Chukchi and western Beaufort Sea (BOEM) in relation to oceanographic conditions, prey abundance, and feeding guilds.

O-7. (H1, H2, H3) Develop a spatially explicit bioenergetics model for Arctic cod and saffron cod as well as juvenile pink and chum salmon utilizing past and proposed integrated ecosystem data and test the impact of warming summer temperatures on their growth and distribution.

O-8. (H1, H2) Connect/collaborate US Chukchi Sea integrated ecosystem surveys to those planned in the exclusive economic zone within Russia.

ASGARD: Mammals (Stafford):

H-1. The presence of sub-Arctic marine mammals will be driven by prey availability (fish, zooplankton) that is in turn driven by water mass characteristics

H-2. The relationship between ice cover and Arctic species migration from the Bering Sea in to the Pacific Arctic can be quantitatively determined by comparing the onset of acoustic detection with ice advance (or formation) from, and retreat towards, the north (in the winter and spring, respectively).

H-3. Temperate marine mammal species will move progressively northwards as seasonal ice cover decreases and remain north of Bering Strait longer.

H-4. There will be differences in the species and seasonal occurrence of species between the eastern (eastern SLI and US Bering Strait) and western (Anadyr Strait and Russian Bering Strait) recordings. Data from the A3 climate site and the NE Chukchi Ecosystem Mooring site help establish if there are northern limits to sub-Arctic species and what the southern limits of Arctic species are.

H-5. The number of ship passages through both sides of the Bering Strait will continue to increase over time.

H-6. The northeastern Bering and southeastern Chukchi Seas are moving from a benthic ecosystem to a more pelagic-driven ecosystem similar to the northeastern Chukchi Sea

O-1. Have hydrophones deployed for two years on 3 moorings in the northern Bering and Chukchi Sea

O-2. Document the inter-seasonal and inter-annual presence of vocal marine mammals in the Pacific Arctic Region and compare of acoustic detections in the eastern, western, and central PAR

O-3. Integrate oceanographic drivers with acoustic detections to better understand how the physical environment influences the biological inhabitants of that environment.

O-4. Collaborate with other ASGARD PIs to develop an integrated understanding of the ecosystem components of the Pacific Arctic Region from physical forcing through to upper trophic level consumers.

Objective #1: Analyze existing information about subsistence harvests and traditional knowledge																						
Identify existing sources	PI, Co-PIs		x																			
Compile information from those sources	PI, Co-PIs			x	x																	
Analyze information and draft paper	PI					x																
Objective #2: Discuss with other PIs how existing information informs their research & findings																						
Meet at PIs meetings	PI, Co-PIs			x				x				x				x				x		
Follow up as appropriate	PI, Co-PIs				x	x	x		x	x	x		x	x								
Share results of Objective #1	PI					x																
Develop appropriate topics/questions for community workshops, regional meetings	PI, Co-PIs			x	x	x	x	x	x	x	x	x										
Objective #3: Document additional information through community workshops	Co-PIs																					
Hold regional meetings	Co-PIs, PI			x								x										
Choose dates, participants with communities	Co-PIs						x															
Hold workshops	Co-PIs							x														
Analyze information and prepare summaries	Co-PIs								x	x												
Objective #4: 4. Analyze existing and additional information to develop (a) summary of the Chukchi ecosystem as seen by coastal residents and (b) collaborations to connect local understanding with the results of other project																						
Prepare summary paper based on LTK	PI, Co-PIs									x	x	x	x									
Prepare collaborative papers with other PIs	PI, Co-PIs											x	x	x	x	x	x	x	x	x	x	x
Other

Arctic Integrated Ecosystem Research Program Final Report

ASGARD

Arctic Shelf Growth, Advection, Respiration and Deposition
Rate Experiments Project

25 June 2022

S.L. Danielson, R.R. Hopcroft, A.M.P. McDonnell, S.L. Mincks, B.L. Norcross, D.A. Stockwell, B.R. Charrier, R.E. Collins, L. Copeman, A. Deary, L. Eisner, C.E. Forster, T.D. Hennon, C. Lalande, R.M. Lekanoff, M.W. Lomas, J.M. Nielsen, S.H. O'Daly, A. Poje, and A.C. Zinkann

Table of Contents

Executive Summary

The ASGARD project

The Arctic Shelf Growth, Advection, Respiration and Deposition (ASGARD; NPRB awards A91-99a, A91-00a) Rate Experiments project and associated efforts (NPRB awards A94-00, A98-00a, A96, A97) proposed to address known information gaps that hinder a robustly comprehensive application of an ecosystem-based approach to resource management in the U.S. Pacific Arctic region. An ecosystem-based approach to resource management is needed to inform and guide policy-driven actions, but this approach requires synthesis of a detailed knowledge base that at the start of the Arctic Integrated Ecosystem Research Program (Arctic IERP) effort remained incomplete in three important ways. First, existing data were strongly biased to July through October although important ecosystem processes occur in spring, late fall and winter when access is difficult. Second, while we now understand the basic summer regional biogeography (Sigler et al., 2017), net community production (Codispoti et al., 2013), and drivers of species distributions for some taxonomic groups (Feder et al., 1994; Eisner et al. 2013; Blanchard, 2014; Grebmeier et al., 2015a; Ershova et al. 2015), we had scant information from any season about the fundamental chemical and biological rates that mediate carbon cycling and energy flows through the Northern Bering and Chukchi Sea ecosystem. Third, these knowledge gaps curtailed our ability to model the ecosystem, and our ability to make useful projections for management or policy decisions.

Accordingly, the hypotheses developed and addressed by the ASGARD project are:

H-1: *The structure (timing, magnitude and direction) of the wind field is the primary regulator of: a) variations in the partitioning of flow to either side of St. Lawrence Island, b) variations in advective pathways, sediment resuspension and sediment deposition events, c) two-way coupling of nutrient-poor coastal water masses with nutrient-rich mid-shelf water masses, d) temporally variable advective contributions to the pre-bloom nutrient concentrations throughout the water column and to near-bottom nutrient concentrations year-round.*

H-2: *Near-surface stratification during the period of ice retreat regulates macronutrient availability, the depth, location, and magnitude of primary productivity, and the type (small vs. large) of phytoplankton community that subsequently dominates.*

H-3: *Fluxes and quality of particulate matter supplied to the benthos are tightly coupled to the phenology of sea-ice retreat and primary production. Beginning with under-ice phytoplankton blooms in the late spring and continuing through the summertime open-water season, sinking fluxes of fresh planktonic-derived organic matter provide a sustained food supply. In other times of year, supply of organic matter is small and less labile, coming primarily from resuspended, reprocessed and advective sources further south.*

H-4: *Although zooplankton are unable to contain the phytoplankton bloom, they are nonetheless important in both transferring some portion of this production into the metazoan planktonic food-web and efficient at repackaging material into fecal pellets for accelerated export to the benthos. The composition of the zooplankton community, and the temperatures at which they are operating, determine the efficiency of energy transfer into the zooplankton (i.e. losses to respiration versus growth and reproduction) and the rates of fecal flux. Some of these rates*

are consistent with emerging empirical global relationships (i.e. respiration), while others (i.e. growth rate) deviate significantly because polar data is currently underrepresented in such syntheses.

H-5: *Benthic respiration, carbon biomass, production, macrofaunal community structure, functional group composition, and community-level production all vary with oceanic advection, water mass characteristics, and pelagic production regimes.*

Summary of Findings

Select key findings and descriptions of novel sample collections that target the proposed hypotheses and that are presented in the chapters of this report include the following highlights.

- Compilation and analysis of a nearly 100-year (1922-2018) historical record shows that the Bering and Chukchi continental shelves are differently impacted by climate change - including the magnitude of their warming trends. We show that the heat engines of both shelves accelerated over 2014-2018, with increased surface heat flux exchanges and increased lateral oceanic heat advection (Danielson et al., 2020).
- In contrast to prior observations that showed near-freezing waters in Anadyr Strait for many winter months, we show that 2017-2018 winter near-bottom waters advecting into Chirikov Basin were 1-2 degrees above the freezing point for all but a few weeks of time (Danielson et al., in prep.).
- We collected the first year-round northern Bering Sea set of whole water samples for major macronutrient analysis using a moored time series bag sampler. These samples are allowing us to refine our understanding of the seasonally varying heat and nutrient flux into the Arctic via the Anadyr Current (Hennon et al., in prep).
- We quantified the abundance of the *Synechococcus* and other picophytoplankton in the Northern Bering and Chukchi Seas. These observations support an increased importance of a previously marginal phytoplankton group during a warming period in the Chukchi Sea (Lomas et al., in prep.)
- We analyzed total lipids, lipid classes, fatty acids (FA) and alcohols in the dominant mesozooplankton (five taxa: euphausiids, copepods, chaetognaths, and pteropods) collected on both spring (ASGARD, 2017 and 2018) and late summer (Integrated Ecosystem Survey (IES) 2017 and 2019) Chukchi Sea research cruises. Preliminary analyses show that lipid-rich zooplankton have a high degree of reliance on diatom-sourced lipids (Eisner et al., in prep).
- We found significant seasonal differences in seston FA compositions, with diatom biomarkers more prevalent in spring, followed by a community shift to dinoflagellate and small flagellate FA biomarkers in late fall. Our analysis provide new information on FA phytoplankton dynamics and the important nutritional role of phytoplankton for higher trophic level consumers in the Northern Bering and Chukchi Sea regions (Nielson et al., in review).
- We measured sinking particulate organic carbon (POC) fluxes with drifting and moored sediment traps, as well as rates of primary production and particle-associated microbial respiration. In Bering Shelf/Anadyr Water masses, sinking POC fluxes ranged from 0.8 to 2.3 g C m^{-2} day^{-1}, making them among the highest fluxes ever documented in the global oceans. These results highlight the

extraordinary strength of the biological carbon pump on the Pacific Arctic shelf during an unusually warm and low-sea ice year (O'Daly et al., 2020).

- Fluxes of living algal cells, chlorophyll *a*, total particulate matter (TPM), POC, and zooplankton fecal pellets, along with zooplankton and meroplankton collected in the traps, were used to evaluate spatial and temporal variations in the development and composition of the phytoplankton and zooplankton communities in relation to sea ice cover and water temperature (Lalande et al., 2021).
- We present the first large-scale metabarcoding survey of 18S rRNA gene diversity in this region. Based on their biogeographical distributions, we identified exact sequence variants of *Chaetoceros*, *Pseudonitzschia*, *Micromonas*, and *Phaeocystis* as abundant taxa that may be negatively affected as the region warms (Collins et al., in review).
- We observed higher abundances of Pacific-affinity copepods (*Neocalanus* spp. and *Eucalanus bungii*) in 2017 compared to 2018. Multivariate analyses of the combined 2017 and 2018 150-µm datasets revealed five major community groupings. Euphausiids, composed of several *Thysanoessa* species, were present across the sampling domain. Amphipods, decapods, and the predatory chaetognath *Parasagitta elegans* were present in both years but did not show a particular spatial pattern. There was often a significant biomass in *Aglantha digitale* and other jellyfish and ctenophores present in the plankton nets.
- Egg production and copepodite growth rates were measured for the calanoid copepods *Pseudocalanus* spp., *Calanus marshallae/glacialis*, and *Metridia pacifica* in the northern Bering and southern Chukchi Seas during June of 2017 and 2018. Rates suggest considerable discrepancies between growth rates and egg production weights that we propose are due to differences in life history strategies. Consistent with other studies, we find that global growth models do not match our observations particularly well, likely because they are dominated by egg production estimates at lower latitudes (Poje, 2020).
- Spatial generalized additive models mapped the distribution of polar cod (also termed arctic cod by some and in some places in this report) by size class and relative to environmental variables. Seasonal differences in polar cod abundance suggest that polar cod migration may follow a classical 'migration triangle' route between nursery grounds as juveniles, feeding grounds as subadults, and spawning grounds as adults, in relation to ice cover and seasonal production in the Chukchi Sea (Forster et al., 2020).
- Polar cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*) are ecologically important forage-fish species in the Arctic. For the first time, we were able to synthesize the seasonal distribution, abundance, and growth of two co-occurring Arctic forage fishes. Kotzebue Sound was likely a source of early-stage prctic cod and saffron cod found offshore of Point Hope / Cape Lisburne and in nearshore coastal areas to the north. However, polar cod found in the Hanna Shoal region are not likely hatched from Kotzebue Sound, but from other areas such as Bering Strait and Chukotka Peninsula. Growth rates estimated in 2017, an extremely warm year in the Arctic, were higher than in previous studies, although this should be confirmed using otolith-derived growth rates (Deary et al. 2021).
- Closed-system respirometry using non-invasive oxygen optodes was conducted using five bivalve species *(Macoma sp., Serripes groenlandicus, Astarte sp., Hiatella arctica* and *Nuculana pernula*) and one amphipod species (*Ampelisca macrocephala*). Results revealed species-specific respiration rates with high metabolic demand for *S. groenlandicus* and *A. macrocephala* compared to that of the other

species. These results suggest that observed shifts in spatial distribution of the dominant macrofaunal taxa across this region will impact carbon demand of the benthic community. Hence, ecosystem models seeking to incorporate benthic system functionality may need to differentiate between communities that exhibit different oxygen demands (Jones et al., 2021).

- Four clusters of polychaete functional guilds were identified in the northern Bering and southern Chukchi sea. Polychaete functional composition and vertical distribution reflected the quality and quantity of organic matter input and the depositional environment, with likely impacts on biogeochemical and carbon cycling within the sediment (Charrier et al., in prep).
- Meiofauna community structure largely mirrored that of polychaete communities, with similar relationships to sediment grain size and organic matter characteristics. Macrofauanl-sized nematodes represented a distinct community relative to meiofaunal nematodes, and accounted for a large portion of total macrofaunal biomass, suggesting further investigation of this neglected group is warranted (Charrier et al., in prep).
- In light of changing temperature and productivity regimes across the Pacific-Arctic domain, we measured respiration rates of sediment communities at in situ (0 ºC) (ambient) and elevated (5 ºC) temperatures. On average, sediment community oxygen demand, a proxy for organic carbon consumption, was ~30% higher in the warmer treatments (Mincks et al., in prep).
- A mass balance Chukchi Sea ecosystem model incorporated terrestrial matter as an energy source, especially for benthic consumers. This component allowed us to adjust phytoplankton biomass to better match recent empirical measurements and to update the system-wide mass-balance (Zinkann, 2020; Zinkann et al., in review).
- Iterations of the mass-balance model showed that climate-driven increased retention of phytoplankton biomass in the pelagic realm would depress biomass of most benthic-feeding organisms across several larger ecosystem groups (invertebrates, fishes, mammals). However, simulated increases in both terrestrial matter inflow and bacterial biomass have the potential to compensate for some of the reductions in the energy supply from phytoplankton to the benthic food web, as well as to diversify the supply of organic matter to the seafloor (Zinkann, 2020; Zinkann et al., in review).
- Using empirical biomass and rate measurements, we applied inverse food web modeling to in-situ phytoplankton, microzooplankton, zooplankton, sedimentation and primary production data collected from four ecosystem surveys in the Chukchi and Northern Bering seas, June (spring) 2017 and 2018, and August-September (summer) 2017 and 2019. Our results indicate variable carbon transfer efficiencies among seasons and areas of nutrient replete and nutrient deplete conditions (Nielson et al., in prep).
- Extremely warm conditions from 2017 into 2019 – including loss of ice cover across portions of the region in all three winters – were a marked change even from other recent warm years. Biological indicators suggest this state change could alter ecosystem structure and function (Huntington et al., 2020).

Acknowledgements

We thank Captain Eric Piper, the crew of R/V Sikuliaq, Seward Marine Center shore support, and the Sikuliaq technical support team of Steven Hartz, Dan Nabor and Ethan Roth for their fantastic support throughout the program. Given the size and complexity of our experiments and especially our requirements of extensive climate-controlled incubation space, we believe that no other vessel would have been able to support such a wide array of activities and generate such across-the board successes in our field work.

We thank Bill Wiseman and the National Science Foundation for the addition of funded days at sea in 2017, and UAF's Alaska Sikuliaq Program for major support of ship days in 2017 and 2018. We thank Brendan Smith for accompanying us on the ASGARD cruises and providing photo documentation of our work and we thank Danielle Dickson and Matt Baker for guidance and support of the project through all of its phases. We thank all of the Arctic IERP funders for sponsoring the program: the North Pacific Research Board (NPRB), the Collaborative Alaskan Arctic Studies Program (formerly the North Slope Borough/Shell Baseline Studies Program), the Bureau of Ocean Energy Management (BOEM), and the Office of Naval Research (ONR) Marine Mammals and Biology Program for funding the main ASGARD proposal and all associated linked studies and gap projects (grants A91-99a, A91-00a, A94-00, A98-00a, A96, A97, A99).

We acknowledge that our field work was conducted on the waters where traditional subsistence harvest activities have been conducted by Inupiaq, Siberian Yupik, and Yupik peoples, and we thank them for their continued stewardship. Out of the field, our research is also conducted at the University of Alaska Fairbanks Troth Yeddha' campus, on the customary homelands of the Lower Tanana Dene. Robert Sudyam, Craig George and the Alaska Eskimo Whaling Commission provided valuable guidance for helping us avoid conflict with subsistence harvest activities. We thank Opik Ahkinga of Little Diomede for joining both research cruises and contributing as a valued member of the benthic team and for helping us better understand perspectives of the Bering Strait region residents.

Preamble

The Arctic Integrated Ecosystem Research Program

The Arctic Integrated Ecosystem Research Program (Arctic IERP, 2016-2021) was motivated by the rapid changes occurring in the waters of the northern Bering and Chukchi Seas. While much research has been done in the region, many important questions remain. As a cohesive research endeavor, the Arctic IERP was designed to address a single, overarching question:

How will reductions in Arctic sea ice and the associated changes in the physical environmental influence the flow of energy through the ecosystem in the Chukchi Sea?

The report you are reading now is one of five final reports from the fieldwork phase of the Arctic IERP (a synthesis phase was initiated in 2022 after the completion of the Arctic IERP field-based projects). This preamble provides a brief overview of the Arctic IERP, both to place each final report in the broader context of the whole program, and to encourage readers to examine the other final reports to learn more about the research that was done. More detailed information about the Arctic IERP can be found at https://www.nprb.org/arctic-program.

The spatial domain of interest for the Arctic IERP extended across the Chukchi Sea Large Marine Ecosystem (LME) as redefined by the Arctic Council's Protection of the Arctic Marine Environment (PAME) working group, and the northern Bering Sea (above 61.5° N) as it strongly influences dynamics in the Chukchi Sea from the upstream direction. The main focus has been on the greater Bering Strait region and the Chukchi Sea. The program included the Arctic Basin and Beaufort Sea insofar as processes in the Chukchi Sea are influenced by these adjacent areas.

Development of the Arctic IERP

Before any Arctic IERP research proposals were written, the NPRB administered an assessment program, the Pacific Marine Arctic Regional Synthesis (PACMARS; https://www.nprb.org/assets/uploads/files/Arctic/PacMARS_Final_Report_forweb.pdf), that applied $1.5M provided by Shell and ConocoPhillips to compile and synthesize existing information about the ecosystem and inform research priorities. This assessment included community meetings in 2013 in Savoonga, Gambell, Kotzebue, Nome, and Barrow (now Utqiaġvik), in which representatives from 17 communities between St. Lawrence Island in the Bering Sea and Barter Island in the Beaufort Sea participated. One major area of emphasis that emerged from these community meetings was concern about food security for the region's residents in light of the rapid environmental changes taking place. Results from the scientific assessment and input provided via the community meetings informed the creation of the Arctic IERP. The PACMARS report informed both the IERP Request for Proposals (https://www.nprb.org/arctic-program/request-for-proposals/) and the submitted proposals.

Following a proposal review process, the Arctic IERP formally began in 2016 with funding from the North Pacific Research Board (NPRB), the Collaborative Alaskan Arctic Studies Program (formerly the North Slope Borough/Shell Baseline Studies Program), the Bureau of Ocean Energy Management (BOEM), and the Office of Naval Research (ONR) Marine Mammals and Biology Program. Generous in-kind support was contributed by the National Oceanic and Atmospheric Administration (NOAA), the University of Alaska Fairbanks (UAF), the U.S. Fish & Wildlife Service (USFWS), and the National Science Foundation (NSF). This coordinated program was developed in cooperation with the Interagency Arctic Research Policy Committee (IARPC) and the U.S. Arctic Research Commission.

The Research

The Arctic Integrated Ecosystem Research Program (IERP) invested approximately $18.6 million in studying marine processes in the northern Bering and Chukchi Seas in 2017-2021, beginning in the summer of 2017. The research was divided into three main, complementary projects. The Arctic Shelf Growth, Advection, Respiration, and Deposition Rate Experiments (ASGARD) project carried out research in late spring and early summer of 2017 and 2018 aboard R/V Sikuliaq. The Arctic Integrated Ecosystem Survey (Arctic IES) conducted fieldwork aboard R/V Ocean Starr in late summer and early fall 2017 and 2019. In addition to the vessel-based surveys, sub-surface moored sensors were deployed to gather biophysical information continuously from June 2017 to September 2019.

In addition to the vessel-based work, a team of Arctic residents and social scientists, including members from eight communities in the North Slope and Northwest Arctic Boroughs and the Bering Strait region, met several times during the project to assess and analyze Indigenous observations and experiences with various types of change occurring in the region from Savoonga to Utqiaġvik. This group also compiled an annotated bibliography of Traditional Knowledge or Indigenous Knowledge (available through the data portal described below), to help researchers from other components of the Arctic IERP find information relevant to their studies.

Prior to the commencement of fieldwork, meetings were held in the three hub communities of Nome, Kotzebue, and Utqiaġvik. Scientists from the Arctic IERP and NPRB staff met with community members from each region to discuss the research purpose and plans. Research plans were also shared and discussed at meetings of the Alaska Eskimo Whaling Commission (AEWC), the Indigenous Peoples Council for Marine Mammals (IPCoMM), and with the Tribal Councils of Gambell and Savoonga on St. Lawrence Island. One result of these meetings was a shift in timing of the ASGARD cruises from May until June as well as a shift in timing and survey regions for the Arctic IES cruises, to avoid conflicts with subsistence hunting activities during what is traditionally the time for walrus hunting. Another result was the creation of communication protocols to avoid conflicts by alerting coastal communities to the presence of research vessels and adjusting the ships' routes to avoid areas where hunting was taking place. These communication protocols included regular radio broadcasts and daily emails to community members throughout the research area.

Results from the research are published in a growing list of peer-review journal articles, as well as cruise reports that provide contemporary accounts of the cruises, and many social media postings that are available through the NPRB website. Data are publicly available as described below.

Collaborations

The NPRB collaborated and coordinated with several other U.S. agencies and organizations that fund Arctic marine research. NPRB staff worked closely with the U.S. Interagency Arctic Research Policy Committee (IARPC) and the U.S. Arctic Research Commission. As the Arctic IERP was developed, the NPRB secured commitments for collaboration from 22 existing research projects that were detailed in Appendix A of the request for proposals, and made connections with new projects as they were funded.

International researchers also collaborated with the Arctic IERP via the Pacific Arctic Group (PAG), the North Pacific Marine Science Organization (PICES), and the Intergovernmental Consultative Committee (US/Russia - bilateral) as well as collaborations developed by individual investigators. PAG participants, including researchers from Canada, China, Japan, Korea, Russia, and the United States, have coordinated their cruise plans to sample standard stations in the Chukchi and Beaufort Seas termed the Distributed Biological Observatory (DBO). The Arctic IERP contributed to this effort. US-Russian data sharing initiatives were hosted in San Diego in 2016 and Vladivostok in 2017 to promote collaboration and exchange and to facilitate collaboration and synthesis of data and trends of patterns observed in the US and Russian waters in the northern Bering and Chukchi seas (PICES Press, Volume 26, Issue 1). ICC

collaborations and other connections also brought scientists from the Russian Federal Research Institute of Fisheries and Oceanography (VNIRO), the Russian Pacific Scientific Fisheries Research Center (TINRO), and Hokkaido University to the US to participate in the Arctic IES cruises and co-author results. This collaboration is expected to connect research interests within respective EEZs (Russia/US) of the Chukchi Sea.

COVID-19

While the fieldwork of the Arctic IERP was completed before the outbreak of COVID-19, the final meeting of researchers in November 2020 was changed from an in-person event to an online format. Other plans for in-person events, such as meetings in hub communities within the US Arctic region (Nome, Kotzebue, and Utqiaġvik), were cancelled. Laboratory work and some collaborations were postponed or cancelled due to COVID-related restrictions and concerns. The NPRB made supplemental funds available to assist researchers with unanticipated expenses due to the pandemic. The overall productivity of the Arctic IERP was likely not greatly reduced, due both to good fortune in the fieldwork being completed and to the collaborative relationships that had been built or strengthened during the program.

Data Portal

Axiom Data Science, Inc. provided data management support to the Arctic IERP throughout the field program. Axiom staff assisted the scientists in authoring metadata and publishing the datasets to public archives. The data collected by the Arctic IERP are publicly accessible at https://arctic-ierp.dataportal.nprb.org/

General Introduction

ASGARD Background & Scientific Rationale

As a changing climate and sea-ice retreat progressively expose the Chukchi Sea to a longer open water season, society will confront new resource management issues. These include the future of the cultures and subsistence lifestyles of local Indigenous communities, potential impacts of industrial activities (e.g. commercial fishing, oil and gas extraction), potential changes to regional ocean carrying capacity, and resilience of the Arctic marine ecosystem (NRC, 2014).

An ecosystem-based approach is needed to inform and guide policy-driven actions but this approach requires synthesis of a detailed knowledge base that at the start of the Arctic IERP remained incomplete in three important ways. First, existing data are strongly biased to July through October although important ecosystem processes occur in spring, late fall and winter when access is difficult. Second, while we now understand the basic summer regional biogeography (Sigler et al., 2017), net community production (Codispoti et al., 2013), and drivers of species distributions for some taxonomic groups (Feder et al., 1994; Eisner et al. 2013; Blanchard, 2014; Grebmeier et al., 2015a; Ershova et al. 2015), we have scant information from any season about the fundamental chemical and biological rates that mediate carbon cycling and energy flows through the Northern Bering and Chukchi Sea ecosystem. Third, these knowledge gaps curtail our ability to model the ecosystem with even a basic level of confidence – and our ability to make useful projections upon which we can base management or policy decisions.

The Arctic Shelf Growth, Advection, Respiration and Deposition Rate Experiments projects (ASGARD; NPRB awards A91-99a, A91-00a, A94-00, A98-00a) proposed to address the above limitations by:

- undertaking environmental and LTL rate and distribution measurements from spring-season expeditions to the northern Bering and southern Chukchi seas in 2017 and 2018;
- coordinating and collaborating with other ongoing projects, including participating in ship-of-opportunity sampling later in those years; and
- carrying out year-round biophysical mooring deployments.

With this approach, we gathered missing information required for next generation modeling and follow-on synthesis activities, such as sought by Gibson and Spitz (2011) and Whitehouse et al. (2014). As shown in this report, some of these synthesis analyses have already been begun in the course of our initial publication efforts. Although the Arctic IERP as whole has advanced our understanding, the analyses that we might approach today include new questions that were not well appreciated just a few years ago when the program began.

The northern Bering and Chukchi continental shelves (*Figure 1*) annually transmit freshwater, heat, nutrients, and carbon (dissolved, particulate, and planktonic) from the North Pacific into the Arctic (Woodgate et al., 2005; Carmack & Wassmann, 2006). Previous work during the 1982-1988 Inner Shelf Transfer and Recycling (ISHTAR) program (with field work primarily in July and August) showed that the Chukchi inflow is an important source of new nitrogen for western Arctic productivity and the Arctic carbon budget as a whole (Walsh et al., 1989). Recent estimates of net community production (NCP) by

Codispoti et al. (2013) on the order of 70-100 g C m^{-2} identify the northern Bering and Chukchi shelves as the singular most productive region across the entire Arctic marine system, exceeding the NCP of the Nordic seas by a factor of 2-3 and exceeding other Arctic shelf and basin systems by factors of 6-100.

A defining feature of the northern Bering and Chukchi shelf that fundamentally shapes the regional ecosystem is the year-round delivery of substantial nutrient concentrations (NO_3 > 10 µM) to a region of the shelf that lies many hundreds of kilometers from the nearest continental slope (Sambrotto et al., 1984; Kinder et al., 1986; Walsh et al., 1989). Nutrient delivery to the Chirikov Basin euphotic zone is maintained at consistently high levels by the nutrient rich Anadyr Water (AW) carried by the Anadyr Current where production is estimated at 250–300 g C m^{-2} y^{-1} (Sambrotto et al., 1984; Grebmeier et al., 1988; Springer, 1988; Walsh et al., 1989). The Bering Strait transport can vary by nearly a factor of two inter-annually (Woodgate et al., 2012) and nutrient concentrations vary year-to-year (Danielson et al., 2017) but nutrient flux variations into the Chukchi have remain unquantified until this program (Mordy, 2020; Hennon et al., in prep.).

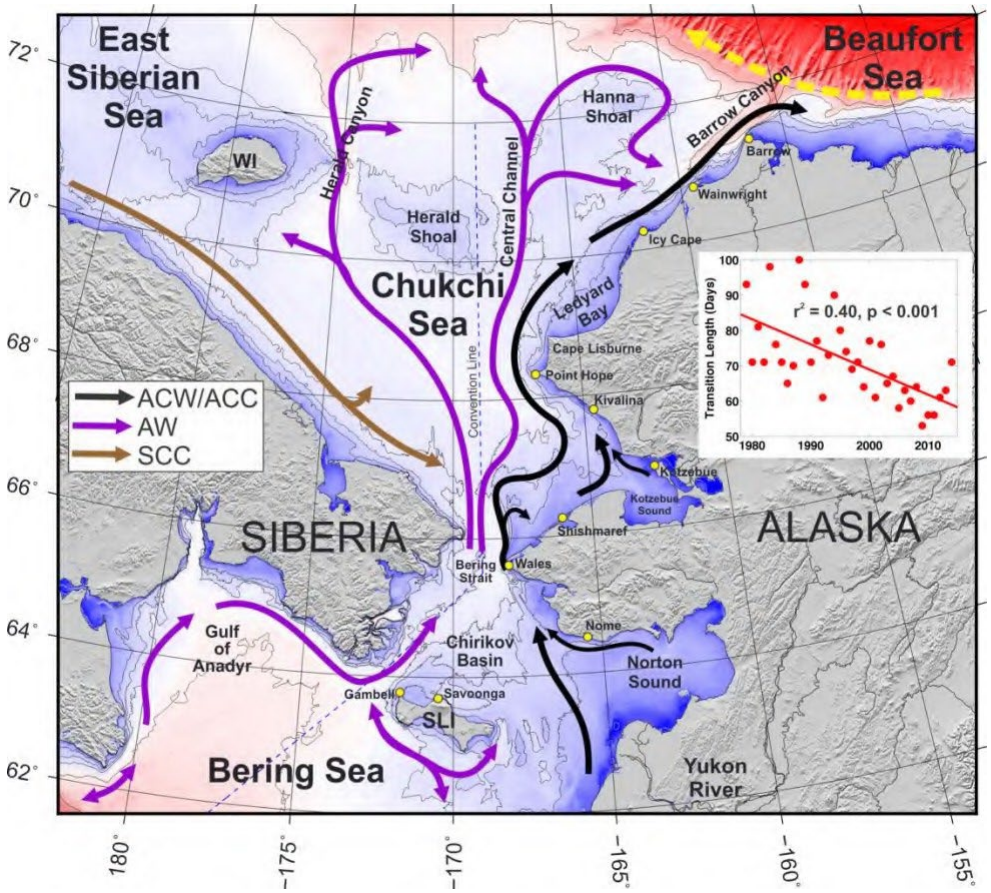

Figure 1. Map showing place names, persistent current systems, bathymetry (color shading). Inset: Decline in the regional duration of the annual spring sea-ice retreat, computed as the time between 80% and 20% ice cover.

Primary production begins initially in early spring, leading to rich sympagic communities (Gradinger, 2009). Phytoplankton growth accelerates in late spring once ice retreat and snow melt permit sufficient

light penetration into the water column (Hill et al., 2005; Mundy et al., 2005). Production quickly outpaces consumption by grazers, leading to the spring bloom. With an overall thinning of sea-ice, substantial under-ice blooms may also occur (Arrigo et al. 2012, Zhang et al. 2015). As the bloom wanes, ungrazed cells age and tend to settle quickly to the shallow (< 60 m) shelf, but the degree to which sinking particles are remineralized or repackaged in the pelagic zone is mostly unknown. Nonetheless, a large fraction of the organic matter makes it to the seafloor where it sustains a thriving benthic community (Highsmith & Coyle, 1990; Feder et al., 2007; Grebmeier & Maslowski, 2014, and references therein) that supports benthic-feeding fish and marine mammals. However, during this critical period of ice retreat, the magnitude and spatial extent of the spring bloom, phyto- and zooplankton growth rates, planktonic grazing rates, and benthic deposition rates are all poorly known, thus precluding construction of a robust carbon budget. Even later in the season when zooplankton communities support rich seabird communities (Day et al., 2013; Gall et al. submitted), rate measurements of primary and secondary production remain scarce (Nelson et al., 2014).

Substantial insight into the structure of zooplankton communities, and the physical factors that shape their distribution in the northern Bering and Chukchi Sea, have emerged in the past decade (e.g. Lane et al. 2008, Hopcroft et al. 2010, Eisner et al. 2013, Questel et al. 2013; Ershova et al. 2015). In contrast, direct measurements of process rates and carbon transfer for zooplankton are seldom determined because they are inherently more laborious. Four key vital rates of interest are intricately interconnected: growth rate is the net result of grazing rate less losses to egestion, respiration, and excretion (primarily as nitrogen compounds). With the exception of egg production studies (e.g. Plourde et al. 2005; Hopcroft & Kosobokova, 2010) that typically underestimate the (somatic) growth rates of prior life stages (Hirst and Bunker 2003), and two studies of grazing rate (Campbell et al. 2008), our knowledge of vital rates for copepods in the cold waters of the Bering and Chukchi Seas is lacking. Even globally, rate measurements are rare in water colder than 5°C (Hirst & Bunker 2003, Bunker & Hirst 2004) such as occur most of the year for the Chukchi. A rich understanding of somatic and reproductive rates of copepods is available from the Gulf of Alaska (Napp et al. 2005; Hopcroft et al. 2005; Liu & Hopcroft 2006a,b) as well as grazing rate estimates for *Neocalanus* (Liu et al 2005, 2008), but caution should be employed in applying them to the colder and more productive water of the northern Bering and Chukchi Seas (thereby stressing the need for direct measurements proposed by the ASGARD study). Simultaneous measurement of carbon flow into zooplankton growth/reproduction, grazing rate, respiration and fecal flux from the zooplankton community would establish the extent to which primary production is captured, burned off, or exported by the metazoan zooplankton versus settling to fuel the benthos.

Regardless of its form as grazed or ungrazed material, the high quantity of production reaching the seafloor sustains populations of numerous large and energy-dense prey items in “hotspot” regions, which serve as prey resources for a number of benthic feeding predators (Grebmeier et al., 2006). Hotspots of benthic biomass may be maintained by interactions of water circulation with bathymetry, resulting in locally elevated deposition of organic material (Feder et al., 2007; Blanchard & Feder, 2014; Blanchard 2015; Grebmeier et al., 2015a). Blanchard & Feder (2014) hypothesize that these variations in mechanisms delivering food to the benthos and associated indirect effects of related environmental interactions may be unrecognized sources for change in hotspot production. In addition, advection of particulate carbon northward also appears to make a significant but unquantified contribution to the annual carbon budget in the eastern Chukchi Sea (Feder et al. 1994; Dunton et al. 2005). While previous

studies in the region focused on patterns of overlying productivity and the signatures of organic matter deposition in the underlying sediments, little work has been devoted towards investigating the sizes, types, distributions, vertical fluxes, and lateral transport of water column particles that form mechanistic links between the pelagic and benthic realms. Recently-developed optical tools coupled with more traditional methods of particle collection have potential to provide new insights into the fluxes, impacts, and mechanisms of carbon cycling on the northern Bering and Chukchi Shelves.

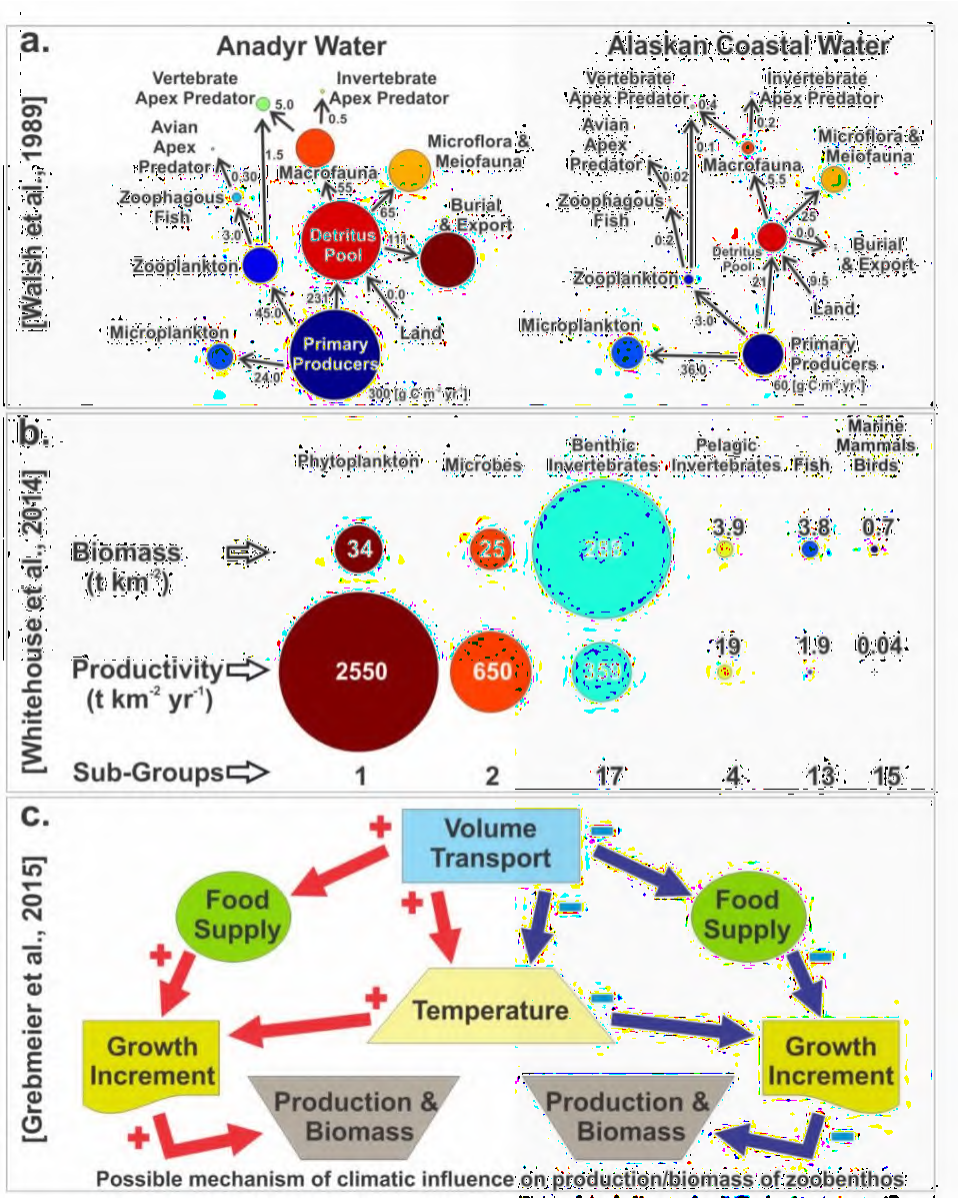

Figure 2. Three ways to consider the Pacific Arctic ecosystem. Top: Estimates of annually averaged carbon transfer rates for AW (left) and ACW (right); Middle: Biomass and productivity estimates along with number of functional subgroups per category. Bottom: Possible ramifications of a warming climate.

While macroscopic benthic communities have been relatively well-studied, the size and composition of the sediment microbial communities (bacteria, metazoan meiofauna) are largely unknown in this region,

even though these communities are most likely to show rapid responses to periodic or spatially patchy organic inputs because they are essentially non-motile and generally do not produce dispersive larval stages. Evidence from elsewhere suggests the magnitude, and perhaps quality, of particle flux influences microbial community structure, such that key ecosystem functions like remineralization rates and pathways may vary with magnitude of flux (Bienhold et al. 2012; Leduc et al. 2012). Moreover, the degradation rates of labile organic matter in sediments – crucial information in building models of energy flow for this system – have not been quantified, although they may be slower in this and other polar regions, constituting a longer-term benthic food reservoir (Mincks et al. 2005, Pirtle-Levy et al. 2009). Recent modeling attempts identify the lack of quantitative information on these key parameters describing ecosystem functioning, variability, and carbon flow in the benthos as critical data gaps (Whitehouse et al., 2014).

The ASGARD project was designed to refine existing paradigms that explain some facets of the regional ecosystem but that are otherwise known to be incomplete or outdated. Three separately published compilations that summarize many important aspects of our understanding are depicted in *Figure 2*. Together these show differences in carbon fluxes based on water mass, the importance of various functional groups to biomass and productivity, and possible ramifications of a warming climate. Inspection of each of these three cases reveals questions and information gaps that the ASGARD program addressed. For example, the seminal Walsh et al. (1989) depiction of carbon fluxes in different water masses (Figure 2a) shows microzooplankton, microflora and meiofauna as trophic dead-end carbon sinks. The Whitehouse et al. (2014) depiction (Figure 2b) provided relatively fine granularity to the upper trophic level functional groups (which account for ~1% of the biomass and 0.05% of the productivity) but does not adequately resolve the dominant contributions of the phytoplankton (1 group), microbes (2 groups), and pelagic invertebrates (4 groups). The balance described by Whitehouse et al. (2014) also utilizes many parameterizations derived from lower-latitude shelf ecosystems that may not hold for an Arctic shelf; both benthic and pelagic functional groupings require a more realistic parsing of ecological roles. Grebmeier et al. (2015b) hypothesize (Figure 2c) that warming temperatures will increase overall production and biomass, but do not explicitly include potentially important feedbacks associated with an ecosystem that is adjusting to new relations between altered timing and speed of ice retreat, spring blooms, and carbon pathways. Our proposed process studies were designed to complement – but not duplicate – the significant compilations of survey data collected in the Bering, Chukchi and Beaufort seas in recent years, positioning us to update these paradigms and write new ones.

Contemporary research programs have maintained an extensive set of summer-fall open-water Chukchi Sea observations over the last decade and more (Grebmeier & Harvey, 2005; Day et al. 2013, Pisareva et al. 2015), demonstrating that invertebrates, and to a limited degree small fishes, support the apex predators (marine mammals and seabirds) there. However, with a few notable exceptions, their cruises have sampled the Chukchi in July, August, September or October. Furthermore, many of these cruises targeted the northern Chukchi shelf or Chukchi/Beaufort slope region, far north of where much of the AW-fueled production takes place. Most of these recent Chukchi cruises were survey cruises that did not undertake the rate-process experiments that we believe hold the key to advancing our understanding of Arctic shelf carbon cycles. The 2007-2012 NSF-NPRB Bering Sea Project incorporated some valuable rate- measuring studies in multiple seasons but with a focus on the subarctic Bering shelf south of St.

Lawrence Island. Hence, our study helped fill data gaps that existed between the central and southeastern Bering Sea shelf and the northern Chukchi and Beaufort seas.

The ASGARD project was conceived as a coordinated ensemble of vessel- and mooring-based process studies consisting of physical, chemical, biological, and biogeochemical rate measurements that are designed to better constrain our knowledge of carbon and nutrient dynamics on the northern Bering and Chukchi sea continental shelves.

The fundamental science question posed in the ASGARD proposal was: **What regulates variations in carbon transfer pathways and how will the changing ice environment alter these pathways and ecosystem structure in the Pacific Arctic and beyond?**

Project Objectives

The ASGARD program was designed to address the NPRB Arctic Program's overarching questions that were outlined in their Request for Proposals (NPRB, 2015): "How do physical, biological and ecological processes in the Chukchi Sea influence the distribution, life history, and interactions of species or species guilds critical to subsistence and ecosystem function? How might those processes change in the next fifty years?". In addition to biological rate measurement studies, our research was designed to demonstrate how environmental conditions regulate flow rate variations and the associated advection of water masses, macronutrients, and particulate matter over the Northern Bering and Southern Chukchi continental shelves.

We aimed to contribute to M.S. and Ph.D. graduate student educations, including both students fully funded by the project and students not requiring financial support from ASGARD, but who participated in our cruises and collected data for use in their externally-supported research projects. We sought to strengthen existing and build new collaborations with national and international partners and scientific programs. We facilitated cruise and post-cruise involvement of outreach specialists in order to help us communicate our science and results to targeted stakeholders and the general public. We worked on strengthening our ties with coastal communities by participating in numerous co-management and other Alaskan Native Organization meetings, including Tribal Council consultations and by welcoming a Bering Strait region observer on board our research cruises as a member of the science team.

Specific objectives outlined in the ASGARD proposal are as follows:

O-1: *Quantify ice, water volume, heat, salt, nutrient, carbon, and planktonic fluxes at under-sampled locations and times in the northern Bering and Chukchi seas.*

O-2: *Assess particulate organic matter sinking and deposition rates and lower trophic level growth and respiration rates in locations and times that currently lack data.*

O-3: *Better quantify synoptic, seasonal, and inter-annual changes in the regional biological carbon pump dynamics and kinematics.*

O-4: *Collect physical, chemical, biogeochemical, and biological process rate data needed to constrain and evaluate biophysical and ecosystem models.*

O-5: *Help develop educational and outreach materials to communicate compelling narratives about our research to indigenous and non-indigenous local, regional, national and international audiences.*

O-6: *Contribute to the education and research programs of at least 6 M.S. and Ph.D. graduate students.*

O-7: *Support additional Arctic IERP research projects with moored and ship-based measurement platforms.*

O-8: *Form coordinated data collection and analysis collaborations with national and international partners.*

O-9: *Enhance the Distributed Biological Observatory (DBO) program by occupying DBO stations at a time of year in which few samples have been collected previously.*

Measurements and Approach

The ASGARD study consisted of ship-based and mooring-based studies designed to integrate with other proposed field, modeling, and human dimensions efforts. We selected the following focal measurements to help us address our main science question:

- Advective fluxes of physical, biotic and abiotic components of the water column
- Phytoplankton primary productivity
- Zooplankton growth/reproduction, respiration and fecal pellet production rates
- Particle deposition rates from the water column to the seafloor
- Quality of organic matter deposited to the seafloor
- Benthic respiration and organic matter decomposition rates
- Abundance and biomass of benthic microbial and metazoan fauna
- Distribution of fishes at different life history stages (NPRB Award A98-00a)
- Underwater sound and seasonal distributions of marine mammals (NPRB Award A94-00)

We sailed to the northern Bering and southern Chukchi shelf in 2017 and 2018 (Figure 4) on *R/V Sikuliaq*. In each year, working south to north, we first occupied ten "process" stations (yellow circles in Figure 3), setting up growth rate experiments (Table A1). that required extended (1-10 day) incubation times, along with collecting our broad suite of standard measurements (Table A2). As the ship visited the process stations, we paused to deploy and/or recover moorings (Table A3, Figure 3) that recorded year-round time-series. Following the process study phase, the ship transitioned to a "survey" mode of operation, rapidly working north-to- south along multi-station transects (Table A2, Figure 3) and re-occupying the process stations with a more limited sampling suite to provide information about short-term (~days) changes to the water-column. Along the way, we continued trawl and multi-core benthic samplings. Throughout the cruise we collected continuous underway navigational, ocean surface, ocean profile, and meteorological data (Table A4) to provide additional environmental context for subsequent analyses. The mooring array (Table A3, Figure 4) consists of four biophysical moorings south of Bering Strait, two moorings in the southern Chukchi Sea, plus the NPRB Long-Term Monitoring Program NE Chukchi Sea Ecosystem Observatory (CEO) moorings located on the southern flank of Hanna Shoal near Barrow Canyon.

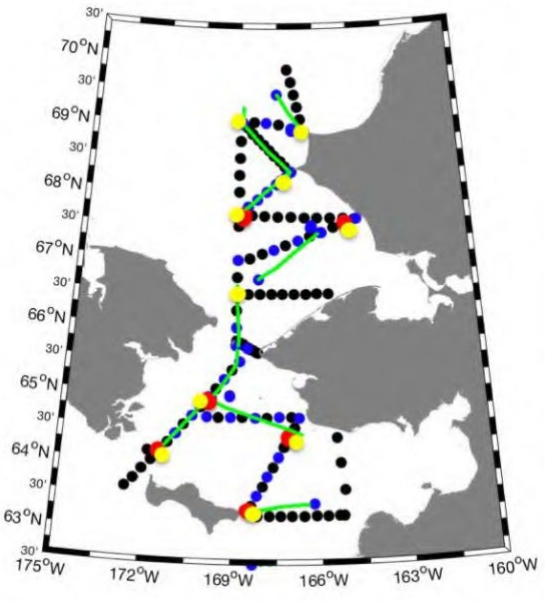

Figure 3. Location of field effort. Most 2018 stations (blue circles) were also occupied in 2017 (black circles). The Acrobat tows took place only in 2018. Some circles were shifted slightly on the map to reduce overlap.

Field Expeditions

ASGARD field efforts (Figures 3 and 4) are documented in two detailed scientific cruise reports (Danielson et al., 2017; 2018) and one community observer report (Ahkinga, 2017) that are available at the NPRB Arctic IERP website: https://www.nprb.org/arctic-program/about-the-program/. The cruises took place in June 2017 and June 2018. We joined the Arctic IES component of the IERP for final mooring recoveries in August 2019. Weather conditions and cruise timing allowed us to occupy more survey stations in 2017 than in 2018, but in 2018 we also operated a towed undulating Acrobat® sensor system that helped compensate for the reduction in occupied stations.

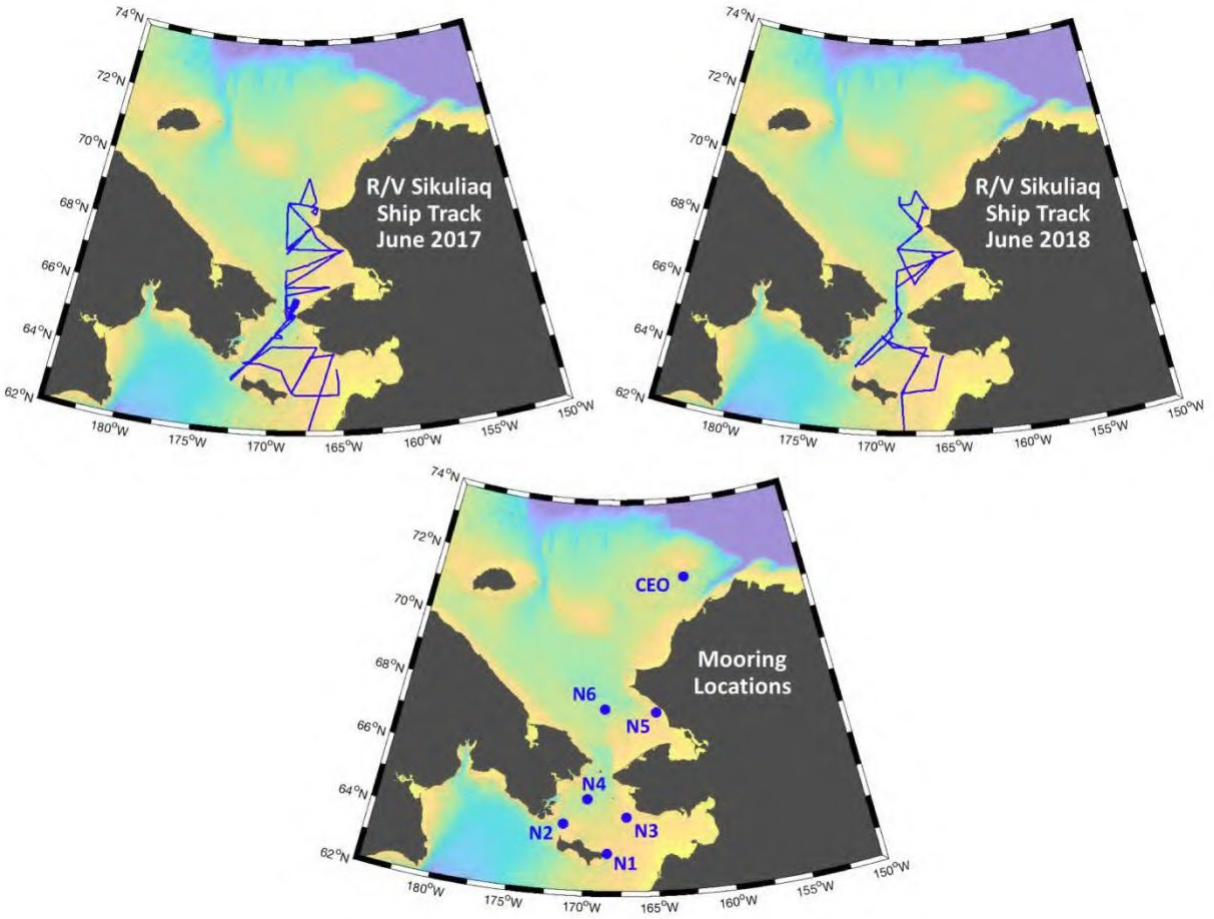

Figure 4. Vessel track lines (blue) for cruise SKQ2017-09S (June 2017, upper left), SKQ2018-13S (June 2018, upper right) and year-round mooring locations (blue circles, bottom). Identifying names for ASGARD moorings N1-N6 and the Chukchi Ecosystem Observatory (CEO) mooring cluster are labeled.

Project Objective Milestones

ASGARD objectives O-1 through O-4 are core scientific objectives that were achieved through collecting data and its subsequent analysis. Objectives O-5 through O-9 are programmatic objectives that are not specific to any particular disciplinary study. The objectives were addressed in the following fashion:

O-1: *Quantify ice, water volume, heat, salt, nutrient, carbon, and planktonic fluxes at under-sampled locations and times in the northern Bering and Chukchi seas.*

- Advective and state data from moorings (currents, CTD, sediment traps)
- Samples from drifting sediment traps
- Advective, station, and state data from ship-based sampling (currents, nets, acoustics)
- ASGARD Studies #1, 2, 3, 4, 5, 6, 7, 8, 12, 13, 14 (see *Results in Brief*)

O-2: *Assess particulate organic matter sinking and deposition rates and lower trophic level growth and respiration rates in locations and times that currently lack data.*

- Samples from moorings with sediment traps
- Samples from drifting sediment traps
- Data from optical sensors mounted on CTD rosette
- ASGARD Studies #8, 10, 11, 12, 13, 14, 15, 18, 19, 20 (see *Results in Brief*)

O-3: *Better quantify synoptic, seasonal, and inter-annual changes in the regional biological carbon pump dynamics and kinematics.*

- Advective and state data from moorings (currents, CTD, sediment traps)
- Samples from drifting sediment traps
- Data from ship-based sampling (nets, acoustics)
- Samples from multi-core sampler
- Data from growth and respiration incubations
- All ASGARD Studies (see *Results in Brief*)

O-4: *Collect physical, chemical, biogeochemical, and biological process rate data needed to constrain and evaluate biophysical and ecosystem models.*

- Advective flux data from moorings
- Zooplankton egg production, artificial cohort growth, and respirometery incubations
- Benthic macrofaunal incubations
- Benthic community oxygen utilization incubations
- Drifting sediment trap incubations
- All ASGARD Studies #1, 2, 3, 6, 8, 10, 12, 13, 14, 15, 18 (see *Results in Brief*)

O-5: *Help develop educational and outreach materials to communicate compelling narratives about our research to indigenous and non-indigenous local, regional, national and international audiences.*

- Contributions to the Arctic IERP informational flier
- ASGARD Synopsis products
- Numerous social media posts, blog postings, videos and other products
- Presentations delivered to scientific and public stakeholders

O-6: *Contribute to the education and research programs of at least 6 M.S. and Ph.D. graduate students.*

- All of the following graduate students participated in our cruises. Students denoted with a star (*) also analyzed samples and data collected by the ASGARD project in their thesis or dissertation:
  - Zane Chapman (UAF)*
  - Brittany Jones Charrier (UAF)*
  - Erica Escajeda (UW)*
  - Caitlin Forster (UAF)*
  - Silvana Gonzalez (UW)
  - Rachel Lekanoff (UAF)*
  - Kofan Lu (UAF)
  - Heidi Mendoza (UAF)
  - Stephanie O'Daly (UAF)*
  - Alex Poje (UAF)*
  - Jessica Pretty (UAF)
  - Sarah Seabrook (OSU)
  - Ann Zinkann (UAF)*

O-7: *Support additional Arctic IERP research projects with moored and ship-based measurement platforms.*

- We provided the ASGARD moorings as a platform for passive acoustic sensors.
- Arctic IERP scientists in the Arctic IES UTL and Arctic IES LTL projects joined the ASGARD cruises.
- Scientists with funding from NOAA, NSF, Japan, and other sources joined the ASGARD cruises.

O-8: *Form coordinated data collection and analysis collaborations with national and international partners.*

- Scientists from twelve universities, agencies, or research institute participated in the ASGARD cruises, including one from Hokkaido University in Japan.
- Scientists from at least 24 institutes in the US along with Japan, Russia, Canada and Germany participated in ASGARD PI-led manuscripts.
- ASGARD scientists participated in International symposia and data synthesis and analysis efforts.

O-9: *Enhance the Distributed Biological Observatory (DBO) program by occupying DBO stations at a time of year in which few samples have been collected previously.*

- We occupied DBO-1, DBO-2, and DBO-3 stations in June 2017 and June 2018.
- We deployed year-round moorings in the DBO-2, DBO-3, and DBO-4 regions and one mooring between DBO-1 and DBO-2.

Emerging Stories

This report documents ASGARD project activities and results through the end of the initial phase of research and analysis (2016-2021) of the Arctic IERP program. We were successful in collecting data that have been and will continue to be applied to all of our focal objectives and hypotheses, and, as shown below, we addressed each from several vantage points. The present list of ASGARD-associated publication currently numbers 55 (this number includes non-peer-reviewed cruise reports, peer-reviewed "core" ASGARD studies, studies that have leveraged data collected on ASGARD cruises, studies that leveraged ASGARD data products, and studies in which ASGARD PI participation was facilitated by participation in the Arctic IERP). At the same time, we have only begun tapping the vast suite of potential results that the rich Arctic IERP dataset may yet reveal.

The *Results in Brief* section documents experiments, observations, and analyses that use data collected in the ASGARD field effort and were written in support of helping fill the three main information gaps identified in the ASGARD proposal (i.e., seasonal data gaps, rate measurements, and model parameterization/validation data) and guiding science question (i.e., ecosystem change in the face of diminishing sea ice). These studies include graduate student theses, dissertation chapters, and peer-reviewed journal articles (published and in preparation) that were written in support of the ASGARD project proposal and the Arctic IERP Integrated Work Plan (NPRB, 2016).

ASGARD Studies are briefly summarized in the *Results in Brief* section, with titles, abstracts and one representative data figure. Studies with complete or extensive analyses correspond to Chapters bearing the same titles in the *Results in Full Section*. Studies 1-3 concentrate on environmental conditions (physics and chemistry) and their temporal and spatial variability. They examine the manifestation of climate warming, wind effects on circulation, and the Pacific-Arctic nutrient flux. Studies 4-12 focus on the pelagic realm, beginning with eukaryotic phototrophs and continuing to picocyanobacteria, phytoplankton community composition, mesozooplankton growth, reproduction, lipid composition, and respiration rates, and the spatial distributions and seasonal growth of polar cod. Studies 13 and 14 link the pelagic realm to the benthos by examining water column export fluxes of carbon. Studies 15-18 assess benthic organic matter consumption, community structure and their implications in a warming climate. Studies 19-20 apply mass balance and inverse modeling approaches, respectively, better constraining our understanding of organic matter flow through the ecosystem. Study 21 raises the question of whether this highly productive ecosystem could be in the midst of a significant ecological transformation.

Results in Brief

Study 1: Manifestation and consequences of warming and altered heat fluxes over the Bering and Chukchi Sea continental shelves

Danielson, S.L., O. Ahkinga, C. Ashjian, E. Basyuk, L.W. Cooper, L. Eisner, E. Farley, K.B. Iken, J.M. Grebmeier, L. Juranek, G. Khen, S. Jayne, T. Kikuchi, C. Ladd, K. Lu, R. McCabe, G.W.K. Moore, S. Nishino, S.R. Okkonen, F. Ozenna, R.S. Pickart, I. Polyakov, P.J. Stabeno, K. Wood, W.J. Williams, T.J. Weingartner, 2020. Manifestation and consequences of warming and altered heat fluxes over the Bering and Chukchi Sea continental shelves. *Deep-Sea Res. II: Topical Studies in Oceanogr.,* 177, 144781, https://doi.org/10.1016/j.dsr2.2020.104781

A temperature and salinity hydrographic profile climatology is assembled, evaluated for data quality, and analyzed to assess changes of the Bering and Chukchi Sea continental shelves over seasonal to century-long time scales. The climatology informs description of the spatial distribution and temporal evolution of water masses over the two shelves, and quantification of changes in the magnitude and throughput of heat and fresh water. For the Chukchi Shelf, linear trend analysis of the integrated shelf heat content over its 1922-2018 period of record finds a significant summer and fall warming of 1.4 ºC (0.14+/-0.07 ºC decade^{-1}); over 1990-2018 the warming rate tripled to 0.43 +/-0.35 ºC decade^{-1}. In contrast, the Bering Shelf's predominantly decadal-scale variability precludes detection of a water column warming trend over its 1966-2018 period of record, but sea surface temperature data show a significant warming of 0.22+/-0.10 ºC decade^{-1} over the same time frame.

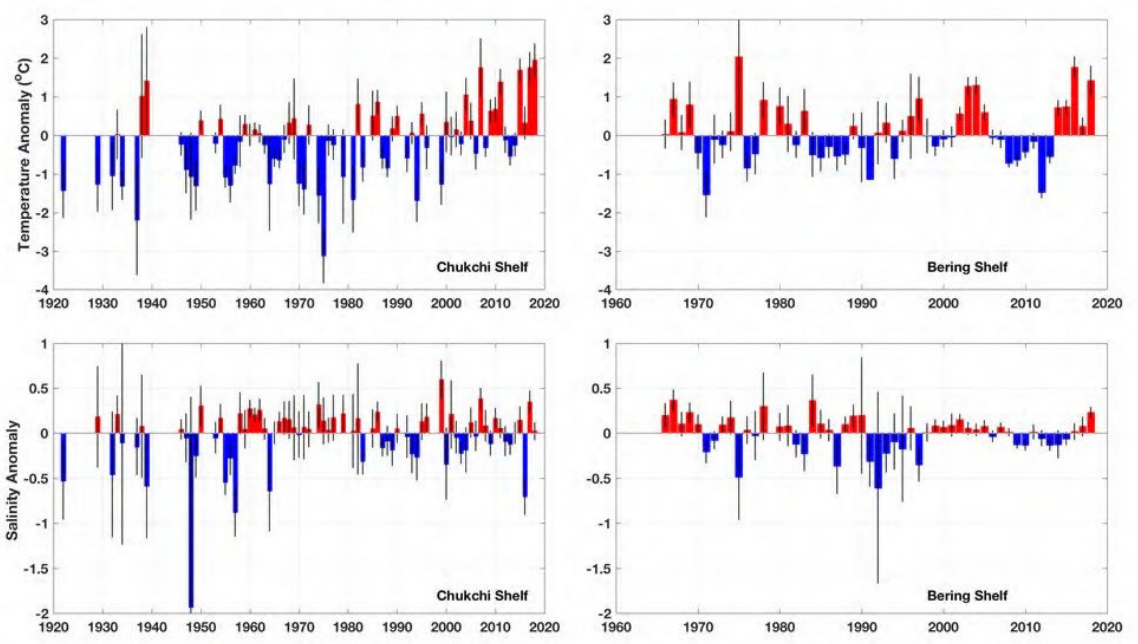

Figure 5. Annually averaged July through October thermal (top) and haline (bottom) anomalies over the Chukchi (left) and Bering (right) continental shelves. Error bar whiskers depict 95% confidence limits on the mean for each year's anomaly.

Heat fluxes over 1979-2018 computed by the European Centre for Medium-Range Weather Forecast (ECMWF) ERA5 reanalysis exhibit no record-length trend in the shelf-wide Bering surface heat fluxes, but the Chukchi Shelf cooling season (October-March) has a trend toward greater surface heat losses and its warming season (April-September) has a trend toward greater heat gains. The 2014-2018 half-decade exhibited unprecedented low winter and spring sea-ice cover in the Northern Bering and Chukchi seas, changes that coincided with reduced springtime surface albedo, increased spring absorption of solar radiation, and anomalously elevated water column heat content in summer and fall. Consequently, the warm ocean required additional time to cool to the freezing point in fall. Fall and winter ocean-to-atmosphere heat fluxes were anomalously large and associated with enhanced southerly winds and elevated surface air temperatures, which in turn promoted still lower sea-ice production, extent, and concentration anomalies.

Likely reductions in sea-ice melt were associated with positive salinity anomalies on the Southeast Bering Shelf and along the continental slope over 2014-2018. Negative salinity anomalies during 2014-2018 on the central and northern Bering Shelf may be related to a combination of 1) long-term declines in salinity, 2) an increase of ice melt, and 3) a decline of brine production. We hypothesize that freshening on the Bering Shelf and in Bering Strait since 2000 are linked to net glacial ablation in the Gulf of Alaska watershed.

We show that the heat engines of both the Bering and Chukchi shelves accelerated over 2014-2018, with increased surface heat flux exchanges and increased oceanic heat advection. During this time, the Chukchi Shelf delivered an additional 5-9 x 10^{19} J yr^{-1} (50-90 EJ yr^{-1}) into the Arctic basin and/or sea-ice melt, relative to the climatology. A similar amount of excess heat (60 EJ yr^{-1}) was delivered to the atmosphere, showing that the Chukchi Sea makes an out-sized contribution to Arctic amplification. A conceptual model that summarizes the controlling feedback loop for these Pacific Arctic changes relates heat content, sea ice, freshwater distributions, surface heat fluxes, and advective fluxes.

Study 2: Chirikov Basin Oceanography: Function, Structure, Drivers and Change (Manuscript in preparation)

Danielson, et al., In prep. Oceanography of Chirikov Basin: Function, Structure, Drivers and Change

Data from a suite of time series moorings, shipboard measurements, and numerical model integrations are assessed in order to build a better understanding of the oceanographic functioning of Chirikov Basin. We assess the regional wind forcing in order to better understand the regulation of the advective flow field over the Northern Bering and Southern Chukchi continental shelves. We show that the partitioning of flow to either side of St. Lawrence Island reflects a leaky switchyard type of balance between the central Bering Sea shelf and Chirikov Basin. Norton Sound may provide capacity to buffer a portion of and the mass transport, but sheared and bidirectional flow in Shpanberg Strait appears to be the main factor that decouples flow here from that in Anadyr Strait. Observations from outside of the Alaska Coastal Current, just downstream of Norton Sound, help show the connectivity between the two estuary and the greater shelf waters. Fluxes of heat, fresh water, ice, nutrients, and carbon are all modulated by the identified flow patterns, which reflect regionally coherent dominant patterns of flow variability. Remote sensing of sea ice presence along with optical sensors from select moorings (chlorophyll *a* fluorescence, photosynthetic available radiation and nitrate) help demonstrate how these flow patterns may influence the distribution, concentration, and productivity of phytoplankton and zooplankton here. We highlight the importance of the winter advection of oceanic heat on the regional sea ice cover and thickness, and how this is potentially affecting the local ecosystem.

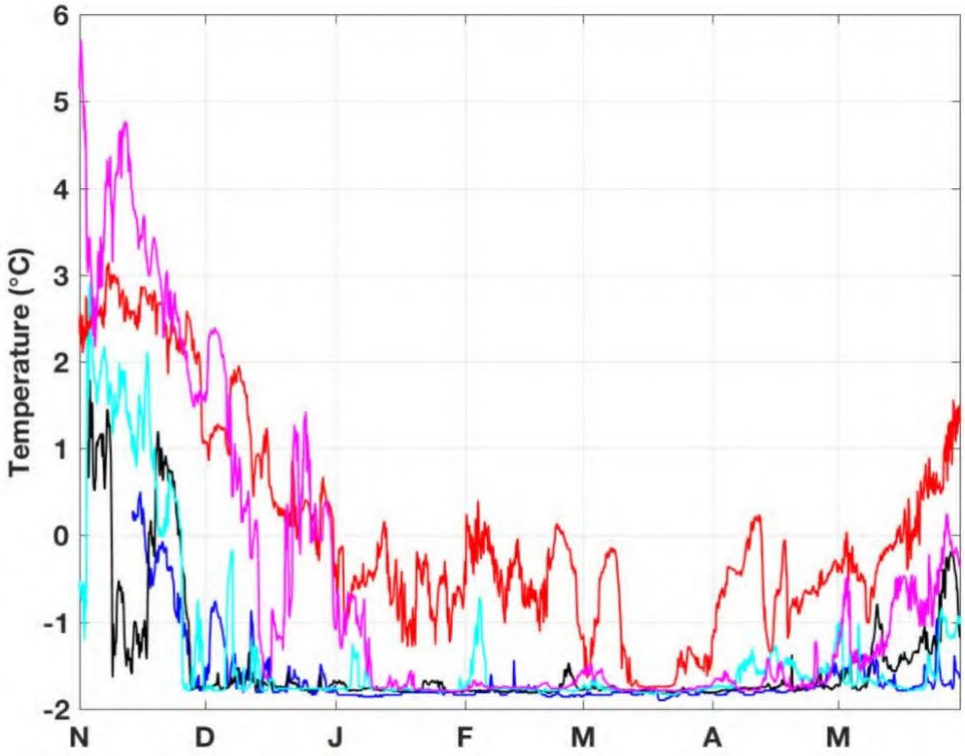

Figure 6.

Near-bottom temperature measured in Anadyr Strait from November (N) through May (M) in the winters of 1980-81 (blue), 1981-82 (black), 1984-85 (cyan), 2017-18 (red) and 2018-19 (magenta).

Study 3: Anadyr Current Contributions to the Arctic-bound Oceanic Nutrient Flux

Hennon, T.D., S.L. Danielson, C. Mordy, S. Stockwell, R. Woodgate. Anadyr Current Contributions to the Arctic-bound Oceanic Nutrient Flux. Manuscript in preparation for submission to *Geophysical Research Letters*.

Based on year-round measurements of nutrients from summer 2017-2018 from the Anadyr Strait, we use a combination of year-round mooring-based in situ measurements and salinity-nutrient relationships established at Anadyr Strait are used to estimate Pacific-to-Arctic fluxes of nitrate, phosphate, and silicate for each month spanning 1998-2018. Annually averaged fluxes are 16 ± 5, 1.6 ± 0.5, and 30 ± 10 kmol s^{-1} for nitrate, phosphate, and silicate, respectively, and inter-annual variability can reach ±30% of the means. Maximum fluxes occur in April, exceeding the annual average by ~50%, while minimum fluxes occur in December. Due to biological uptake, the seasonality of nutrient fluxes is more closely tied to nutrient concentration than transport, which peaks in June.

Our annually averaged estimates are ~ 50% higher than prior estimates, which may be rooted in methodological differences. We find significant ($p < 0.05$) increasing trends in phosphate and silicate fluxes over 1998-2018 that are associated with increasing transport. In contrast, nitrate exhibits no significant long-term trend, suggesting different nutrient composition ratios between surface and deep waters. Our data, taken from the core of the Anadyr current, will be valuable for assessing biogeochemical model performance at a globally important oceanic chokepoint and can contribute to studies that seek to understand the future trajectory of the Arctic ecosystem.

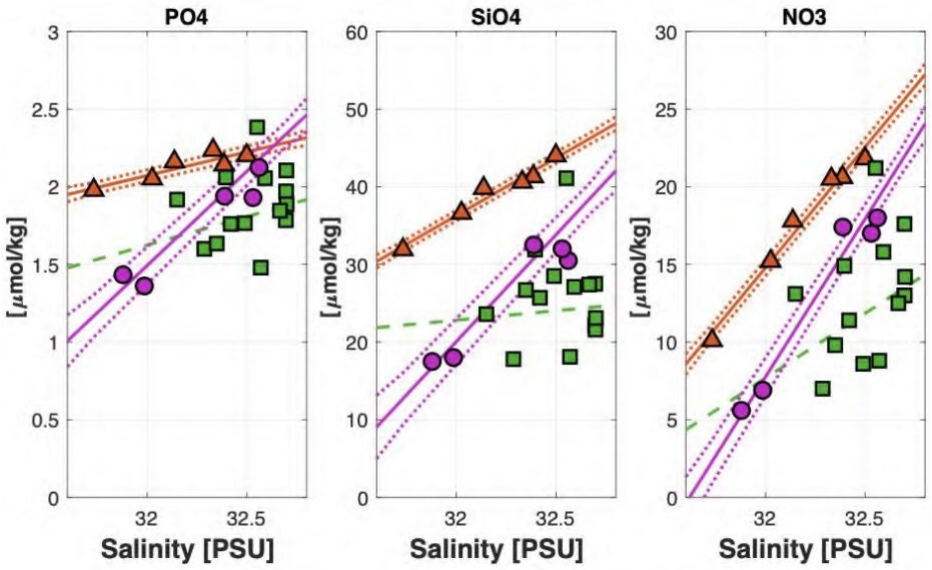

Figure 7. Seasonally-variable relationships between salinity and phosphate, silicate, and nitrate in Anadyr Strait during June 2017 to June 2018 (orange = Jan-Apr; magenta = Sep-Dec; green = May-Aug). Solid lines indicate the linear regressions to significant trends ($p<0.05$), with dotted lines indicating 95% confidence limits. The dashed green line shows the regression for May-Aug, though nutrient-salinity correlations during this time are not significant ($p>0.05$).

Study 4: Diversity and community structure of eukaryotic phototrophs in the Bering and Chukchi Seas

Collins, R.E., A. McDonnell, S. Danielson, R.M. Lekanoff, in review. Diversity and community structure of eukaryotic phototrophs in the Bering and Chukchi Seas, Submitted for review to *PlosONE*

Lekanoff, R.M., 2020. Diversity and Community Structure of Eukaryotic Phototrophs in the Bering and Chukchi Seas. University of Alaska Fairbanks. M.S. Thesis

The northern Bering and Chukchi Seas are productive high latitude ecosystems supported by tight benthic-pelagic coupling. However, warmer waters in Arctic and sub-Arctic regions are expected to alter phytoplankton community composition in the future, with unknown consequences for this critical ecosystem. Here we present the first large-scale metabarcoding survey of 18S rRNA gene diversity in this region, covering the summer 2017, the warmest on record, with sea surface temperatures rising to 10°C.

This report focuses on diatoms and "picophytoplankton" (operationally defined here as Chlorophyta, Haptophyta, and Chrysophyceae), which averaged 39% and 10% of the relative sequence abundance, respectively. In total, 201 diatom taxa and 227 picophytoplankton taxa were detected as exact sequence variants (ESVs) and categorized into 7 distinct diatom assemblages and 11 distinct picophytoplankton assemblages by hierarchical clustering.

Investigating the potential to predict phytoplankton community composition using shipboard CTD data alone, we found that predictions of individual ESV abundance were poor, but predictions of community assemblage were somewhat better, with environmental variables explaining 44% of assemblage variability for diatoms and 32% for picophytoplankton. Among diatoms, the genera *Chaetoceros* and *Thalassiosira* combined to make up 80% of the diatom relative abundance and 43% of the diatom ESVs, while among picophytoplankton the genera *Micromonas* and *Phaeocystis* combined to make up 57% of the relative abundance and 6% of the ESVs. Based on their biogeographical distributions, we identified ESVs of *Chaetoceros*, *Pseudo−nitzschia*, *Micromonas*, and *Phaeocystis* as abundant taxa that may be negatively affected as the region warms.

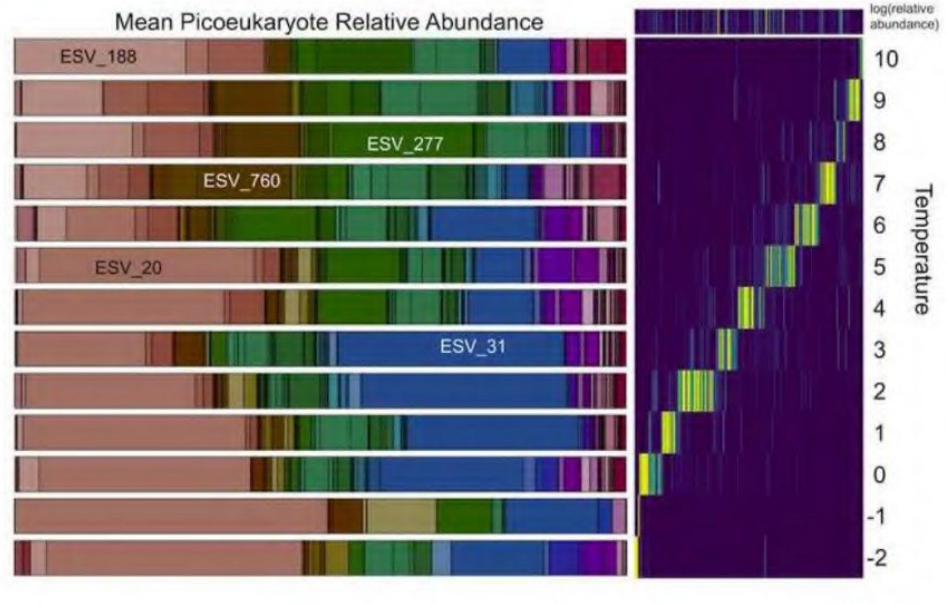

Figure 8. Mean picophytoplankton ESV relative abundance for the northern Bering and Chukchi seas cruises during 2017 after binning by temperature. ESVs are colored by genus. (right) Scaled picophytoplankton ESV relative abundance sorted by temperature at maximum relative abundance (each column is an ESV).

Study 5: Contributions of the picocyanobacteria Synechococcus to phytoplankton biomass during a period of warming in the Chukchi Sea

Lomas, M., Eisner, L., Nielsen, J., et al., In prep. Contributions of the picocyanobacteria *Synechococcus* to phytoplankton biomass during a period of warming in the Chukchi Sea.

Size structure of phytoplankton populations has been shown to be an important determinant of the flow of carbon and energy to higher trophic levels in Arctic ecosystems. Phytoplankton populations dominated by small (<10um) pico- and nanophytoplankton cells are generally dominated by eukaryotic flagellates that are tightly grazed by microzooplankton leading to increases in trophic length. General dogma suggests that the picocyanobacteria *Synechococcus* is detectable but comprises a negligible fraction of phytoplankton carbon in Arctic ecosystems.

As part of the Arctic IERP sampling program, we quantified the abundance of the *Synechococcus*, and other picophytoplankton, during the spring to fall period between 2017-2019 in the Northern Bering and Chukchi Seas. *Synechococcus* abundances increased from <500 cells/ml in spring to >50,000 cells/ml in the fall around Kotzebue Sound. Furthermore, the spatial extent of regions with elevated *Synecococcus* abundances in late summer/fall, as well as the absolute abundances, increased from 2017 to 2019, coincident with increasing late summer/fall water temperatures.

When integrated over the euphotic zone, *Synechococcus* contributed up to 40% of estimated total phytoplankton carbon during late summer/fall in Kotzebue sound and the region near Icy Cape. These observations support an increased importance of a previously marginal phytoplankton group during a warming period in the Chukchi Sea. The full implications of these changes in the phytoplankton community remain to be resolved.

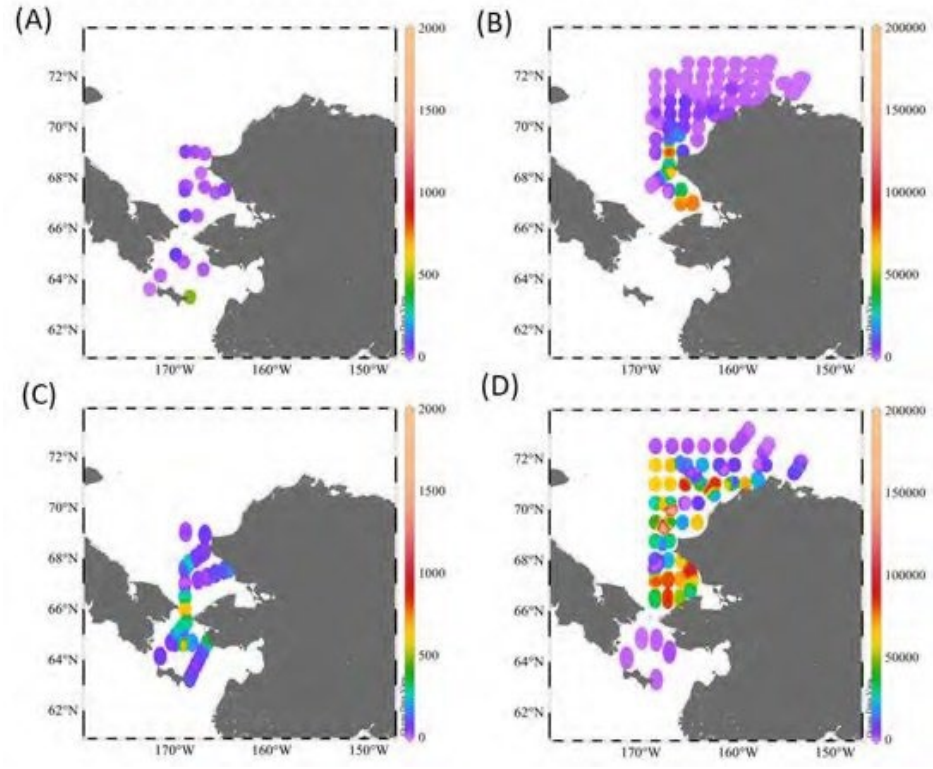

Figure 9. Spatial and seasonal distribution of *Synechococcus* abundance (cells ml^{-1}) in surface waters of the Northern Bering and Chukchi Seas. (A) Spring 2017; (B) Late Summer 2017; (C) spring 2018; (D) Late Summer 2019. Note the 100-fold difference in scales between spring and late summer.

Study 6: Variations in phytoplankton community composition, phytoplankton biomass, and primary production in a warming Arctic (Manuscript in preparation)

Eisner, Lomas, Nielsen, et al., In prep. Variations in phytoplankton community composition, phytoplankton biomass, and primary production in a warming Arctic.

Marine phytoplankton community composition, biomass and primary production are important to carbon cycling and consequently also the quality and quantity of dietary resources for higher trophic level consumers. Phytoplankton dynamics can vary considerably between spring and summer, nutrient deplete and replete water masses, and between surface and subsurface depths in Arctic seas. Phytoplankton taxonomic information, chlorophyll a biomass, and primary production data were collected during ecosystem process surveys in the Chukchi Sea in 2017 as part of Arctic ecosystem projects: Arctic Shelf Growth, Advection, Respiration & Deposition (ASGARD) and the Arctic Integrated Ecosystem Survey (Arctic IES) in June (spring) and August-September (summer), respectively. Measured primary production is compared to modelled phytoplankton growth based on equations incorporating light, temperature, and nutrient data.

Initial observational data confirm the highest chlorophyll a biomass was associated with the larger size fraction (> 5 um). As expected, diatoms were in higher abundance, primary production rates were higher although more patchy, and subsurface blooms were less prevalent in spring than in fall. Phytoplankton growth was nutrient- limited in surface waters at the majority of stations in summer. Chlorophyll biomass and production for the small (< 5 µm) size fraction, and abundance of dinoflagellates (combined autotrophic and heterotrophic) was higher in summer 2019 (the warmest year) than 2017.

These changes in phytoplankton community, in addition to reduced biomass and primary productivity, are likely to result in reduced food quality with negative ramifications for higher trophic levels.

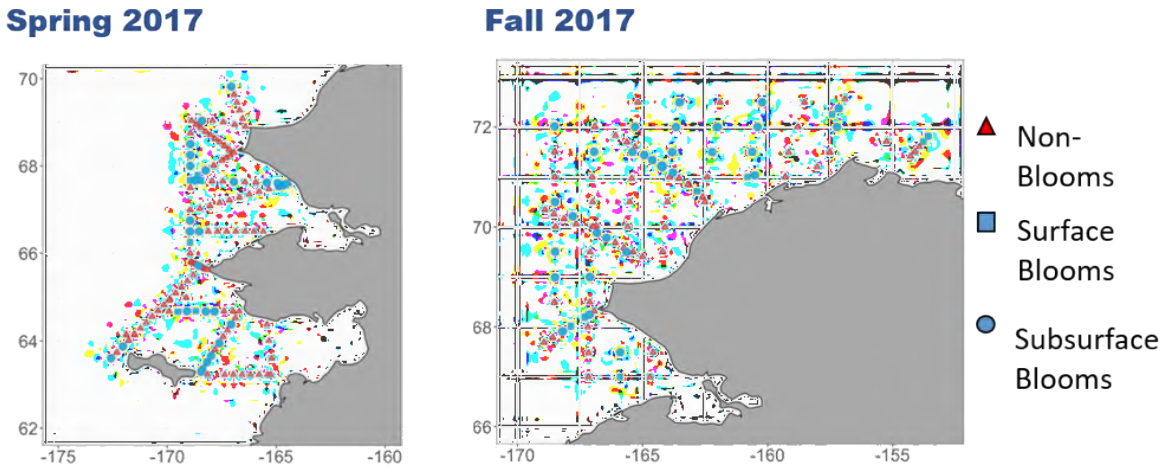

Figure 10. Phytoplankton blooms were defined as having a maximum chlorophyll a concentration >= 1 ug l^{-1} of the median for each cast. Spring: 7% surface blooms, 26% subsurface blooms, and 67% non-blooms. Fall: 8% surface blooms, 41% subsurface blooms, and 51% non-blooms. Subsurface blooms more prevalent in the fall than the spring.

Study 7: Phytoplankton and seston fatty acids dynamics in the northern Bering-Chukchi Sea region

Nielsen, J., L.A. Copeman, L.B. Eisner, K.E. Axler, C.W. Mordy, M.W. Lomas, In review, Phytoplankton and seston fatty acids dynamics in the northern Bering-Chukchi Sea region

Arctic and subarctic ecosystems are transitioning due to ocean warming, resulting in conditions that will lead to shifts in phytoplankton communities, their nutritional compositions, and production of fatty acids (FA). FA biomarkers are useful indicators of changing phytoplankton community composition and provide insight into basal resource quality for higher trophic level consumers such as zooplankton, fish, birds and marine mammals, yet phytoplankton FA information is largely lacking from the Bering and Chukchi Sea region. Therefore, we analyzed suspended particulate matter (seston) fatty acids (FA), chlorophyll-a (Chl-a) and environmental data collected from four surveys in the North Bering and Chukchi Seas, two during June of 2017 and 2018 and two during August and September of 2017 and 2019. Our objectives were to determine 1) whether, seston FA composition was correlated with phytoplankton taxonomic composition analyzed using imaging microscope (FlowCAM) techniques, 2) seasonal differences in seston FA concentrations, and 3) how FA concentrations vary with environmental parameters. We found significant seasonal differences in seston FA compositions, with diatom biomarkers more prevalent in spring, followed by a community shift to dinoflagellate and small flagellate FA biomarkers in late fall. These results were overall confirmed by FlowCAM analyses. FA seston concentrations were correlated with total and large size-fractioned Chl-a concentrations, nitrogen concentration and temperature. Lastly, we used a model framework to predict availability of the diatom-associated essential FA, eicosapentaenoic acid (EPA, 20:5n-3). Combined our analysis provide new information on FA phytoplankton dynamics and the important nutritional role of phytoplankton for higher trophic level consumers in the Northern Bering and Chukchi Sea regions.

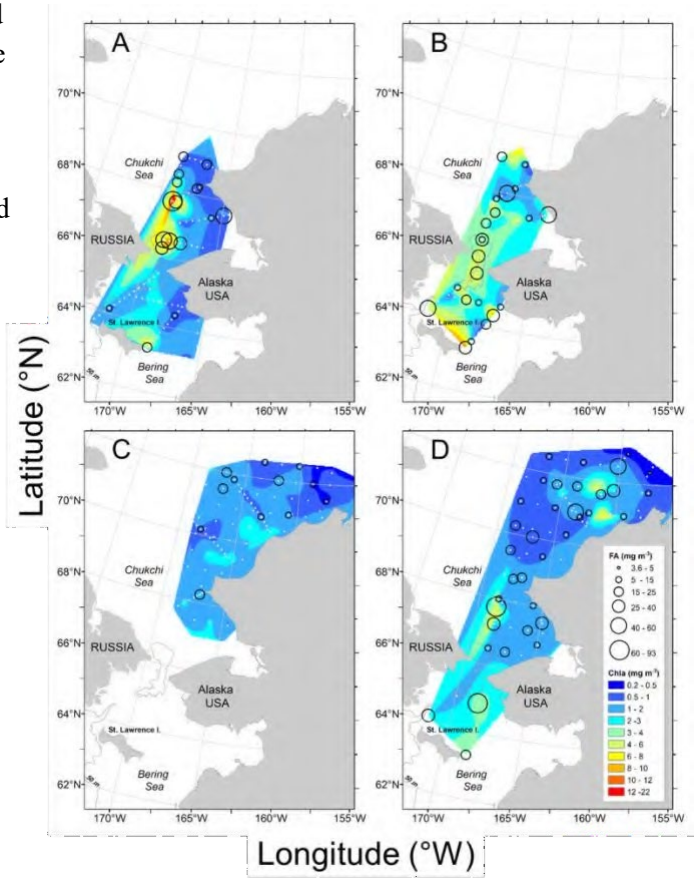

Figure 11. Mean in situ Chl-a [mg m-3] averaged from surface to 50 m and mean total FA concentrations [mg m-3] measured at each station in: A) June 2017, B) June 2018, C) Aug/Sep 2017 and D) Aug/Sep 2019 in the northern Bering and Chukchi Seas. White diamonds indicate station locations.

Study 8: Zooplankton communities of the Arctic's Bering Strait region during the spring bloom, 2017-2018 (Manuscript in preparation)

Hopcroft, R.R., C. Smoot, In prep. Zooplankton communities of the Arctic's Bering Strait region during the spring bloom, 2017-2018 (Manuscript in preparation)

Planktonic communities have been shown to serve as useful "beacons of climate change" (Richardson, 2008) due to relatively rapid response changing temperatures and their strong coupling to water mass characteristics. The Arctic Shelf Growth, Advection, Respiration and Deposition Rate Experiments (ASGARD) conducted a pair of cruises in June of 2017 and 2018 to examine the structure and function of communities during the bloom. The broad-scale survey of the zooplankton communities at those times provides context for the vital rates determined within those communities as summarized elsewhere within this report. Smaller-bodied zooplankton were collected with a vertically-hauled 60-cm diameter twin-ring net fitted with 150-µm nets pulled at ~0.5 m s^{-1}. Larger-bodied and more mobile zooplankton were targeted with an obliquely-towed 60-cm diameter Bongo net fitted with 505-µm nets pulled at ~0.5 m s^{-1}.

The zooplankton community was dominated by the copepods *Calanus marshallae/glacialis*, *Pseudocalanus* spp., *Oithona similis*, and *Metridia pacifica* that are best assessed with the 150-µm nets. These copepods were present at nearly all stations during both 2017 and 2018. The copepod *Acartia* was also present across the sampling domain in both 2017 and 2018 but had a more coastal signal. We observed higher abundances of Pacific-affinity copepods (*Neocalanus* spp. and *Eucalanus bungii*) in 2017 compared to 2018.

Multivariate analyses of the combined 2017 and 2018 150-µm datasets revealed five major community groupings. Euphausiids, composed of several *Thysanoessa* species, were present across the sampling domain in both years, with slightly higher abundances observed in 2017. The euphausiids were also primarily composed of larval calyptopsis and furcilia stages in both years. Amphipods, decapods, and the predatory chaetognath *Parasagitta elegans* were present in both years across the sampling domain but did not show a particular spatial pattern. *Aglantha digitale*, a common hydrozoan, did not display a strong spatial pattern. There was often a significant biomass in other jellyfish and ctenophores present in the plankton nets.

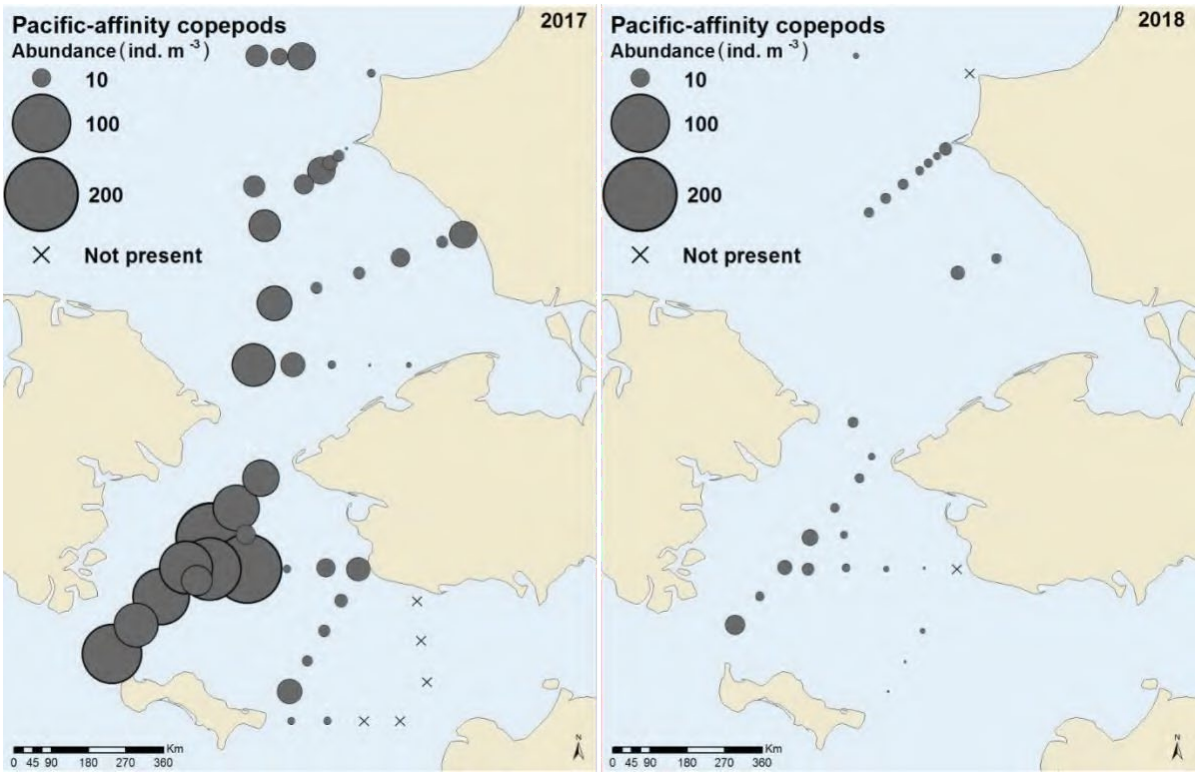

Figure 12. Abundance (ind. m^{-3}) of Pacific-affinity copepods based on the 150-µm net.

Study 9: Growth and Reproductive Rates of Calanoid Copepods in the Northern Bering and Southern Chukchi Seas

Poje, A., 2020. Growth and Reproductive Rates of Calanoid Copepods in the Northern Bering and Southern Chukchi Seas. University of Alaska Fairbanks. M.S. Thesis.

Egg production and copepodite growth rates were measured for the calanoid copepods *Pseudocalanus spp., Calanus marshallae/glacialis*, and *Metridia pacifica* in the northern Bering and southern Chukchi Seas during June of 2017 and 2018. For all taxa, instantaneous growth rates generally decreased with increasing copepodite stage, though the differences between most stages was not significant. The growth rates for *Pseudocalanus spp*. averaged 0.03 ± 0.002 day^{-1}, *Calanus spp*. 0.09 ± 0.004 day^{-1} , and *M. pacifica* 0.05 ± 0.03 day^{-1}. Egg production rates increased with prosome length for all species, but when standardized to body weight this trend reversed. All *Pseudocalanus* species had similar weight-specific egg production (SEP): 0.18 ± 0.01 for *P. acuspes*, 0.15 ± 0.00 for *P. newmani*, and 0.11 ± 0.02 *for P. minutus.* The SEP for *Calanus* was considerably lower, 0.09 ± 0.01, while for *M. pacifica* it was 0.11 ± 0.01.

These rates suggest considerable discrepancies between growth rates and egg production weights that we propose are due to differences in life history strategies. *Pseudocalanus* reproduce nearly year round, they appear to invest less in somatic growth, preferring to quickly reach their adult stage where they invest heavily into reproduction. *Calanus spp*. have 1 or possibly 2 generations per year in this region, they invest more into somatic growth in order to ensure their population is ready for a reproductive season timed to the spring phytoplankton bloom. The more omnivorous *M. pacifica* is also likely limited to 1 or 2 generations, although their ability to thrive on a wider range of food sources than *Calanus* seems to allow for relatively higher investment in reproduction and perhaps lower investment in somatic growth. Consistent with other studies, global growth models do not match our observations particularly well, likely because they are dominated by egg production estimates at lower latitudes.

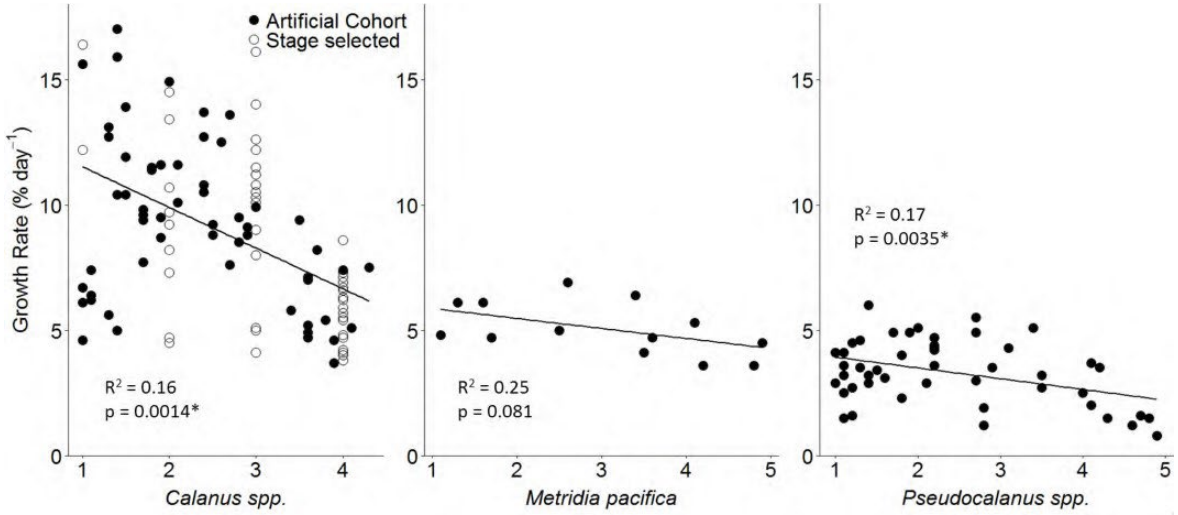

Figure 13. *Calanus spp., Metridia p*acifica, and *Pseudocalanus spp*. growth rates relative to initial copepodite stage from the artificial cohort experiments (avg. temp 4° C) during June 2017 and 2018 in the N. Bering and S. Chukchi seas.

Study 10: Seasonal and annual variation in the lipid composition of mesozooplankton from the Chukchi Sea (Manuscript in preparation)

Copeman, L., Eisner, L., Kimmel, D., Hopcroft, R. et al., In preparation and final data generation stages. Seasonal and annual variation in the lipid composition of mesozooplankton from the Chukchi Sea.

Zooplankton are major prey items for fish, seabirds and marine mammals and they also play an essential role in marine food webs where they efficiently transform energy from primary producers into lipid storage. Arctic zooplankton store particularly high levels of lipid per unit mass which is generally viewed as an adaptation to extreme seasonality in their food supply. Despite their trophic importance, we know relatively little about lipid dynamics in major zooplankton groups from the Chukchi Sea. We analyzed total lipids, lipid classes, fatty acids and alcohols in the dominant mesozooplankton (five taxa: euphausiids, copepods, chaetognaths, and pteropods) collected on both spring (ASGARD, 2017 and 2018) and late summer (IES 2017 and 2019) Chukchi Sea surveys.

Lipid-rich and abundant spring copepods included *Pseudocalanus* spp. and *Neocalanus* spp. that contained on average ~87% wax esters and only 4% triacylglycerols. Spring-collected *Pseudocalanus* spp. were the most lipid rich (308. 5 ± 42.4 mg g^{-1} WWT) compared to *Neocalanus* spp. (168.3 ± 15.3 $mg.g^{-1}$) and *Metridia* spp. (38.6 ± 3.3 $mg.g^{-1}$), but the large size of *Neocalanus* spp. resulted in much higher values per individual (579 ± 33 µg) than in other spring-collected copepods (~10 to 92 µg). Euphausiids of the species *Thysanoessa raschii* and *Thysanoessa inermis* had lipid class storage reflective of both short (16% triacylglycerols) and longer-duration (22% wax esters) energy storage. The relatively large size of *Thysanoessa* spp. combined with their elevated lipid concentrations (56.4 ± 5.0 $mg.g^{-1}$), resulted in a high value of lipids per individual, 2552 ± 299 µg. *Thysanoessa* spp. had significantly higher lipid concentrations and double the lipid per individual in spring than in fall collections. *Calanus* spp. (*C. marshallae* and *C. glacialis*) from fall surveys had total lipid per WWT of 93.1 ± 21.4 mg g^{-1} and total lipid per individual of 140.5 ± 13.9 µg. As found in other Arctic studies, *Calanus* spp. contained the majority of their lipids as wax esters (80.2 ± 1.6%).

Fatty acid biomarkers and fatty alcohols have been run on all 409 zooplankton samples. Biomarker data analyses and finalization are underway with metadata being uploaded in September 2021. Preliminary analyses show that lipid-rich zooplankton have a high degree of reliance on diatom-sourced lipids. Ongoing analyses of zooplankton fatty acids will help us understand the trophic component of spatial and annual variability in their lipid storage. Our ultimate goal is to estimate the lipid and fatty acid pools available to zooplankton predators using species-specific zooplankton lipid values coupled to zooplankton abundance data.

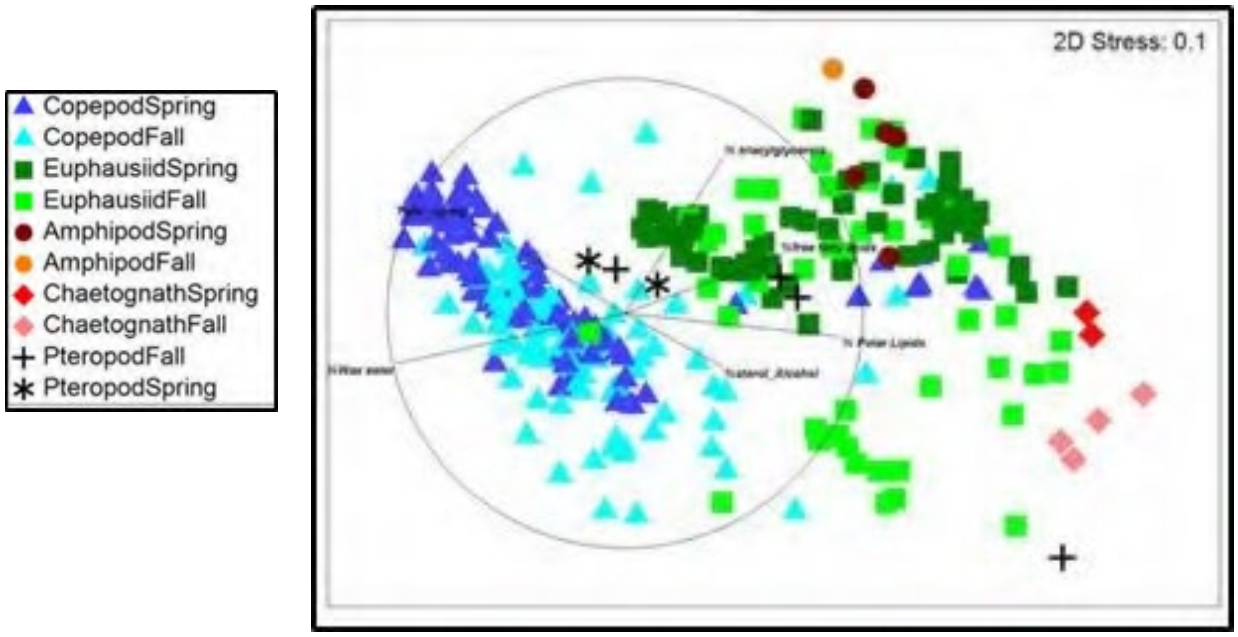

Figure 14. Nonmetric multidimensional scaling (nMDS) of major zooplankton taxa based on their lipid class composition. Zooplankton were collected on four ecosystem surveys during spring and fall of 2017 to 2019 in the Chukchi Sea. Vectors are shown for individual lipid classes.

Study 11: Respiration rates of calanoid copepods during the spring bloom for the Arctic's Bering Strait region (Manuscript in preparation)

Hopcroft, R.R., C. Smoot, In prep. Respiration Rates of calenoid copepods during the spring bloom for the Arctic's Bering Strait region

Like most living organisms, zooplankton consume oxygen. Knowing how much oxygen they consume, how much they eat, and how much they grow are important to understanding the quantity and efficiency with which they move energy through an ecosystem.

We measured the respiration of the dominate zooplankton – copepods – in the northern Bering and Southern Chukchi Seas during the ASGARD project for 2017 and 2018. Rates were determined for adult stages of four species: *Calanus glacialis*, *Metridia pacifica*, *Pseudocalanus minutus* and *Pseudocalanus acuspes*. These rates increase with increasing body mass, but weight-specific rates decline with body mass.

Rates are generally consistent with a global model proposed by Ikeda et al., but are consistently higher than those predicted. We propose this increase was a direct consequence of the either poor skill of that model for the study region or the high rates of growth and grazing occurring at the time of measurement that coincided with the region's "spring" bloom having raised overall metabolic activity.

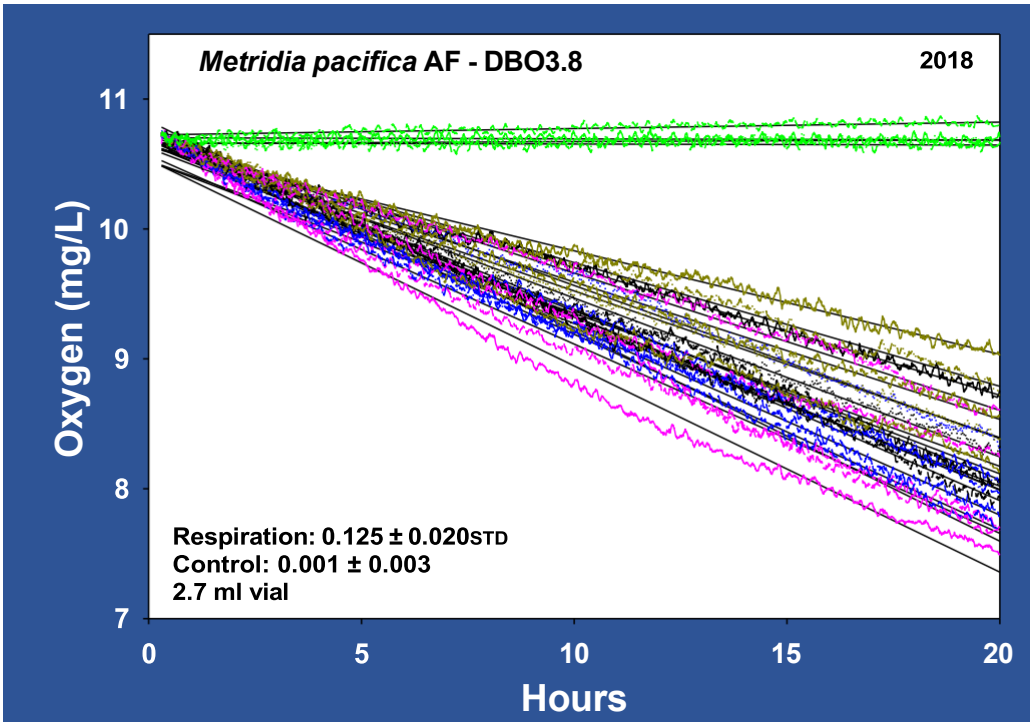

Figure 15. Example data traces from the copepod respiration incubations. Control vial (no zooplankton) measurements are shown in green.

Study 12: Spatial patterns, environmental correlates, and potential seasonal migration triangle of polar cod (*Boreogadus saida*) distribution in the Chukchi and Beaufort seas

Forster, C. E., Norcross, B. L., Mueter, F. J., Logerwell, E. A., Seitz, A. C. 2020. Spatial patterns, environmental correlates, and potential seasonal migration triangle of polar cod (Boreogadus saida) distribution in the Chukchi and Beaufort seas. Polar Biology, 43(8), 1073-1094.

Forster, C. E., 2019. Spatial patterns, environmental correlates, and potential seasonal migration triangle of Arctic cod (Boreogadus saida) distribution in the Chukchi and Beaufort seas. University of Alaska Fairbanks. M.S. Thesis.

Polar cod (*Boreogadus saida*) is a key forage fish in the Arctic marine ecosystem and provides an energetic link between lower and upper trophic levels. Despite its ecological importance, spatially explicit studies synthesizing polar cod distributions across research efforts have not previously been conducted in its Pacific range. We used spatial generalized additive models to map the distribution of polar cod by size class and relative to environmental variables. We compiled demersal trawl data from 21 cruises conducted during 2004–2017 in the Chukchi and Beaufort seas, and investigated size-specific patterns in distribution to infer movement ecology of polar cod as it develops from juvenile to adult life stages. High abundances of juvenile polar cod (≤ 70 mm) in the northeastern Chukchi Sea and western Beaufort Sea were separated from another region of high abundance in the eastern Beaufort Sea, near the US and Canadian border, suggesting possible population structure in the Pacific Arctic.

Relating environmental correlates to polar cod abundance demonstrated that temperature and salinity were related to juvenile distribution patterns, while depth was the primary correlate of adult distribution. A comparison of seasonal 2017 abundances of polar cod in the southern Chukchi Sea found low demersal abundance in the spring when compared to the summer.

Seasonal differences in polar cod abundance suggest that polar cod migration may follow a classic 'migration triangle' route between nursery grounds as juveniles, feeding grounds as subadults, and spawning grounds as adults, in relation to ice cover and seasonal production in the Chukchi Sea.

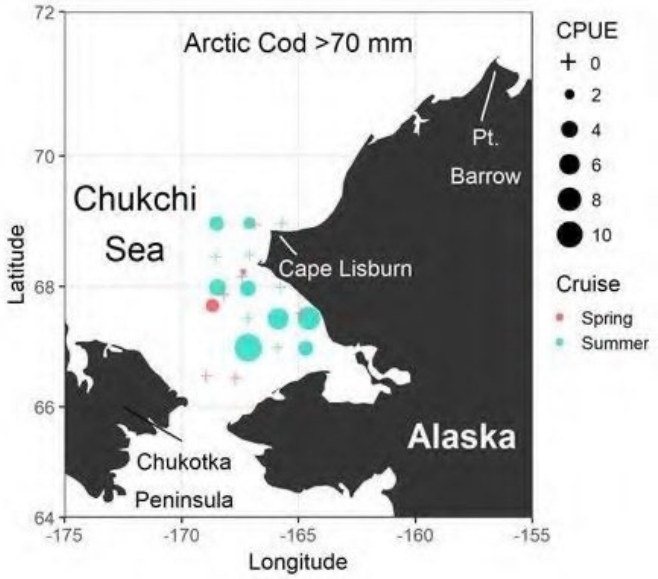

Figure 16. Distribution and length frequency of Arctic (Polar) Cod >70 mm in the Chukchi Sea in spring and summer 2017. Length frequency scaled by CPUE.

Study 13: Seasonal abundance, distribution, and growth of the early life stages of polar cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*) in the US Arctic

Deary, A.L., Vestfals, C.D., Mueter, F.J., Logerwell, E.A., Goldstein, E.D., Stabeno, P.J., Danielson, S.L., Hopcroft, R.R. and Duffy-Anderson, J.T., 2021. Seasonal abundance, distribution, and growth of the early life stages of polar cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*) in the US Arctic. *Polar Biology*, *44*(11), pp.2055-2076.

Polar cod and saffron cod are dominant components of the fish community in the Chukchi Sea and are ecologically important forage fishes linking plankton to upper-level consumers. In 2017, we conducted a study as part of the Arctic Integrated Ecosystem Research Program to characterize the distribution, abundance, and growth of polar cod and saffron cod early life history stages (ELHS) in late spring and late summer in the Chukchi Sea. Ship-based plankton tows showed that polar cod and saffron cod larvae were centered in Kotzebue Sound in the late spring. By late summer, polar cod juveniles were centered offshore in the northern Chukchi Sea whereas saffron cod were distributed nearshore around Cape Lisburne. Empirical fish collections were paired with an individual-based biophysical transport model to examine connectivity and relate changes in seasonal distribution to potential environmental variables. Modeled drift trajectories and growth in spring for polar cod and saffron cod matched well with empirical observations, especially along the northern coastline of Kotzebue Sound, offshore of Point Hope/Cape Lisburne. Given the coherence between modeled and observed distributions, Kotzebue Sound is likely a source of gadid ELHS in the nearshore areas of the Chukchi Sea and offshore of Cape Lisburne/Point Hope, although it is not the likely source of polar cod over Hanna Shoal in the late summer. This is the first study to examine seasonal distribution, abundance, and growth of polar cod and saffron cod in the US Arctic and provides data necessary to evaluate climate change impacts on forage fishes in the Arctic.

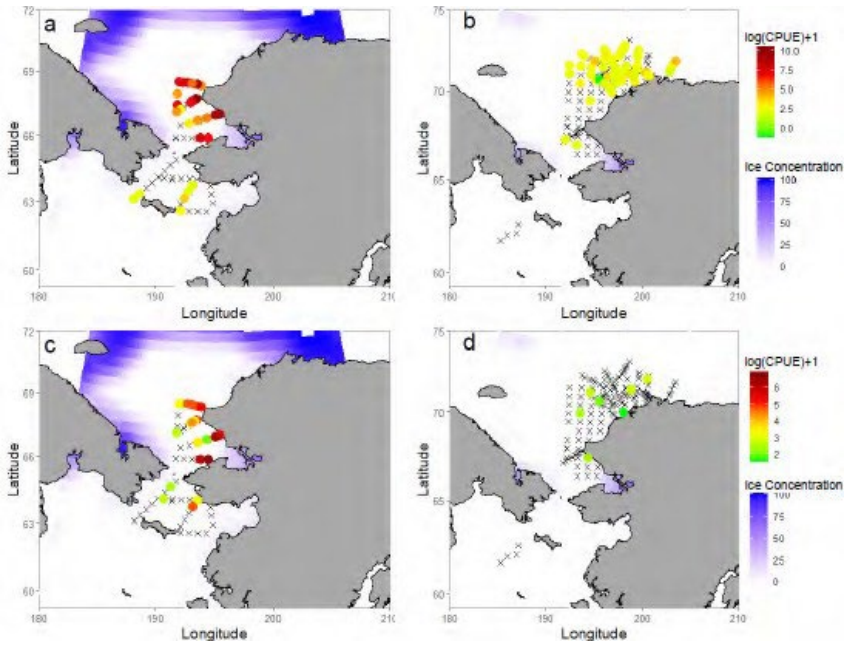

Figure 17. Distribution of polar cod (*Boreogadus saida*) (a, b) and saffron cod (*Eleginus gracilis*) (c, d) in late spring (left column; ASGARD samples) and late summer (right column) 2017 collected in the water column with the 60-cm bongo net. Catch data reported as catch-per-unit-effort (CPUE) and log(CPUE)+1 to highlight variability at low abundance. Ice concentration (% cover) is plotted in the background. Black X's denote sampled stations where polar cod and saffron cod were not caught.

Study 14: Extraordinary Carbon Fluxes on the Shallow Pacific Arctic Shelf During a Remarkably Warm and Low Sea Ice Period

O'Daly, S.H., Danielson, S.L., Hardy, S.M., Hopcroft, R.R., Lalande, C., Stockwell, D.A. and McDonnell, A.M., 2020. Extraordinary carbon fluxes on the shallow Pacific Arctic shelf during a remarkably warm and low sea ice period. *Frontiers in Marine Science*, 7, p.986.

O'Daly, S.H., 2019. Carbon flux and particle-associated microbial remineralization rates in the northern Bering and southern Chukchi seas, University of Alaska Fairbanks. M.S. Thesis.

The shallow Pacific Arctic shelf has historically acted as an effective carbon sink, characterized by tight benthic pelagic coupling. However, the strength of the biological carbon pump in the Arctic has been predicted to weaken with climate change due to increased duration of the open-water period for primary production, enhanced nutrient limitation, and increased pelagic heterotrophy. In order to gain insights into how the biological carbon pump is functioning under the recent conditions of extreme warming and sea ice loss on the Pacific Arctic shelf, we measured sinking particulate organic carbon (POC) fluxes with drifting and moored sediment traps, as well as rates of primary production and particle-associated microbial respiration during June 2018. In Bering Shelf/Anadyr Water masses, sinking POC fluxes ranged from 0.8 to 2.3 g C m^{-2} day^{-1}, making them among the highest fluxes ever documented in the global oceans. Furthermore, high export ratios averaging 82% and low rates of particle-associated microbial respiration also indicated negligible recycling of sinking POC in the water column. These results highlight the extraordinary strength of the biological carbon pump on the Pacific Arctic shelf during an unusually warm and low-sea ice year. While additional measurements and time are needed to confirm the ultimate trajectory of these fluxes in response to ongoing climate change, these results do not support the prevailing hypothesis that the strength of the biological carbon pump in the Pacific Arctic will weaken under these conditions.

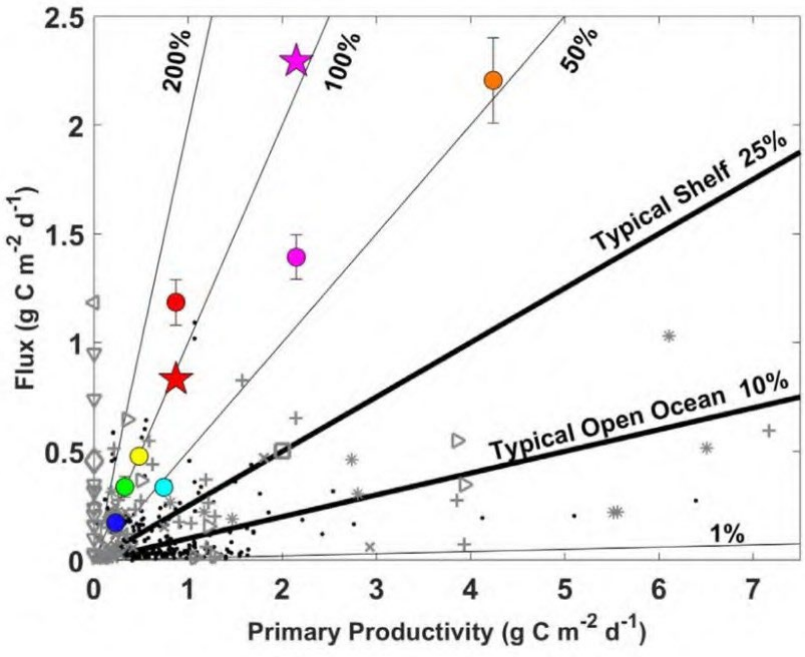

Figure 18. Sinking particulate organic carbon fluxes and primary productivity rates with contours of the export ratio between these two parameters measured during June 2018 on the Pacific Arctic shelf. Colored circles represent flux measurements from the drifting sediment trap. Colored stars represent the final flux measurement from the moored sediment traps (values plotted against the same primary productivity rates). Gray markers provide regional and black markers global context.

Study 15: Impact of a warm anomaly in the Pacific Arctic region derived from time-series export fluxes

Lalande C., Grebmeier J.M., McDonnell A.M., Hopcroft R.R., O'Daly S., Danielson S.L., 2021. Impact of a warm anomaly in the Pacific Arctic region derived from time-series export fluxes. Plos one. 2021 Aug 16;16(8):e0255837

Unusually warm conditions recently observed in the Pacific Arctic region included a dramatic loss of sea ice cover and an enhanced inflow of warmer Pacific-derived waters. Moored sediment traps deployed at three biological hotspots of the Distributed Biological Observatory (DBO) during this anomalously warm period collected sinking particles nearly continuously from June 2017 to July 2019 in the northern Bering Sea (DBO2) and in the southern Chukchi Sea (DBO3), and from August 2018 to July 2019 in the northern Chukchi Sea (DBO4).

Fluxes of living algal cells, chlorophyll *a* (chl *a*), total particulate matter (TPM), particulate organic carbon (POC), and zooplankton fecal pellets, along with zooplankton and meroplankton collected in the traps, were used to evaluate spatial and temporal variations in the development and composition of the phytoplankton and zooplankton communities in relation to sea ice cover and water temperature. The unprecedented sea ice loss of 2018 in the northern Bering Sea led to the export of a large bloom dominated by the exclusively pelagic diatoms *Chaetoceros* spp. at DBO2. Despite this intense bloom, early sea ice breakup resulted in shorter periods of enhanced chl *a* and diatom fluxes at all DBO sites, suggesting a weaker biological pump under reduced ice cover in the Pacific Arctic region, while the coincident increase or decrease in TPM and POC fluxes likely reflected variations in resuspension events. Meanwhile, the highest transport of warm Pacific waters during 2017-2018 led to a dominance of the small copepods *Pseudocalanus* at all sites.

Whereas the export of ice-associated diatoms during 2019 suggested a return to more typical conditions in the northern Bering Sea, the impact on copepods persisted under the continuously enhanced transport of warm Pacific waters. Regardless, the biological pump remained strong on the shallow Pacific Arctic shelves.

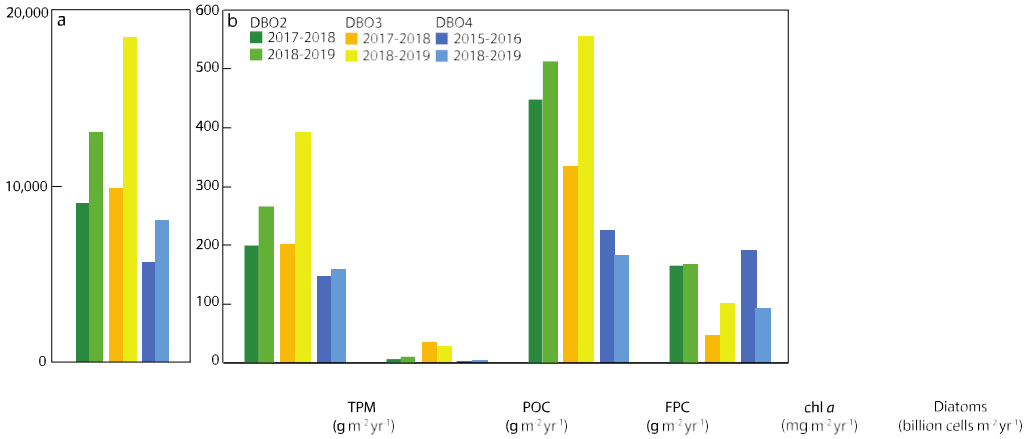

Figure 19. Annual total particulate matter (TPM) fluxes (a), and (b) annual particulate organic carbon (POC), fecal pellet carbon (FPC), chlorophyll a (chl a), andliving diatom fluxes at mooring sites N4, N6, and CEO.

Study 16: Linking polychaete functional traits and benthic ecosystem function to habitat characteristics on a shallow Arctic shelf

Charrier, B.R., T. Dorsaz, N. Matsui, and S.L. Mincks, In prep. Linking polychaete functional traits and benthic ecosystem function to habitat characteristics on a shallow Arctic shelf. Chapter 1 in University of Alaska Fairbanks Ph.D. Dissertation

Polychaetes are often numerically dominant within the macrofauna and serve essential roles in benthic ecosystem function, such as feeding and bioturbation activities. Macrofauna were collected from 12 stations in June 2017 and 11 stations in June 2018 from the northern Bering and southern Chukchi Sea continental shelves from the *R/V Sikuliaq* as part of the Arctic Shelf Growth, Advection, Respiration, and Deposition (ASGARD) project. Samples were collected using an MC-800 multi-corer with 10-cm diameter tubes. Macrofauna were counted, weighed, and identified to phylum or class level.

Polychaetes were identified to family level and assigned a functional guild based on feeding mode, motility, and feeding structures. Four clusters of polychaete functional guilds were identified. Group A was dominated by subsurface and surface/subsurface deposit feeders; had a high portion of filter feeders; and consisted of shallow, sandy stations with low amounts of low-quality food. Group B was dominated by carnivores and subsurface deposit feeders and characterized by moderate amounts of moderate-quality food. Group C was also dominated by carnivores and subsurface deposit feeders but had large amounts of high-quality food. Group C had high abundance and biomass deep within the sediment, suggesting high bioturbation activity. Group D was dominated by subsurface deposit feeders and surface/subsurface deposit feeders, with most of the abundance and biomass concentrated at the surface and mainly consisted of coastal stations. Overall, polychaete functional composition and vertical distribution reflected the quality and quantity of organic matter input, and the depositional environment as indicated by sediment grain size composition, with likely impacts on biogeochemical and carbon cycling within the sediment.

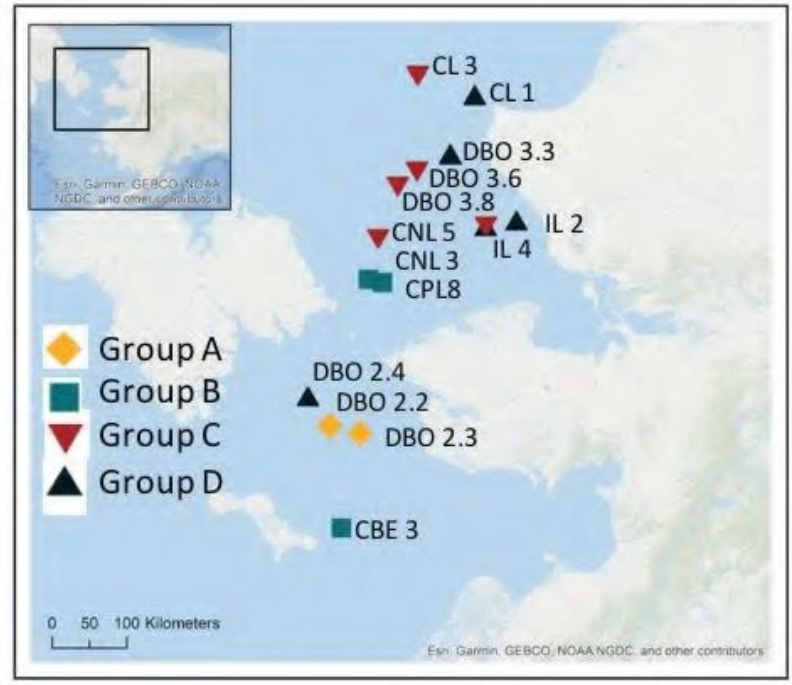

Figure 20. Macrofauna sampling locations in the northern Bering and southern Chukchi Seas in 2017 and 2018. Nine stations were sampled in both years. Symbols based on hierarchical agglomerative clustering. Station IL 4 clustered in Group D in 2017 and Group C in 2018.

Study 17: Meiofauna community structure in Pacific Arctic shelf sediments: a comparison of meiofaunal- and macrofaunal-sized nematodes and functional traits

Charrier, B.R., J. Ingels, and S.L. Mincks, In prep. Meiofauna community structure in Pacific Arctic shelf sediments: a comparison of meiofaunal- and macrofaunal-sized nematodes and functional traits. Chapter 2 in University of Alaska Fairbanks Ph.D. Dissertation

Meiofauna serve essential roles in benthic ecosystems, such as nutrient cycling and linking microbial and upper-trophic levels of the food web, and they serve as bioindicators of environmental change, particularly nematodes. However, in the rapidly changing Pacific Arctic shelf region, meiofauna remain poorly studied, and baseline data for assessing change is lacking. Sediment samples were collected at ten stations in the northern Bering and southern Chukchi Seas in June 2018 as part of the Arctic Shelf Growth, Advection, Respiration, and Deposition (ASGARD) project. We characterized meiofauna (63-500 µm) community structure and abundance at higher taxonomic levels and evaluated genus-level composition of nematodes in both meiofaunal (63-500 µm) and macrofaunal (>500 µm) size fractions. The nematodes were also classified by trophic feeding groups and life-history strategies. Total meiofauna abundance ranged from 1449 to 12875 ind. 10 cm-2 for the upper 5 cm of sediment, and the dry weight (DW) biomass of nematodes in the upper 1 cm of sediment ranged from 33 to 739 µg DW10 cm-2.

Four clusters of meiofaunal-sized nematode communities were identified occupying different regions of the Pacific Arctic shelves: the northern Bering shelf, Bering Strait region, central Chukchi Sea, and coastal Chukchi Sea. These nematodes assemblages reflected impacts of food availability and substrate type, and differences suggest these subregions should be considered separately in ecosystem modeling. Additionally, the meiofaunal- and macrofaunal-sized nematodes represented two distinct communities. The taxonomic composition and large standing stock of the macrofaunal-sized nematodes (2 - 215 µg DW 10 cm-2) suggest they are a critical component of the infauna and merit more in-depth research to consider the ecological role they play, including benthic carbon cycling and trophic dynamics. This study provides the first genus-level characterization of nematode communities in the region and among the first measurements of meiofauna standing stock. Thus, the data presented here can serve as a baseline for assessing ecosystem shifts in a rapidly changing Arctic environment.

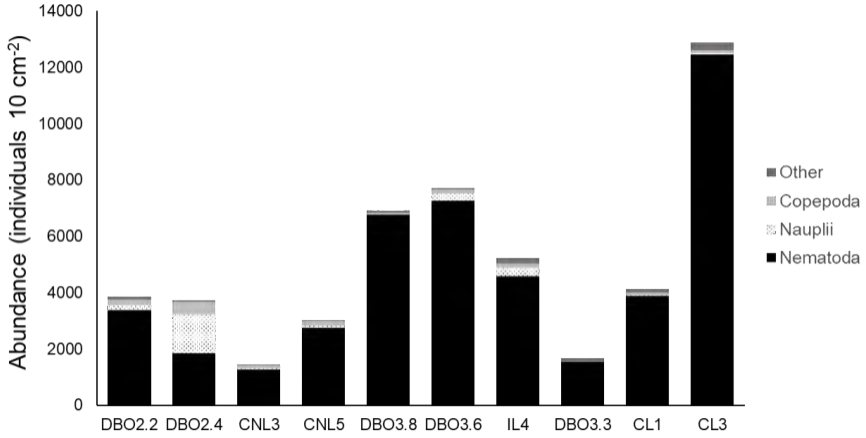

Figure 21: Meiofaunal abundance (ind. 10 cm^{-2}) in the upper 5 cm of sediment at sampling locations on the northern Bering and southern Chukchi Sea continental shelves in 2018

Study 18: Changes to benthic community structure may impact organic matter consumption on Pacific Arctic shelves

Charrier, B.R., A.L. Kelley, and S.L. Mincks, 2021. Changes to benthic community structure may impact organic matter consumption on Pacific Arctic shelves. *Conservation physiology*, *9*(1), p.coab007.

Charrier, B.R., A.L. Kelley, and S.L. Mincks, 2021. Changes to benthic community structure may impact organic matter consumption on Pacific Arctic shelves. Chapter 3 in University of Alaska Fairbanks Ph.D. Dissertation

Changes in species composition and biomass of Arctic benthic communities are predicted to occur in response to environmental changes associated with oceanic warming and sea-ice loss. Such changes will likely impact ecosystem function, including flows of energy and organic material through the Arctic marine food web. Oxygen consumption rates can be used to quantify differences in metabolic demand among species and estimate the effects of shifting community structure on benthic carbon consumption.

Closed-system respirometry using non-invasive oxygen optodes was conducted onboard the R/V Sikuliaq in June 2017 and 2018 on six dominant species of benthic macrofauna from the northern Bering and southern Chukchi Sea shelves, including five bivalve species (*Macoma sp., Serripes groenlandicus, Astarte sp., Hiatella arctica* and *Nuculana pernula*) and one amphipod species (*Ampelisca macrocephala*). Results revealed species-specific respiration rates with high metabolic demand for S. groenlandicus and A. macrocephala compared to that of the other species. For a hypothetical 0.1-g ash-free dry mass individual, the standard metabolic rate of S. groenlandicus would be 4.3 times higher than that of Astarte sp. Overall, carbon demand ranged from 8 to 475 μg C individual^{-1} day^{-1} for the species and sizes of individuals measured. The allometric scaling of respiration rate with biomass also varied among species. The scaling coefficient was similar for H. arctica, A. macrocephala and Astarte sp., while it was high for S. groenlandicus and low for Macoma sp.

These results suggest that observed shifts in spatial distribution of the dominant macrofaunal taxa across this region will impact carbon demand of the benthic community. Hence, ecosystem models seeking to incorporate benthic system functionality may need to differentiate between communities that exhibit different oxygen demands.

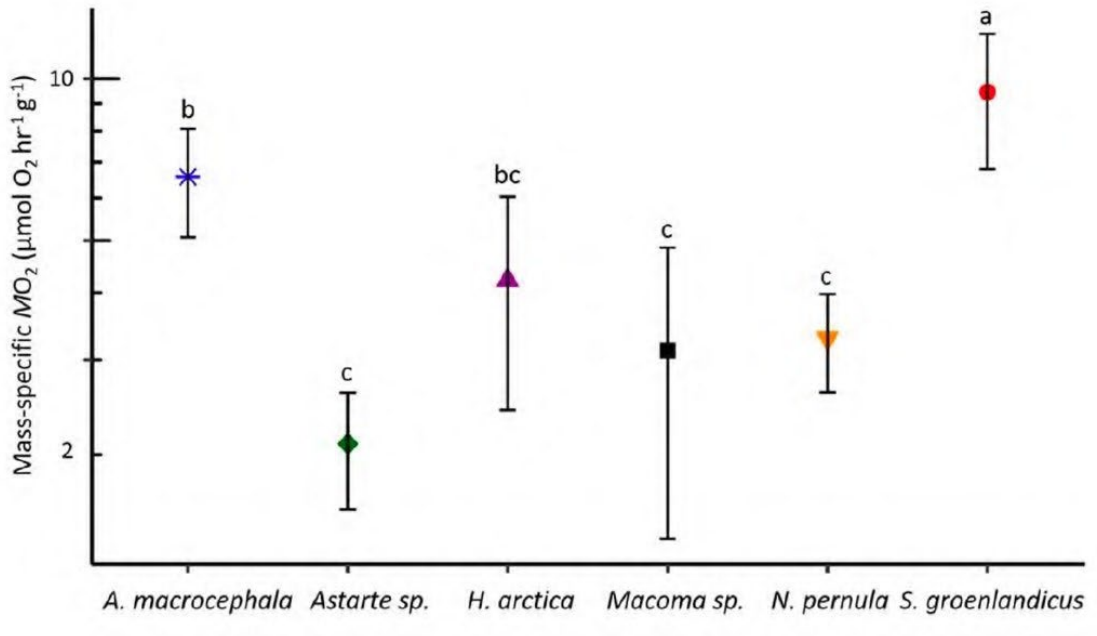

Figure 22. Average mass-specific respiration rates (µmol O_2 hr^{-1} g^{-1}) for each species with standard deviations represented by error bars.

Study 19: Spatial patterns and effects of temperature on rates of organic matter processing in sediments across the northern Bering and southern Chukchi Sea shelf (Manuscript in preparation)

Mincks, S.L., S. Seabrook, B. Charrier, A. Thurber, In prep. Spatial patterns and effects of temperature on rates of organic matter processing in sediments across the northern Bering and southern Chukchi Sea shelf

Labile organic matter deposited at the seafloor is respired by benthic organisms, and respiration rates are highly temperature dependent in both microbes and metazoan in sediments. In light of changing temperature and productivity regimes across the Pacific-Arctic domain, we measured respiration rates of sediment communities at in situ and elevated temperatures at ten locations across the N Bering and S Chukchi Seas. Intact sediment cores were incubated at 0ºC (ambient) and 5ºC (projected warming).

On average, sediment community oxygen demand, a proxy for organic carbon consumption, was ~30% higher in warmer treatments. Substrate type, productivity, and particulate flux rates varied across the study area, resulting in spatial differences in microbial and metazoan biomass. In the southeast Chukchi Sea (DBO 3 region), high biomass of large infaunal species, particularly bivalves, generated somewhat elevated oxygen demand. However, oxygen consumption rates were more consistent across the rest of the study area, with rates increasing more rapidly as a function of microbial biomass than of macrofaunal biomass.

Fluxes of dissolved inorganic carbon (DIC) were also measured in incubation experiments as an additional means of quantifying oxygen consumption due specifically to respiration of infauna. DIC fluxes were decoupled from oxygen fluxes at some locations. In some cases, DIC was taken up by sediment communities, suggesting autotrophic production which could have been producing oxygen during experiments, resulting in underestimation of respiration rates by oxygen flux measurement.

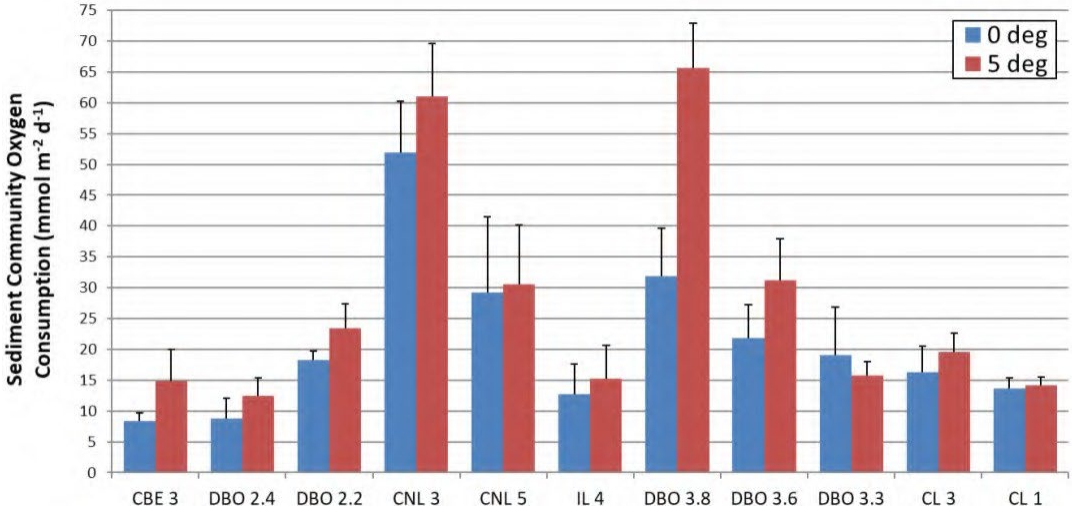

Figure 23. Sediment community oxygen consumption measured in shipboard whole-core incubations at two different temperatures during the ASGARD cruise in June 2018. Positive values indicate net flux into sediments, ±std. dev.

Study 20: The Arctic Chukchi Sea food web: simulating ecosystem impacts of future changes in organic matter flow

Zinkann, A.C., G. Gibson, K. Iken, in review. The Arctic Chukchi Sea food web: simulating ecosystem impacts of future changes in organic matter flow, submitted for review to *Ecological Modeling*

Zinkann, A.C., 2020. Chapter 3 in *Organic Matter Sources on the Chukchi Sea Shelf in a Changing Arcitc*. University of Alaska Fairbanks. Ph.D. Dissertation.

The Chukchi Sea continental shelf is a highly productive inflow shelf of the Arctic Ocean that is experiencing climate warming events and declines in seasonal sea ice cover at one of the fastest rates compared to other Arctic shelves. Climate-induced changes in phytoplankton and ice-algal primary production, inflow of terrestrial matter through riverine discharge and coastal erosion, and increases in bacterial production have previously been predicted to cause shifts in the composition and distribution of organic matter supply and energy flow in this system. The goal of this study was to examine potential shifts in the Chukchi Sea ecosystem energy flow under various future climate scenarios. To address these goals, an existing mass balance Chukchi Sea ecosystem model by was updated by incorporating terrestrial matter as an energy source, especially for benthic consumers. Incorporation of the terrestrial matter component allowed us to adjust current model phytoplankton biomass to better match recent empirical measurements and to update the system-wide mass-balance.

We also modeled potential impacts of future climate-driven alterations in the composition and flow of organic matter supply on major ecosystem groups for the 2015 – 2050 period. Iterations showed that climate-driven increased retention of phytoplankton biomass in the pelagic realm would depress biomass of most benthic-feeding organisms across several larger ecosystem groups (invertebrates, fishes, mammals). However, simulated increases in both terrestrial matter inflow and bacterial biomass have the potential to compensate for some of the reductions in the energy supply from phytoplankton to the benthic food web, as well as to diversify the supply of organic matter to the seafloor. This diversification could make the Chukchi Sea ecosystem more stable to future climate-driven changes.

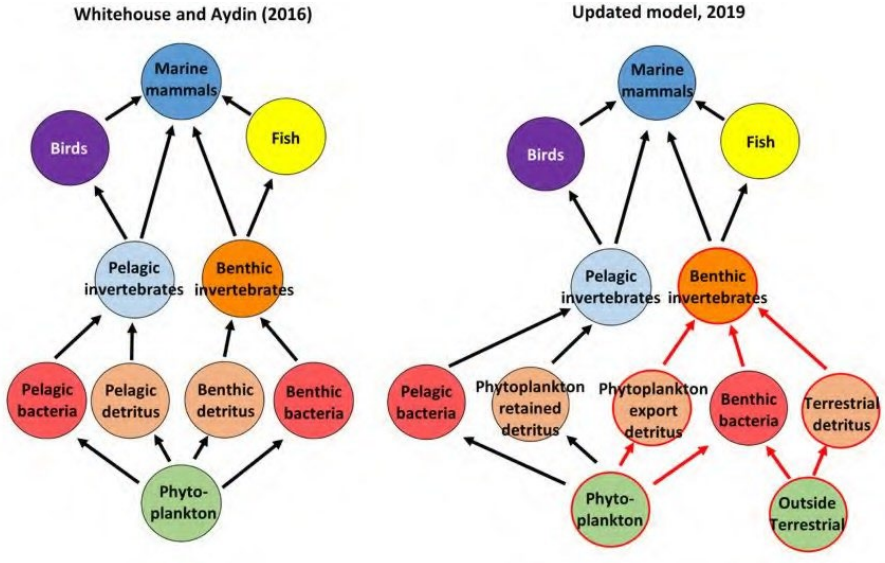

Figure 24. Comparative schematic of the original Whitehouse and Aydin (2016) and our updated mass-balanced Chukchi Sea ecosystem model. Arrows indicate feeding connections and flow of energy between larger functional groups. Red outlines and arrows indicate parameters and functional groups that reflect changes in the updated model.

Study 21: Inverse modelling of the microbial food web in the Northern Bering and Chukchi Seas in Spring and Late summer (Manuscript in preparation)

Nielsen J.M., Lomas M.W., Eisner L.B., Mordy C.W., McDonnell A., O'Daly S., Hopcroft R.R., Stockwell D., Danielson S.L., Juranek L., Cynar H., Krause J., Kimmel D., Schnetzer A., Irby M. et al., In preparation. Inverse modelling of the microbial food web in the Northern Bering and Chukchi Seas in Spring and Late summer

Resolving carbon flows in marine planktonic foodwebs is a fundamental first step for understanding the energy available for higher trophic level consumers and overall food web processes, production and function. Inverse food web modeling is a convenient data driven modeling approach for estimating carbon fluxes in marine food webs. Using empirical biomass and rate measurements, inverse food web modeling allows reconstruction of trophic flows and quantification of biological rates that are commonly challenging to measure. Here we use in-situ phytoplankton, microzooplankton, zooplankton, sedimentation and primary production data collected from 4 ecosystem surveys in the Chukchi and Northern Bering seas, June (spring) 2017 and 2018, and August-September (summer) 2017 and 2019.

Specifically, we assess 1) partitioning of energy, in terms of carbon, between the pelagic food web and deposition to the benthos, 2) how does transfer and major pathways vary between seasons (June vs August/September), and 3) how does food web carbon pathways vary between nutrient replete and deplete areas.

Initial simulations indicate seasonal differences in major carbon pathways. Higher carbon fluxes appeared to be available for benthic consumers in spring (in areas of high primary production) compared to late summer. Our initial analyses also revealed the importance of carbon uptake and transfer in microzooplankton and bacterial compartments, organisms and processes that are often underestimated on many ecosystem models. Overall, our results indicate variable carbon transfer efficiencies among seasons and areas of nutrient replete and deplete conditions, something that should be considered when evaluating larger food web processes.

Study 22: Evidence suggests potential transformation of the Pacific Arctic Ecosystem is underway

Huntington, H.P., S.L. Danielson, F.K. Wiese, M. Baker, P. Boveng, J.J. Citta, A. De Robertis, D.M. Dickson, E. Farley, J.C. George, K. Iken, D.G. Kimmel, K. Kuletz, C. Ladd, R. Levine, L. Quakenbush, P. Stabeno, K.M Stafford, D. Stockwell and C. Wilson, 2020. Evidence suggests potential transformation of the Pacific Arctic ecosystem is underway. *Nature Climate Change*, 10(4), pp.342-348

The highly productive northern Bering and Chukchi marine shelf ecosystem has long been dominated by strong seasonality in sea ice and water temperatures. Extremely warm conditions from 2017 into 2019 – including loss of ice cover across portions of the region in all three winters – were a marked change even from other recent warm years. Biological indicators suggest this state change could alter ecosystem structure and function. Here we report observations of key physical drivers, biological responses, and consequences for humans, including subsistence hunting, commercial fishing, and industrial shipping.

We consider whether observed state changes are indicative of future norms, whether an ecosystem transformation is already underway, and if so, whether shifts are synchronously functional and system-wide, or reveal a slower cascade of changes from the physical environment through the food web to human society. Understanding of this observed process of ecosystem reorganization may shed light on transformations occurring elsewhere.

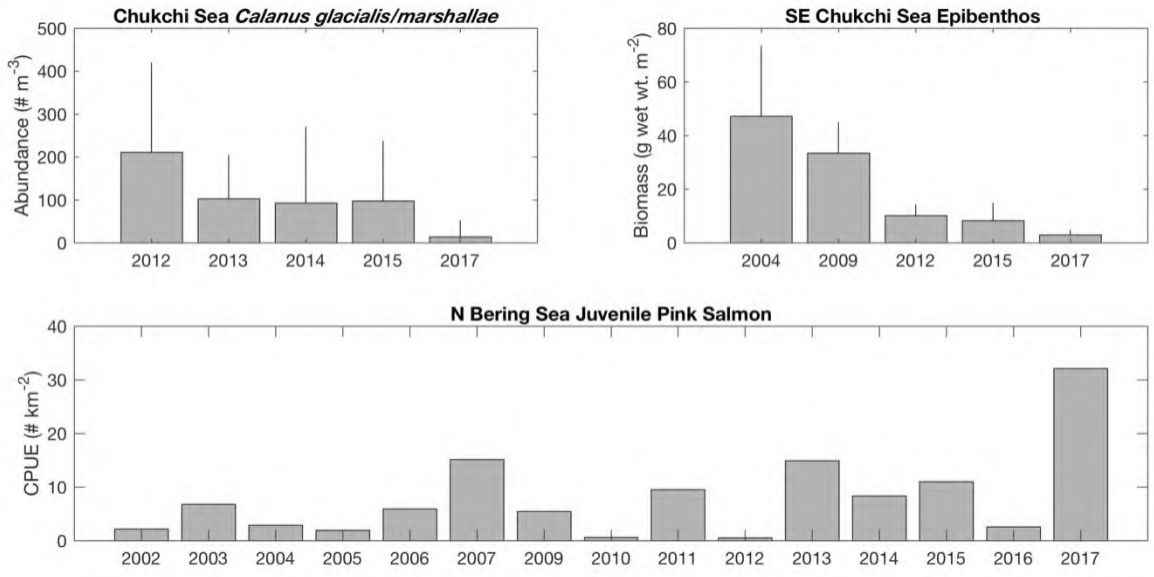

Figure 25. Observations show declines in Calanus glacialis/marshallae abundance (upper left) and epibenthic biomass (upper right) in 2017 relative to earlier years, and an increase in catch per unit effort (CPUE; bottom) for juvenile pink salmon. The upper two graphs show means and standard deviation error bars.

Additional and Leveraged Studies

In addition to the studies described in brief above, this section lists citations of other studies that leveraged ASGARD project personnel, logistics or data. These papers utilized samples collected on the ASGARD field expeditions, made use of data products compiled by the ASGARD project under the support of Arctic IERP funding, and/or ASGARD PI participation was facilitated in part by the Arctic IERP. Some of these papers are published, some are in review, and others are currently in preparation.

General Discussion

Environmental Setting

The Arctic IERP proposals were written in 2016, in the midst of the well-documented North Pacific Marine Heatwave (refs; Walsh et al, 2018). Although "the Blob" of warm water was first identified in the Gulf of Alaska (Freeland et al., 2014; Bond et al., 2015) and many dramatic examples of Gulf of Alaska ecosystem impacts were evident at that time and documented in the years since (Piatt et al., 2018, Suryan et al, 2021), anomalous warmth also extended across the Pacific Arctic at this time (Danielson et al., 2020). Little did we know, however, that the Northern Bering and Chukchi seas were about to enter a period of unprecedented winter sea ice loss (Stabeno and Bell, 2018; Thoman et al., 2020) and equally as anomalous distribution shifts and changes in abundance of target commercial, non-commercial and subsistence harvest fishes and invertebrates (Huntington et al, 2020, Stevenson and Lauth, 2019).

Analysis of a nearly 100-year-long historical record (Danielson et al. 2020) shows that the Bering and Chukchi continental shelves exhibit different trends and multi-year intervals of warm and cold conditions – suggesting that while the Chukchi receives input from the Bering Sea it operates somewhat independently of the Bering's upstream heat inputs: more local processes dominate. Analyses show that the heat engines of both shelves accelerated over 2014-2018, with increased surface heat flux exchanges and increased lateral oceanic heat advection.

In retrospect, it appears that the Arctic IERP field years (2017-2019) encompassed the peak of the thermally anomalous conditions in this particular multi-year phase of regionally warm conditions; they are the only three years in the record with annual mean monthly temperature anomalies of greater than 1.5 °C (Figure 25). Given the likelihood of continued future warming, these years likely represent a preview of what may eventually be considered typical.

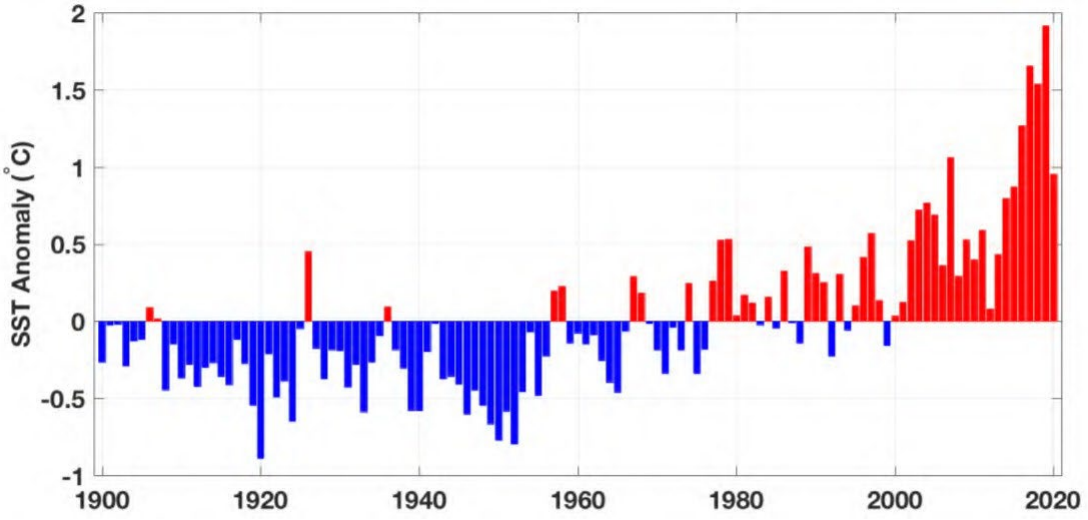

Figure 26. Sea surface temperature (SST) annual mean of all monthly anomalies over 1900-2020 from the Version 5 Extended Reconstructed SST dataset (ERSSTv5). Anomalies are computed relative to the full duration of this 1990-2020 time series. The integration region region for the data shown here extends °across the whole of the Northern Bering and Chukchi Seas (60-75 °N, 180-155 °W).

Our project collected a year-round northern Bering Sea set of whole water samples for major macronutrient analysis using a moored time series bag sampler, which was co-located with an optical SUNA sensor for hourly nitrate samples (Figure 26). This is the first year-round set of nutrient samples collected in the Pacific Arctic and represents a significant contribution to our understanding of nutrient dynamics through the months in which vessel-based samples have not been available. In particular, these data are allowing us to refine our understanding of the seasonally varying nutrient flux into the Arctic via the Anadyr Current. Using salinity as a conservative tracer, we were also able to identify an advective time scale of about two weeks for waters transiting between Anadyr Strait (mooring N2) and Bering Strait (UW mooring A3). This time scale allows us to make some rough estimates of net primary production within Chirikov Basin and thereby provide additional refinement to our estimates of nutrients entering the Arctic at Being Strait. Trend analysis of the nutrient fluxes reveal increasing concentrations of phosphate and silicate, but no trend for nitrate.

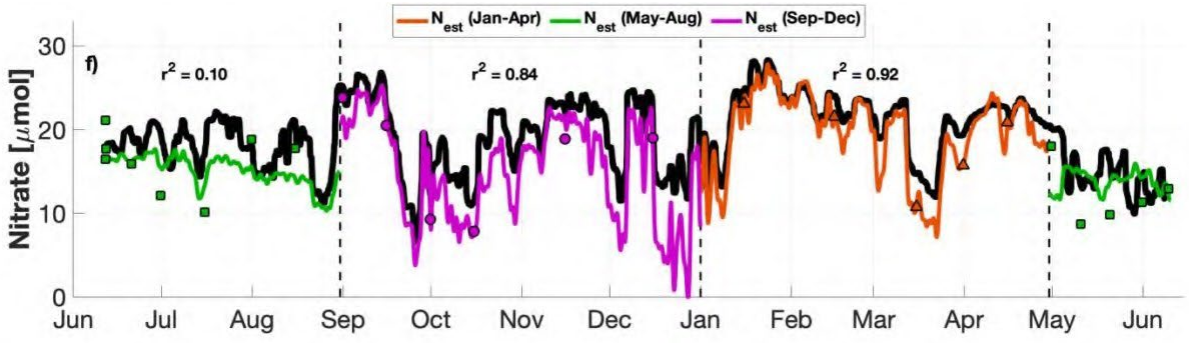

Figure 27. Colored markers show 25 nitrate/salinity pairs taken by the Green Eyes Aqua Monitor and a temperature/salinity datalogger at mooring N2, where color corresponds to the seasons denoted in the legend. SUNA nitrate (thick black) is shown in comparison to a nitrate:salinity-based regression (colored lines). Vertical dashed lines show delineations for the seasons (Jan-Apr, May-Aug, Sep-Dec).

The Pelagic Realm

As noted above, the Bering Strait region benefits from a year-round influx of high nutrient concentrations (Figure D2), helping portions of the system (e.g., Chirikov Basin and southern Hope Sea Basin) achieve relatively persistent levels of elevated productivity, although productivity exhibits a strongly patchy distribution with a regional average close to 2 gC m^{-2} day^{-1} for each of 2017 and 2018 (Figure 27). This characteristic – which is a consequence of the persistent Anadyr Current nutrient supply, the variable and energetic flow field, mixing dynamics, and variations in stratification – allows the system to initiate and/or maintain phytoplankton blooms as long as there is sufficient light to fuel primary productivity.

While large-celled diatoms are currently the most important primary producers in the Arctic, recent studies suggest that phytoplankton communities may shift towards mixotrophy (single cells capable of both photosynthesis and phagotrophy or osmotrophy) in response to climate change (Stoecker et al. 2017a; Stoecker and Lavrentyev 2018). Should these predictions prove correct, the decreased presence of diatoms could result in a reduced flux of carbon to the benthos. Other studies speculate that regional productivity could increase on the Chukchi shelf (Arrigo et al. 2008; JM Grebmeier 2012), with the potential to offset some excess CO_2 emissions. We present the first large-scale metabarcoding survey of

18S rRNA gene diversity in this region. Based on their biogeographical distributions, we identified exact sequence variants of *Chaetoceros*, *Pseudo−nitzschia*, *Micromonas*, and *Phaeocystis* as abundant taxa that may be negatively affected as the region warms.

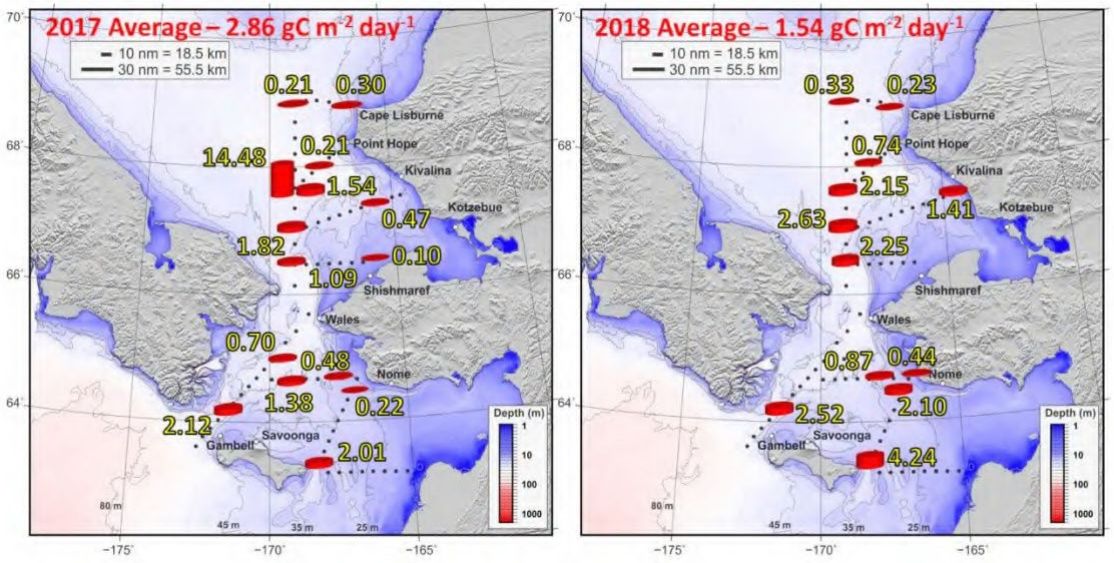

Figure 28. Primary productivity measured in June 2017 and 2018 in the ASGARD study region.

The abundance of the *Synechococcus* and other picophytoplankton was quantified across the Northern Bering and Chukchi Seas. The observations support an increased importance of a previously marginal phytoplankton group during a warming period in the Chukchi Sea. Seasonality of phytoplankton blooms, in particular the 'fall bloom' are gaining increasing recognition as being important in the trophic transfer of carbon and energy (Sigler et al., 2014). In the eastern Bering Sea shelf system, while *Synechococcus* has been observed (e.g., Liu et al., 2002; Moran et al., 2012) their abundances are generally low and represent a minor contribution to total phytoplankton carbon. The data presented by Lomas et al. [in prep.] suggest a different pattern in the Chukchi Sea, with a stronger seasonal amplitude in the abundance of *Synechococcus* and contribution to total phytoplankton carbon. Given the niche that *Synechococcus* fills globally (Flombaum et al., 2013; Visintini et al., 2021), our observations are consistent with *Synechococcus* growing into waters that are warmer and nutrient depleted.

Analyses of total lipids, lipid classes, fatty acids and alcohols in the dominant mesozooplankton (five taxa: euphausiids, copepods, chaetognaths, and pteropods) were performed on samples collected on both spring (ASGARD, 2017 and 2018) and late summer (IES 2017 and 2019) Chukchi Sea surveys. On these four cruises we also analyzed suspended particulate matter (seston) fatty acids, chlorophyll-a (Chl-a) and associated environmental data. Preliminary analyses show that lipid-rich zooplankton have a high degree of reliance on diatom-sourced lipids and our results suggest seasonality to the partitioning of the fatty acid concentrations, with diatom biomarkers more prevalent in spring, followed by a community shift to dinoflagellate and small flagellate fatty acid biomarkers in late fall. The seasonality, quality and composition of lipids and fatty acids in phytoplankton and zooplankton suggest potential ecosystem consequences under warming ocean scenarios in which the balance between nutrient concentrations and phytoplankton community assemblages shifts.

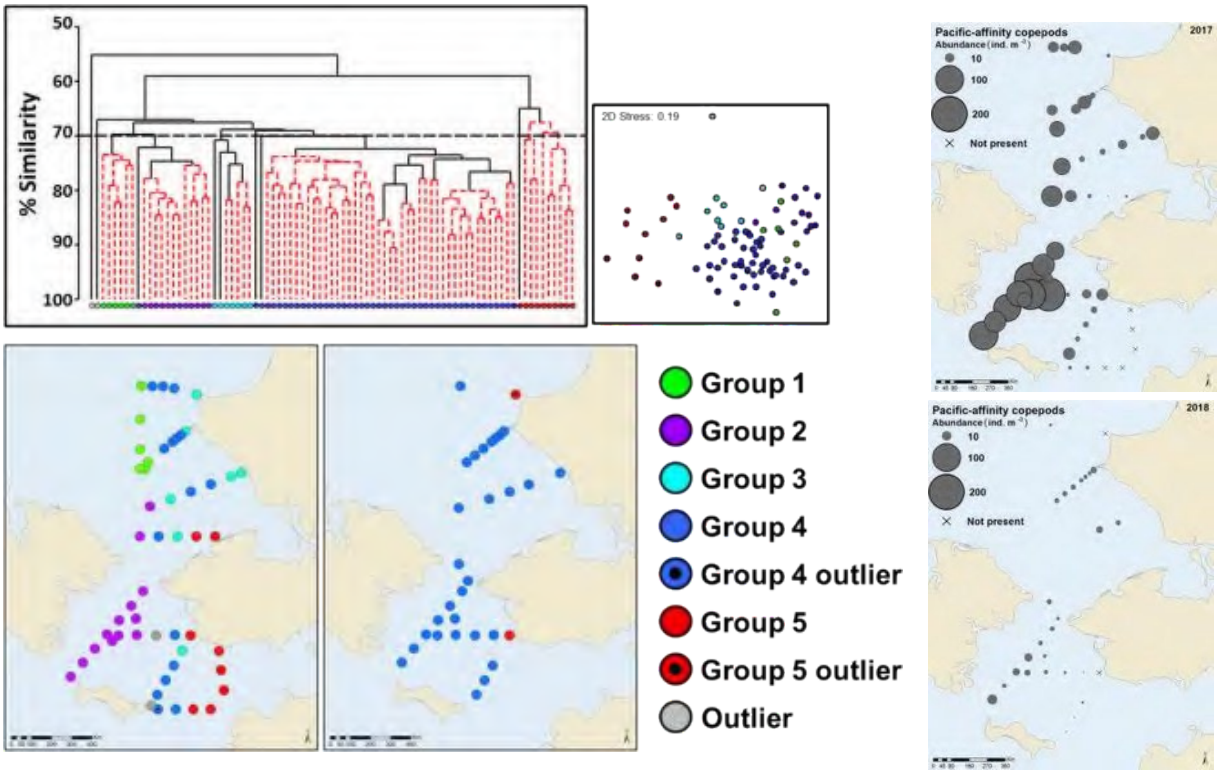

Figure 29. Non-dimensional principal component analysis shows that 2017 (bottom left and top right) and 2018 (bottom middle and bottom right) exhibited strongly contrasting mesozooplankton community structures.

Despite the similarity in the (low) prior winter ice cover, our net tows showed strongly contrasting zooplankton communities in 2017 and 2018 (Figure 28). Egg production and copepodite growth rates were measured for the calanoid copepods *Pseudocalanus* spp., *Calanus marshallae/glacialis*, and *Metridia pacifica* in the northern Bering and southern Chukchi Seas during June of 2017 and 2018. Rates suggest considerable discrepancies between growth rates and egg production weights that we propose are due to differences in life history strategies. Consistent with other studies, we find that global growth models do not match our observations particularly well, likely because they are dominated by egg production estimates at lower latitudes.

Using empirical biomass and rate measurements, we applied inverse food web modeling to in-situ phytoplankton, microzooplankton, zooplankton, sedimentation and primary production data collected from four ecosystem surveys in the Chukchi and Northern Bering seas, June (spring) 2017 and 2018, and August-September (summer) 2017 and 2019. Our results indicate variable carbon transfer efficiencies among seasons and areas of nutrient replete and nutrient deplete conditions.

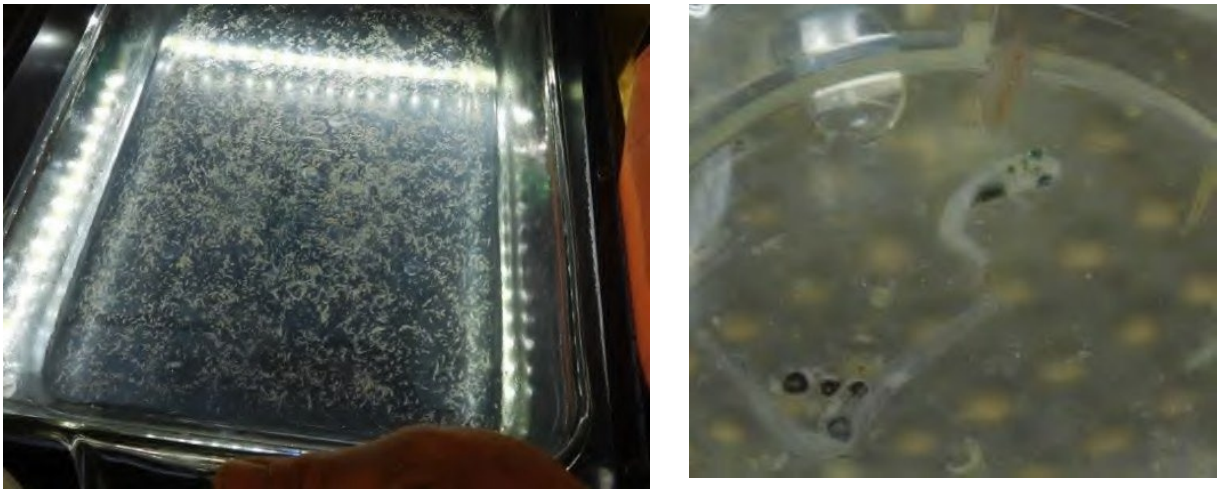

Figure 30. Larval polar cod sampled on the ASGARD SKQ201709S research cruise.

Spatial generalized additive models mapped the distribution of polar cod by size class and relative to environmental variables. Seasonal differences in polar cod abundance suggest that polar cod migration may follow a classical 'migration triangle' route between nursery grounds as juveniles, feeding grounds as subadults, and spawning grounds as adults, in relation to ice cover and seasonal production in the Chukchi Sea. High concentrations of larval polar cod sampled in coastal waters (Figure 29) having a high percentage of ice melt have allowed us to document at least one place near which these young fishes reside in at least some years (Deary et al., 2021).

Export Fluxes

We measured sinking particulate organic carbon (POC) fluxes with drifting and moored sediment traps, as well as rates of primary production and particle-associated microbial respiration. In Bering Shelf/Anadyr Water masses, sinking POC fluxes ranged from 0.8 to 2.3 g C m^{-2} day^{-1}, making them among the highest fluxes ever documented in the global oceans (O'Daly et al., 2020). These results highlight the extraordinary strength and efficiency of the biological carbon pump on the Pacific Arctic shelf during an unusually warm and low-sea ice year (Figure 30).

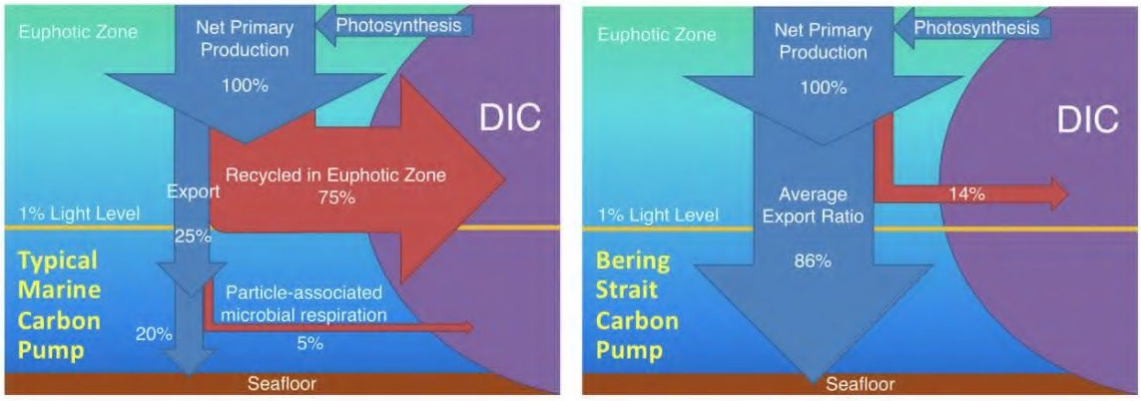

Figure 31. A typical marine carbon pump (left) and the Bering Strait region carbon pump (right), demonstrating the high export efficiency of the shallow Pacific Arctic continental shelf system.

Fluxes of living algal cells, chlorophyll *a*, total particulate matter (TPM), POC, and zooplankton fecal pellets, along with zooplankton and meroplankton collected in the traps, were used to evaluate spatial and temporal variations in the development and composition of the phytoplankton and zooplankton communities in relation to sea ice cover and water temperature.

The Benthic Realm

While most prior infaunal and benthic sediment work in the Chukchi Sea has been done with Van Veen grabs, our project used a multi-core sampler. The multi-corer allowed us to collect undisturbed samples of the seafloor/seawater interface, thereby facilitating rate-measuring incubation experiments and allowing for analysis of vertical structure of microbial and infaunal communities, including the first assessment of meiofaunal communities in this region.

The ASGARD multi-core and beam-trawl sampling provided live specimens for closed-system respirometry using non-invasive oxygen optodes to directly measure the metabolic rates of five bivalve species *(Macoma sp., Serripes groenlandicus, Astarte sp., Hiatella arctica* and *Nuculana pernula*) and one amphipod species (*Ampelisca macrocephala*). Results revealed (Figure 31) species-specific respiration rates with high metabolic demand for *S. groenlandicus* and *A. macrocephala* compared to that of the other species. These results suggest that observed shifts in spatial distribution of the dominant macrofaunal taxa across this region will impact carbon demand of the benthic community. Hence, ecosystem models seeking to incorporate benthic system functionality may need to differentiate between communities that exhibit different oxygen demands.

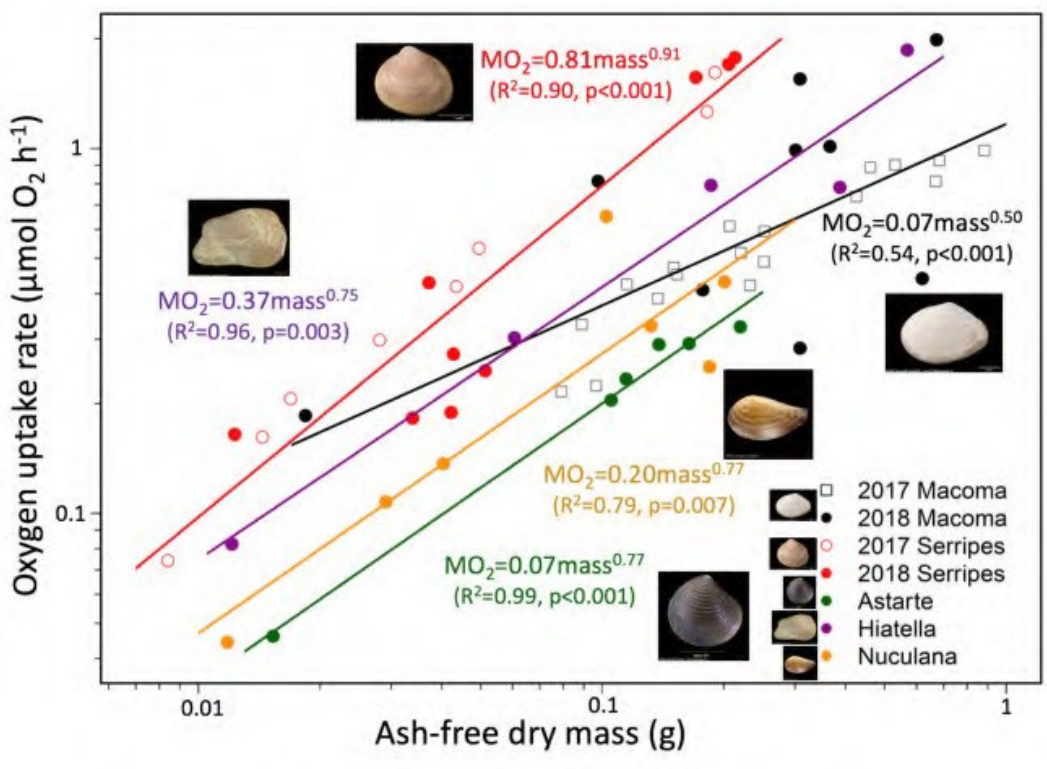

Figure 32. Species-specific respiration rates show an order-of-magnitude spread in oxygen demand amongst the various species.

In light of changing temperature and productivity regimes across the Pacific-Arctic domain, we also measured respiration rates of whole sediment communities at in situ (0 ºC) and elevated (5 ºC) temperatures. These experiments were made possible by multi-core sampling combined with *Sikuliaq's* capabilities for experimental work in temperature-controlled rooms. On average, sediment community oxygen demand, a proxy for organic carbon consumption, was ~30% higher in the warmer treatments; no differences in rates were observed between years. While locations in the "hot-spot" area in the southeast Chukchi Sea (SECS; DBO 3 region) showed markedly higher respiration rates likely due to the presence of large bivalves, all other sampled areas showed comparable rates. With the exception of the SECS sites, oxygen consumption rate showed a much stronger relationship with microbial biomass than with macro-infaunal biomass, suggesting microbial communities should not be overlooked in considering the fate of organic matter at the seafloor.

Four clusters of polychaete functional guilds were identified in the northern Bering and southern Chukchi sea. Polychaete functional composition and vertical distribution reflected the quality and quantity of organic matter input and the depositional environment, with likely impacts on biogeochemical and carbon cycling within the sediment. Meiofaunal communities similarly reflected grain size characteristics and organic matter content in sediments. Two distinct communities of nematodes were observed in the meio- and macrofaunal size fractions, with macrofaunal nematodes making up a large fraction of the total macrofaunal biomass.

A mass balance Chukchi Sea ecosystem model incorporated terrestrial matter as an energy source, especially for benthic consumers. This component allowed us to adjust phytoplankton biomass to better match recent empirical measurements and to update the system-wide mass-balance. Iterations of the mass-balance model showed that climate-driven increased retention of phytoplankton biomass in the pelagic realm would depress biomass of most benthic-feeding organisms across several larger ecosystem groups (invertebrates, fishes, mammals). However, simulated increases in both terrestrial matter inflow and bacterial biomass have the potential to compensate for some of the reductions in the energy supply from phytoplankton to the benthic food web, as well as to diversify the supply of organic matter to the seafloor.

The Over-arching Question

What regulates variations in carbon transfer pathways and how will the changing ice environment alter these pathways and ecosystem structure in the Pacific Arctic and beyond? Our observations and experiments revealed numerous insights into the character of the bottom-up forcing that helps maintain the Pacific Arctic shelf ecosystem, into how energy (carbon) is routed amongst the various marine system components, and into how it may change in a warming climate. Temperature clearly stands out as a key factor in the regulation of energy consumption and trophic transfers, but temperature alone is far from the whole answer. The aggregate combination of species abundance and distributions and environmental setting (geomorphology of the Pacific Arctic shelves, large-scale pressure gradients driving mean flows, nutrient supply, strong seasonality in light, ice, winds) combined with the ability of the Pacific Arctic ecosystem to maintain its many services ultimately sets this ecosystem's unique biological character. While this character has never been static in nature, it appears to be crossing thresholds into states that have not previously been observed (Huntington et al., 2020).

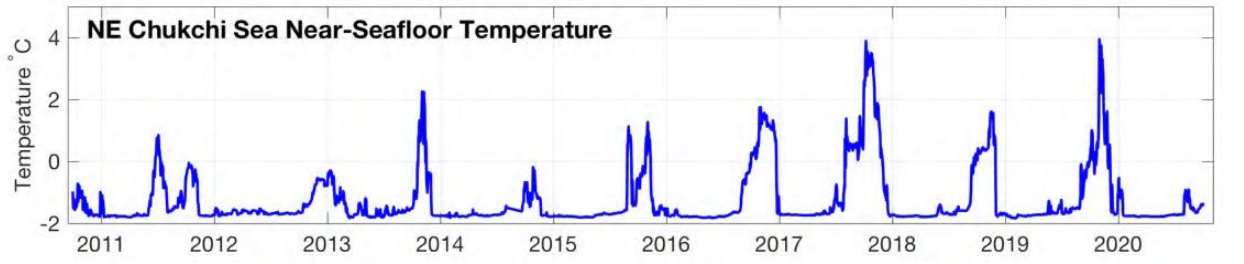

Figure 33. Near-bottom measurements of temperature in the NE Chukchi Sea at the CEO mooring site (2014-2020) and at a nearby site (2011-2014) showing an increase in the duration of waters > 0 °C over 2016-2019

Extremely warm conditions from 2017 into 2019 – including loss of ice cover across portions of the region in all three winters – were a marked change even from other recent warm years and may represent a proxy for future decade "normal" conditions. Temperature-controlled respirometry experiments show that benthic oxygen consumption increases significantly (~30%) with warming temperatures and our mooring measurements showed an extended duration of time that the seafloor water temperatures remained 2-6 degrees above the freezing point during these recent warm years (Figure 32). Biological indicators, such as these temperature-dependent benthic respiration rates, suggest that thermal state change exhibits potential to alter ecosystem structure and function (Jones et al., 2021), but our measurements also show that the system exhibits resilient capacity to buffer some of the changes from a bottom-up perspective. For example, direct measurements of upper water column export fluxes showed that even in these remarkably warm years, water column export to the benthos is extremely efficient (O'Daly et al., 2020) due to the fast sinking rates that large diatoms exhibit.

While the environmental alterations represent a bottom-up forcing, recent upper trophic level observations (Stevenson, D.E., Lauth, R.R., 2019; Huntington et. al. 2020) suggest that top-down forcing of the ecosystem will also play a key, and possibly dominant, role in determining future changes to the overall character of the Pacific Arctic ecosystem. For example, the influx of sub-Arctic Pacific Cod and Walleye Pollock exhibit potential to impart a more substantive impact on the benthic community than changes in benthic productivity due to altered pelagic realm export. Sensitivity of the local upper trophic level populations to anthropogenic disturbance (e.g. shipping traffic, noise) and intra-species competition represent other potential vulnerabilities.

In aggregate, our results have helped both define and constrain our understanding of the conditions in which the future warmer Pacific Arctic ecosystem will exist. The examples summarized here, and many others in the published manuscripts cited and reprinted in this report, directly contribute to our understanding of how energy in the marine ecosystem is routed now, and how it may change as the duration of sea ice cover continues to decline. The results of the ASGARD experiments will continue to be analyzed, synthesized, and published in coming years, each further revealing partial answers to the ASGARD and Arctic IERP over-arching question.

Relevance to Resource Management and Alaska Communities

Coastal Community Interests and Concerns

Food security is a paramount concern to residents of coastal communities that depend on a subsistence-based economy. Environmental conditions are changing rapidly and hunters find themselves dealing with a multitude of factors that can degrade hunt success (Fall et al., 2013). For example, hunters report that their ability to forecast the weather is now at times diminished, fuel costs are high; ice conditions are different and less safe, and game can be less accessible. Hunters are concerned with the impact of vessel traffic on the behavior and location of marine mammals, bycatch from commercial fisheries, and increasing rates of coastal erosion that threaten the placement of entire villages.

Practical applications of our research will directly address issues, questions and concerns posed by coastal community members (e.g., Huntington et al, 2021). These include: sea ice conditions and timing; whale, seal and walrus distributions with respect to vessel traffic noises; ramifications of changing climate conditions to the presence and success of marine mammals, clams, crabs, fish, and other animals; and toxic algae blooms that may impact whales and other marine mammals.

In particular, our research allows us to provide scientific lenses through which we can help interpret the causes and consequences of environmental change. As communities continue to adapt – as they have done for millennia – information from scientific studies and scientific observations can help inform community decisions. Such decisions now commonly deal with the practical aspects of addressing climate change impacts to the environment or location availability of subsistence food resources.

Harmful algal blooms (HAB) pose a significant potential public health risk to communities that harvest shellfish and marine mammals that consume shellfish. Recent studies have documented an increased potential for latent HAB spores to bloom from the seafloor (e.g., Anderson et al., 2021). Warmer waters also enhance the probability that a pelagic HAB boom may occur. Filter-feeding shellfish can bioaccumulate toxic plankton and pass such toxins on to marine mammals (e.g., walrus) and people. The research done in the ASGARD study is helping us understand the potential for such blooms and will help us determine future actions that can help decrease the potential for serious health impacts.

Equity in access to marine resources and economic development activities by Alaska Native communities is related to the scientific research that is conducted in the Bering and Chukchi seas because the resource management agencies consider in part the scientific data for informing their policy and management decisions. As commercially viable biomass shifts northward under a warming climate, important questions face both the coastal communities and the management of the resource. For example, in a region that has traditionally not hosted large scale commercial fisheries, what groups should be granted the right to fish: local Indigenous community members who are the sole traditional users of the local waterways, or commercial fishing entities that have no cultural or historical ties to the region? Who should economically benefit from new resources? These and many other similar questions may have once lacked immediate urgency, but we now face the reality that such decisions must be considered in the present.

Management Implications

Perhaps even sooner than many had anticipated, state and federal agencies are confronting resource management issues tied to loss of sea ice and northward-shifting distributions of sub-Arctic marine species.

The incursion of Pollock and Pacific Cod into the Bering Strait region – and farther north – demand consideration and a careful assessment of new management actions. Considerations need to include biodiversity, ecosystem structure, and ecosystem function in relation to any potential fishery harvest levels. The recent (since the start of the Arctic IERP) increase of commercial fishing in the Chukchi Sea waters of the Russian Federation suggests that despite insufficient data from the US side of the convention line in the Chukchi Sea, there likely exists significant quantities of Pollock and Pacific Cod on the US side as well. In US waters, any potential fishing activities must consider the cultures and subsistence lifestyles of local indigenous communities, potential impacts of industrial activities (e.g. commercial fishing, oil and gas extraction), potential changes to regional ocean carrying capacity, and resilience of the arctic marine ecosystem (NRC, 2014). An ecosystem-based approach to fisheries management necessitates consideration of food security of the coastal Indigenous communities, their traditional subsistence hunting activities, and conservation of endangered marine mammal and seabird species.

With carbon (or sometimes nitrogen) as the basic currency with which we describe and quantify biological and biophysical interactions - including growth, respiration, energy conversion, energy movement, energy storage and intra-trophic transfers - we need to understand the rate at which carbon is consumed, converted, stored, buried, and relocated. Biophysical numerical models require as inputs sinking rates, growth rates and respiration rates for all important species or functional groups (Stock et al., 2013). As outputs, models predict primary productivity, secondary productivity and biomass. ASGARD data provide spatially-explicit measures of the production and respiration rates for the dominant pelagic and benthic species, along with more basic information about composition, biomass and abundance. Such data will prove critical for advancing spatially and temporally explicit models of ecosystem structure, and applying them in appropriate and statistically robust to future scenario projections.

Beyond the fisheries management applications by NOAA, other federal agencies also may find the ASGARD data useful in their policy-making processes. For example, the protection of marine mammals and seabirds demands an examination of vessel regulations in locations at which there exists potential for negative interactions between species of concern and vessel traffic. Vessel routing and speed limits in Bering Strait and other shipping choke points may help decrease the probability of marine mammal strikes. Lighting protocols for vessels during the migration period for threatened seabird may reduce bird kill events. The USFWS, NOAA and USGS all must study the potential for harmful interactions relative to the species of concern that fall within their management directives. Similarly, the US Coast Guard has an opportunity to apply the environmental data assembled under the Arctic IERP program to their efforts, which include the planning for and response to oil and other contaminant spills, search and rescue missions, and fisheries enforcement activities.

Directions for Future Research

Following a concentrated effort of field work, analysis and publication, further advancements in scientific understanding relies on testable hypotheses and experimental designs that probe the edges of our knowledge base, and place our findings into a more complete ecological context. The process of analysis and interpretation of the Arctic IERP results is still ongoing, but a number of future research needs are already apparent. Below, we list a series of specific research directions that could further improve our ability to dig deeper into the ASGARD and Arctic IERP guiding questions, and could provide management agencies with actionable guidance.

Below, we identify ten study focal areas that would, if addressed, lead to a fuller understanding of the Pacific Arctic ecosystem, its drivers, and future trajectory. The ASGARD project was designed around the gaping need for more rate measurement studies, and while we have filled some needs in this realm, many still remain. Our recommendations are separated into two categories: *Rate Studies* and *Ecosystem Status and Change*. All of the below listed studies would fill information gaps and/or needs that resource management agencies could apply to their task mandates.

Biological Rate Studies and their Applications

1. **Comparison of ASGARD data to more typical years**
   Our campaign existed across the two warmest years on record for the study region and are thus not well characteristic of typical conditions found in the first two decades of the 21st century. Repeated measurements in more "normal" years would allow us to better assess our warm phase June month shipboard measurements and year-round mooring measurements.

2. **Benthic flux processes**
   Fluxes of many chemical constituents across the sediment-seawater interface are important for the Pacific Arctic ecosystem. Oxic and anoxic processes that influence sulfate reduction, denitrification, and nitrification help regulate nutrient availability and oxygen concentrations. A better understanding of the key rates and drivers of these fluxes is key to a better understanding of the future Alaskan Arctic marine realm.

3. **Species-specific biological rate measurements**
   We previously targeted a few key species for respiration and productivity rate experiments. Expanding the number of species for which we well know their biophysical models would allow future efforts to more realistically incorporate a multi-species approach to ecosystem modeling.

4. **Year-round export fluxes in the coastal realm**
   Our sediment traps were all deployed in Bering Shelf Water and Anadyr Water flow pathways. A time series sediment trap in Alaska Coastal Waters is needed to better characterize this important biophysical domain.

5. **Identifying carbon pump controls and dynamics balances**
   The microbial loop in the pelagic realm is not well described in our study region. Understanding the species and rates at which remineralization and other key processes operate is important to understanding the balance between pelagic and benthic zone carbon sources, nutrient availability, and productivity potential.

6. **Applying ASGARD measurements to ecosystem models**
   The ASGARD project was designed in part to provide data useful for the parameterization and/or validation of numerical models. The need for such modeling efforts has not diminished and we now have significant amounts of data that can help bring model studies to a more advanced stage of operation.

Ecosystem Status and Change

7. **Non-summer observations**
   The ASGARD expeditions in June provided valuable data outside of the more typical sampling months of July-September, but seasonal coverage in sampling remains heavily biased to summer and early fall months. Mooring data provided some first-ever year-round depictions of nutrient chemistry and biological observations in the study region, but these data are limited in scope by the sampling that is achievable from moored sensor packages. Shipboard biological sampling in late fall, winter and early spring could provide data that are important to our understanding during the dark and cold portion of the year.

8. **Ecosystem ramification of multiple stressors in the Pacific Arctic**
   Warming, ocean acidification, hypoxia, and increasing vessel traffic and other anthropogenic impacts present the likelihood of unanticipated outcomes due to the nature of nonlinear coupling between multiple stressors. Our ability to assess future ecosystem conditions in the study region depends on improvements in our understanding of how the system as a whole responds to such factors.

9. **Management of vessel locations and speeds in the Pacific Arctic region**
   Increasing vessel traffic poses a risk to protected marine mammal and seabird species. Modeling that assesses potential dynamic and/or adaptive management approaches would improve conservation efforts and reduce the potential for conflict. This need applies year-round due to the different migration timings of the various species of interest, and the fact that vessels are now transiting through the Bering Strait region in all months.

10. **Tracking of sub-Arctic species distribution, abundance, and biodiversity**
    Sub-Arctic species range distributions have been increasing northward in recent decades, and more recent indications show potential for displacement of endemic Arctic species as ranges over

11. **Changing phenologies**
    As the ice, temperature and light conditions change, the timing of species presence, absence, match-mismatch timing with food resources, migration considerations and human interactions all should be assessed with respect to animal behaviors and environmental conditions.

12. **Combined US and Russian sector studies**
    Many data collections end at the international dateline, but the ecosystem is not bound by national boundaries. Studies that bridge both the US and Russian Federation sectors of the Bering and Chukchi seas are needed to gain holistic understanding of the system.

Publications, Presentations, Outreach, and Collaborations

The ASGARD publications listing below includes ASGARD cruise reports, "core" ASGARD publications to date, publications in preparation, and other publications that utilize ASGARD data or the participation of an ASGARD PI was facilitated by the Arctic IERP.

Presentations

2021

- Danielson, S., K. Hedstrom, T. Hennon, C. Mordy, P. Stabeno, D. Stockwell, R. Woodgate, 2021. Recent volume, heat, and nutrient fluxes on the Pacific Arctic continental shelf, Alaska Marine Science Symposium, Anchorage, AK, oral presentation
- Deary, A.L., J.T. Duffy-Anderson, F. Mueter, C.D. Vestfals, E.D. Goldstein, E.A. Logerwell, P. Stabeno, S. Danielson, R.R. Hopcroft, 2021. Seasonal abundance and distribution of larval polar cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*) in the US Arctic, Arctic Science Summit Week International Arctic Science Committee. Lisbon, Portugal (virtual), Oral Presentation
- Gonzalez, S., J. Horne, S.L. Danielson and L. Lieber 2021, Representative Range of Acoustic Point Source Measurements in the Chukchi Sea, Alaska Marine Science Symposium, Anchorage, AK
- Lalande, C., S. Danielson, A. McDonnell,R. Hopcroft, J. Grebmeier, 2021. Time-Series Measurements of Export Fluxes across the Bering Strait, Alaska Marine Science Symposium, Anchorage, AK, poster presentation.
- Walker, A., A. Thurber, S.L. Mincks, 2021. Effects of a changing environment on microbial communities in Chukchi shelf sediments. Alaska Marine Science Symposium, Anchorage, AK, oral presentation

2020

- S. Danielson et al., 2020. Heat Over the Pacific Arctic Continental Shelves: Recent Changes in Content, Surface Fluxes and Throughput, AGU/ALSO Ocean Sciences Meeting, San Diego, CA, Poster presentation
- S. Hardy et al., 2020. Rates and pathways of sediment organic-matter processing across the northern Bering and southern Chukchi Sea shelf, AGU/ALSO Ocean Sciences Meeting, San Diego, CA
- T. Hennon et al., 2020. Linking Offshore Oceanography to Alaskan Lagoon Dynamics, AGU/ALSO Ocean Sciences Meeting, San Diego, CA
- K. Kuletz et al., 2020. Seabirds Signal Changes in the Pacific Arctic, AGU/ALSO Ocean Sciences Meeting, San Diego, CA
- K. Lu et al., 2020. Impacts of Short-Term Wind Events on Chukchi Hydrography and Sea Ice Retreat, AGU/ALSO Ocean Sciences Meeting, San Diego, CA
- A. Poje et al., 2020. Copepod Production in a High Latitude Shelf System, AGU/ALSO Ocean Sciences Meeting, San Diego, CA
- S. Danielson et al., 2020. Heat Over the Pacific Arctic Continental Shelves: Recent Changes in Content, Surface Fluxes and Throughput, Alaska Marine Science Symposium, Anchorage, AK, Poster presentation
- Farley et al., 2020. The Arctic Integrated Ecosystem Research Program: Are We Experiencing the Future Arctic?, Alaska Marine Science Symposium, Anchorage, AK, Oral Presentation
- Hennon et al., 2020. Linking Offshore Oceanography to Alaskan Lagoon Dynamics"
- Poje et al., 2020. Calanoid Copepod Egg Production and Growth Rates in the Northern Bering and Southern Chukchi Seas, Alaska Marine Science Symposium, Anchorage, AK,

- Kuletz, “Seabirds Signal Changes in the Pacific Arctic, Alaska Marine Science Symposium, Anchorage, AK,
- Axler et al., 2020. Seasonal and Annual Patterns in Fatty Acid Dynamics of Arctic Seston from the North Bering-Chukchi Sea Regions, Alaska Marine Science Symposium, Anchorage, AK,

2019

- Danielson, S. 2019. Recent surface heat fluxes and thermal and sea ice conditions of the Bering-Chukchi Continental Shelf”, Alaska Marine Science Symposium, Anchorage, AK, Oral Presentation
- Danielson, S. and IERP SSC, 2019. The Arctic Integrated Ecosystem Research Program: Observations of 2017-2018 conditions and consequences”, Alaska Marine Science Symposium, Anchorage, AK, Oral Presentation
- Deary, A.L., 2019. Ecosystem research in Alaska, Friday Harbor Laboratories, University of Washington. Friday Harbor, Washington, Oral Presentation
- Deary, A.L., 2019. Fisheries update in the northern Bering Sea and Arctic, Interagency Arctic Research Policy Committee, Washington D.C., Oral Presentation
- Deary, A.L., J.T. Duffy-Anderson, F. Mueter, C.D. Vestfals, E.D. Goldstein, E.A. Logerwell, P. Stabeno, S. Danielson, 2019. A synthesis of the early life history of two forage fishes in the US Arctic during a record sea ice minimum in 2017, Early Life History Section, American Fisheries Society, Mallorca, Spain, Oral Presentation
- Deary, A.L. and D.G. Kimmel, 2019. Fisheries research in the United States Arctic, 45th Anniversary of the American Polish Cooperation Symposium, Gdynia, Poland, Oral Presentation
- L. Eisner, M. Lomas, D. Stockwell, S. Baer, 2019. Primary production in the southern Chukchi Sea: June (ASGARD) and August/September (Arctic IES) 2017 survey results”, Alaska Marine Science Symposium, Anchorage, AK, Poster Presentation
- C. Forster, B. Norcross, F.Mueter, 2019. Spatial patterns, environmental drivers, and potential seasonal differences of Arctic Cod (Boreogadus saida) distribution in the Chukchi Sea, Alaska Marine Science Symposium, Anchorage, AK
- S. Gonzalez, J.K. Horne, S. Danielson, 2019. Temporal variability in densities and vertical distributions of pelagic fish and macrozooplankton on Hanna Shoal, Alaska Marine Science Symposium, Anchorage, AK, Poster Presentation
- B. Jones, S. Hardy, A. Thurber, A. Kelley, 2019. Benthic respiration rates across the northern Bering and southern Chukchi Sea shelf, Alaska Marine Science Symposium, Anchorage, AK, Oral presentation
- R. Lekanoff, E. Collins, A. McDonnell, 2019. Characterizing particle-associated and free-living microbes and their roles in the carbon cycle of the Bering and Chukchi seas, Alaska Marine Science Symposium, Anchorage, AK, Poster Presentation
- C. Smoot, J. Questel, A. Poje, R. Hopcroft, “Springtime zooplankton communities of the Northern Bering and Southern Chukchi Seas, Alaska Marine Science Symposium, Anchorage, AK, Poster Presentation

- S. O'Daly and A.M.P. McDonnell, 2019. Downward organic carbon flux, average particle sinking speed, and the role of particle-associated microbial respiration on the Bering and Chukchi shelf, Alaska Marine Science Symposium, Anchorage, AK, Oral presentation
- A. Poje, C. Smoot & R. Hopcroft, 2019. Growth of Calanoid Copepods on an Arctic shelf, , Alaska Marine Science Symposium, Anchorage, AK, Oral presentation

2018

- Danielson, S. and coauthors. On the Thermal and Sea Ice Conditions of the Bering-Chukchi Continental Shelf, AGU Fall Meeting, Washington DC, December 2018
- Danielson, S. and coauthors. Oral presentation, Rate Experiments of the Arctic Integrated Ecosystem Research Program, IARPC Ecosystem Collaboration Team meeting, November, 2018
- Danielson, S. Oral presentation, National Academies of Science, Engineering, and Medicine: Ocean Studies Board, Fairbanks, AK, September 2018
- B. Jones and S. Hardy, 2018. Macrofaunal respiration rates across the northern Bering and southern Chukchi Sea shelf, Alaska Marine Science Symposium, Anchorage, AK
- A. Poje, C. Smoot & R. Hopcroft, 2018. Growth of Calanoid Copepods on an Arctic shelf, Alaska Marine Science Symposium, Anchorage, AK
- S. O'Daly and A.M.P. McDonnell, 2018. Determining particle abundance, size, and composition in the North Bering and South Chukchi seas during an earlier spring melt, Alaska Marine Science Symposium, Anchorage, AK,
- R. Lekanoff, R.E. Collins, and A.M.P. McDonnell, A.M.P, 2018. Characterizing gene functions of particle-associated microbes and their role in the carbon cycle of the Bering and Chukchi Seas, Alaska Marine Science Symposium, Anchorage, AK

2017

- Danielson, S. Oral presentation, Ice floes to seals, waves to whales. Linking high latitude marine ecosystem studies and researchers through physics. Sitka Whale Fest 2017, Sitka, AK, November 2017
- Oral presentation, AIERP Update to the Pacific Arctic Group, Seattle WA, November 2017
- Danielson S. and coauthors, U.S.-Canada Northern Oil and Gas Research Forum, Anchorage, AK, October 2017
- Danielson, S. Recap of 2017 Arctic Integration Ecosystem Research Program field season to NPRB Board of Trustees, Cordova, AK, September 2017
- Danielson, S. Oral presentation, Attempting Multi-Disciplinary Measurements at Biologically & Physically Relevant Time & Length Scales, Gordon Research Conference, Ventura, CA, March 2017
- Danielson, S.L., Blanchard, A. S. Hardy, R. Hopcroft, K. Kuletz, M. Lomas, A. McDonnell, B. Norcross, K. Stafford, D. Stockwell. Tales from ASGARD: Upcoming in 2017 and 2018, Alaska Marine Science Symposium, Anchorage, AK, poster presentation

Outreach Activities and Products

Ongoing

- Danielson participates in the Ice Seal UME Investigative team, providing remotely sensed and in situ oceanographic updates to the monthly meetings.

2021

- Danielson presented at the Strait Science lecture series on January 7th.
- KNOM article High Frequency Radar Sites in Wales and Shishmaref, Could Help Track Debris and Save Lives.
- Nome Nugget article 1/14/21: High frequency radar maps ocean currents.
- O'Daly presented at the Strait Science lecture series on January 14th.
- Nome Nugget article 1/28/21: Researcher looks at sea ice carbon production reporting on O'Daly's Strait Science talk

2020

- Danielson presented a brief overview of IERP results at the July 2020 Alaska Eskimo Whaling Commission by reviewing paper titles in the AIERP DSR-II first special issue and then highlighting results of Huntington et al. 2020 and Danielson et al. 2020b.
- Danielson was a co-convener of a scientific session at the 2020 AGU/ASLO Ocean Sciences Meeting: Ecosystem Structure and Processes in a Changing Arctic, with over 50 abstract submissions. Combined, the session garnered had two sections of oral presentations and two poster sessions.
- Danielson was a co-convener of a town hall meeting at the 2020 AGU/ASLO Ocean Sciences meeting: McCammon, M., S.L. Danielson, J.M. Grebmeier, A. Holman, C. Rosa, Scientific Response to an Ever Faster Changing Arctic: Making the Most of Our Collective Research Efforts

2019

- The ASGARD project was noted in many social media and blog postings made in 2019 associated with the IERP, with R/V Sikuliaq and CFOS.

2018

- *Nome Nugget* article: 29 June 2018: "UAF Research Vessel Sikuliaq Visits Nome"
- Danielson provided an interview to KNOM for a broadcast on 27 June 2018: "Scientists studying spring transition in Bering Strait waters"
- We presented post-season ASGARD updates to the Alaska Eskimo Whaling Commission on 23 July, 2018.
- We presented post-season ASGARD updates to the Arctic Waterways Safety Committee on 18 October, 2018.
- Numerous social media postings that feature the ASGARD Sikuliaq cruise were and continue to be posted on the UAF's Sikuliaq website.

- Danielson was interviewed on KIAK and on KFBX on 21 November 2018. A link to the KFBX interview is here: http://research.cfos.uaf.edu/faculty/sldanielson/media/Danielson_KFBX_11-21-18.wav
- We presented a project update to the NPRB Board of Trustees in Cordova (September 2018).
- We presented cruise updates at the 27th Annual BIA Provider's Conference (November) and the AEWC and AWSC meetings (December).
- Numerous social media postings that feature the ASGARD Sikuliaq cruise were and continue to be posted on the UAF's Sikuliaq website.

2017

- Danielson highlighted the ArcticIERP ASGARD cruise and research questions in a presentation at the November 2017 Sitka Whale Fest.
- McDonnell, A. 2017. Video compilations featuring ASGARD/Arctic IERP activities. https://www.youtube.com/watch?v=sQDZo9Fw_hw
- Forster, C. 2017. Video compilations featuring ASGARD/Arctic IERP activities. https://www.youtube.com/watch?v=1ddMYLei9vw
- Outreach activities included NPRB-sponsored "hub" meeting in Nome.
- Media articles describing AIERP and ASGARD were published in the Nome Nugget (2 articles) and the Fairbanks Daily New Miner. The FDNM article was picked up by the Associated Press and republished in the Ketchikan Daily News and nationally in US News and World Report.
- UAF published a cruise highlight article as part of the Chancellor's "Cornerstone" weekly update.
- We gave pre-cruise and post-cruise lectures at the UAF campus in Nome as part of the "Strait Science" lecture series, hosted by UAF MAP agent Gay Sheffield. Attendance was about 35 people at each presentation.
- A. McDonnell along with students R. Lekanoff and S. O'Daly gave a public lecture in Dutch Harbor prior to sailing on the 2017 ASGARD cruise. The ship also provided tours to a limited number of community members.
- We gave a post-cruise report to the summer meeting of the Alaska Eskimo Whaling Commission on July 20th in Fairbanks.
- Hundreds of social media posts and a detailed blog were updated regularly from the research cruise. Visit https://blog.arctic.nprb.org/ for details.

2016 and early 2017

- Outreach presentations and discussions at meetings with the AEWC, IPCoMM, AWSC, the NPRB-sponsored Kotzebue "Hub meeting", the native Village of Gambell, and the Native Village of Savoonga.

Research Cruise Collaborations: Participant Home Institutions

- Bigelow Labs for Ocean Science
- BOEM
- Dauphin Island Sea Lab
- Hokkaido University

- Native Village of Diomede
- NOAA-PMEL
- NPRB
- OSU
- UAF
- USFWS
- UW-APL
- UW-Oceanography

Data Sharing and Publication Collaborations: Home Institutions

(Based on *Results* chapters' author lists and first authors of *Appendix B* publications.)

- Alaska Center for Climate Assessment and Policy
- Alaska Department of Fish and Game
- Amundsen Science
- Institute of Ocean Sciences, Fisheries and Oceans Canada (IOS-DFO) Canada
- College of Earth, Ocean and Atmospheric Science, Oregon State University
- Florida State University Coastal and Marine Laboratory
- Huntington Consulting
- International Arctic Research Center and College of Natural Science and Mathematics
- Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Japan
- Native Village of Diomede
- NOAA, Alaska Fisheries Science Center, Auke Bay Lab
- NOAA, Alaska Fisheries Science Center, National Marine Fisheries Service
- NOAA, Pacific Marine Environmental Laboratory
- North Carolina State University
- North Slope Borough Department of Wildlife Management
- Russian Federal Research Institute of Fisheries and Oceanography, Pacific Branch of VINRO, TINRO, Vladivostok, Russia
- Stantec
- University of Toronto Mississauga, Mississauga, ON, Canada
- University of Manitoba, Winnipeg, Manitoba, Canada
- University of Maryland Center for Environmental Sciences, Chesapeake Biological Laboratory
- University of Washington, Applied Physics Laboratory
- University of Washington, Joint Institute for the Study of the Atmosphere and Ocean
- US Fish and Wildlife Service
- Woods Hole Oceanographic Institute

Sample Collections, Lab Analyses and Other Collaborations

(Including intra-Arctic IERP collaborations such as the NOAA-led Arctic IES projects)

- Alaska Center for Climate Assessment and Policy (weather/climate analyses)
- Alaska Ocean Observing System (AOOS) (CEO program support)

- Alaska Sea Grant (UAF Nome Campus cruise support and community liaison support)
- Amundsen Science (sediment trap samples)
- Arctic Marine Biodiversity Observation Network (AMBON) (US Arctic biodiversity)

National and International Symposia Collaborations

- 2016 – present (1-2 times per year). ASGARD representation at Distributed Biological Observatory (DBO) and the Pacific Arctic Group (PAG) collaboration meetings.
- October 2017. Participation in the 4th Pan-Arctic Synthesis: Towards a unifying pan-Arctic perspective of the contemporary and future Arctic Ocean. Workshop convened in Motovun, Croatia. Since 2002 pan-arctic integration symposia have attempted to figure out how the Arctic Ocean can be understood as an independent, mediterranean ocean and the node of the Northern Hemisphere. In order to overcome the sectorial approaches that characterize our research, the intention of the workshop was to add to the pan-arctic comprehension of the Arctic Ocean and adjacent seas. The workshop resulted in the publication of 13 peer-reviewed journal articles and one e-book compendium. Three of these manuscripts include one or two ASGARD PIs (Danielson, Hopcroft) as lead or contributing authors. https://www.frontiersin.org/research-topics/7353/towards-a-unifying-pan-arctic-perspective-of-the-contemporary-and-future-arctic-ocean
- February 2018. AGU/ALSO Ocean Sciences Meeting. Scientific session organization (with DBO and AMBON) and participation: “Linkages Between Environmental Drivers and Structure of

Arctic Ecosystems". Session Abstract: Arctic ecosystems are adjusting to rapidly warming temperatures, sea ice loss and a myriad of other factors that are changing with time. Temperature-growth relations, altered seasonality, expanded and contracted range extents, and new trophic pathways may each affect biodiversity, population status of key species, and relations between humans and marine resources. As environmental change continues, can we anticipate how future Arctic ecosystems will compare to those of yesterday and today? Will the effects of a changing climate be the same across various Arctic regions? We welcome presentations from all regions of the Arctic examining rates, processes and mechanistic controls that impart structure on any aspect of the high-latitude marine ecosystem.

- April 2019. Kitikmeot Sea Science Study (K3S) Synthesis Workshop. A results analysis and writing workshop was convened for compiling data collected in the Kitikmeot Sea region of the Canadian Arctic Archipelago's Northwest Passage in Yellowknife, Canada in March 2019. Participants included international K3S team members from Canada, Norway and the US. ASGARD project results were discussed at this workshop in the context of contrasting different Arctic marine ecosystems.
- May 2019. Japanese OMIX project (*Ocean Mixing*: http://omix.aori.u-tokyo.ac.jp/en/) is a collaborative study between physical, chemical and biological oceanography to understand turbulent vertical mixing and physical, chemical and biological oceanic processes and their relationship in the western North Pacific (2015-2019). In May 2019 OMIX hosted a penultimate international symposium and an associated session at the following Japan Geoscience Union annual meeting. Work from the ASGARD project was presented at these meetings, and the collaboration triggered additional communication between UAF and Japanese scientists, including a visit to Fairbanks by Dr. Toru Hirawake of Hokkaido University in 2020 that involved discussions of planning for future Bering Strait region data sharing collaborations.
- February 2020. AGU/ALSO Ocean Sciences Meeting. Scientific session organization (with DBO and AMBON) and participation: "Ecosystem Structure in a Changing Arctic". Session Abstract: The rate of atmospheric warming in the Arctic is outpacing that of other regions, and is associated with sea ice loss, warming ocean temperatures, changes in the hydrological cycle, and impacted ecosystems. Temperature-growth relations, nutrient cycling dynamics, altered seasonality, changing freshwater balances, expanded and contracted species range extensions, and new trophic pathways may each affect biodiversity, the population status of key species, and relations between humans and marine resources. As environmental change continues, can we anticipate how future Arctic ecosystems will compare to those of the past and present? Will the effects of a changing climate be the same across various Arctic regions? Organizers welcome presentations from all regions of the Arctic examining the drivers, rates, processes, and mechanistic controls that impart structure on any aspect of the high-latitude marine ecosystem.
- February 2020. AGU/ALSO Ocean Sciences Meeting Town Hall organization (with AOOS, USARC and DBO) and participation: "Scientific Responses to an Ever Faster Changing Arctic: Making the Most of our Collective Research Efforts". With the U.S. Arctic experiencing such unprecedented, rapid change, the objective of this town hall was to provide an opportunity for the scientific community to informally discuss causality and linkages across results from recent field work and studies, including if a "new normal" for the Arctic can be determined and what this might look like. We would also like to see proposed actions developed for moving forward with

coordinated research efforts, ideas for emerging research. And observing needs, and suggestion or how we can best oorganize ourselves to deliver the data and information products that northern communities, resource managers, industry, first responders, and other decision makers will need.

Chirikov Basin Oceanography: Function, Structure, Drivers and Change (Manuscript in preparation)

Danielson, et al., In prep. Oceanography of Chirikov Basin: Function, Structure, Drivers and Change

Abstract

Data from a suite of time series moorings, shipboard measurements, and numerical model integrations are assessed in order to build a better understanding of the oceanographic functioning of Chirikov Basin. We assess the regional wind forcing in order to better understand the regulation of the advective flow field over the Northern Bering and Southern Chukchi continental shelves. We show that the partitioning of flow to either side of St. Lawrence Island reflects a leaky switchyard type of balance between the central Bering Sea shelf and Chirikov Basin. Norton Sound may provide capacity to buffer a portion of the mass transport, but sheared and bidirectional flow in Shpanberg Strait appears to be the main factor that decouples flow here from that in Anadyr Strait. Observations from outside of the Alaska Coastal Current - just downstream of Norton Sound - help show the connectivity between the estuary and the greater shelf waters. Fluxes of heat, fresh water, ice, nutrients, and carbon are all modulated by the identified flow patterns, which reflect regionally coherent dominant patterns of flow variability. Remote sensing of sea ice presence along with optical sensors from select moorings (chlorophyll *a* fluorescence, photosynthetic available radiation and nitrate) help demonstrate how these flow patterns may influence the distribution, concentration, and productivity of phytoplankton and zooplankton here. We highlight the importance of the winter advection of oceanic heat on the regional sea ice cover and thickness, and how this is potentially affecting the local ecosystem.

Introduction

The Bering Strait region is the single conduit for oceanic communication between the North Pacific Ocean and the Arctic Ocean and it serves many functions in its role in support of highly productive ecological systems, as a pathway for global shipping, in its regulation of the Pacific Arctic biological carbon pump, as a migratory corridor for protected marine mammal and seabird species, and as a home to numerous Indigenous Alaskan and Siberian coastal communities. This narrow oceanic corridor exerts defining control over the northern Bering and Chukchi sea ecosystems, but many aspects of its functioning remain unknown.

In this analysis, we examine some of the key behaviors that ocean waters take on as they approach and leave the Chirikov Basin region, we examine how some of the conditions have changed over time, and we relate these changes (both short and long-term) to the regional geomorphology, the wind forcing, and other factors that exert control on the circulation pathways. We use the description of the environmental conditions to help interpret the Chirikov Basin geochemical and biological character as documented in the ASGARD studies (refs).

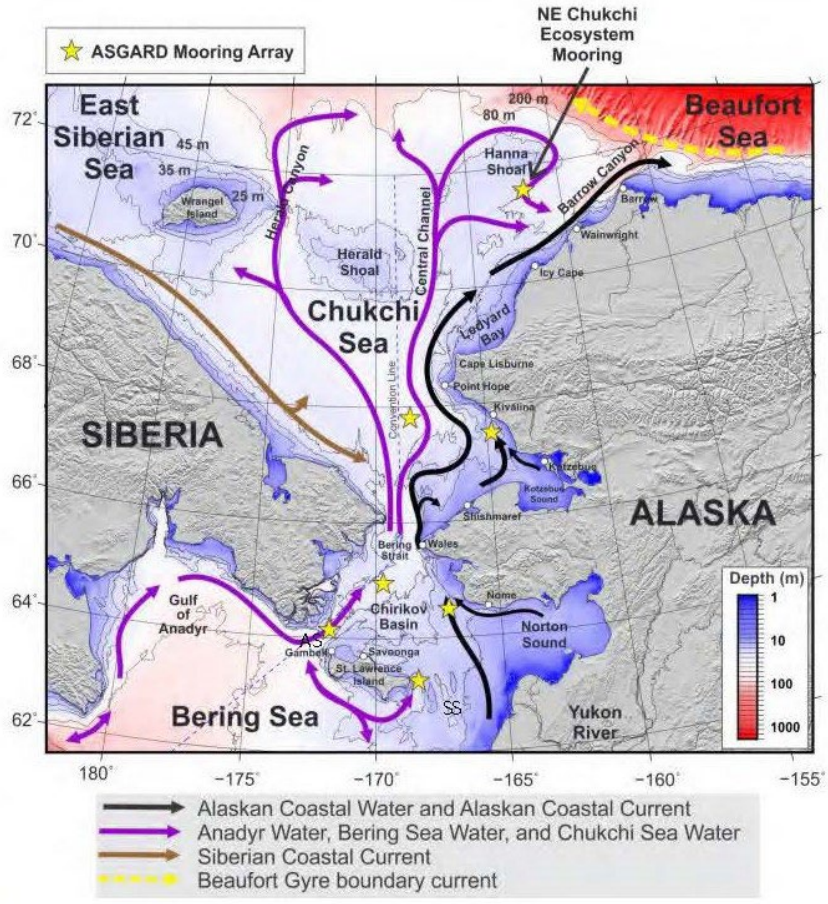

Figure 1. Map of the Bering Strait region, the location of common persistent flow fields, and moorings deployed by the ASGARD project. Abbreviations include: AS = Anadyr Strait; SS = Shpanberg Strait.

The width and depth of Anadyr, Shpanberg and Bering Straits (Figure 1) set the basic parameters of the northern Bering shelf circulation field. St. Lawrence Island separates Anadyr and Shpanberg straits on the southern side of Chirikov Basin and Bering Strait bounds Chirikov Basin to the north. Analysis of ocean circulation model results of the northern Bering Sea flow field has previously shown that the monthly-averaged flow through Anadyr and Shpanberg straits are not well coupled (Figure 1; also see discussion in Danielson et al., 2014), raising the question of how the Chirikov Basin and Norton Sound maintain mass balance and where nutrients and heat are delivered to the system. A branch of the Anadyr Current that at times extends along the southern shore of St Lawrence Island has the capacity to deliver heat and nutrient-enriched waters into Shpanberg Strait and along the east side of the St Lawrence Island, although the magnitude of the fluxes here are know well known. At the same time, structure of the flow field and its variations downstream (north) of Bering Strait are not well known, but the lateral advection of heat and nutrients and delivery to places that are biologically productive are important to reveal as we build a more complete understanding of the Pacific Arctic ecosystem.

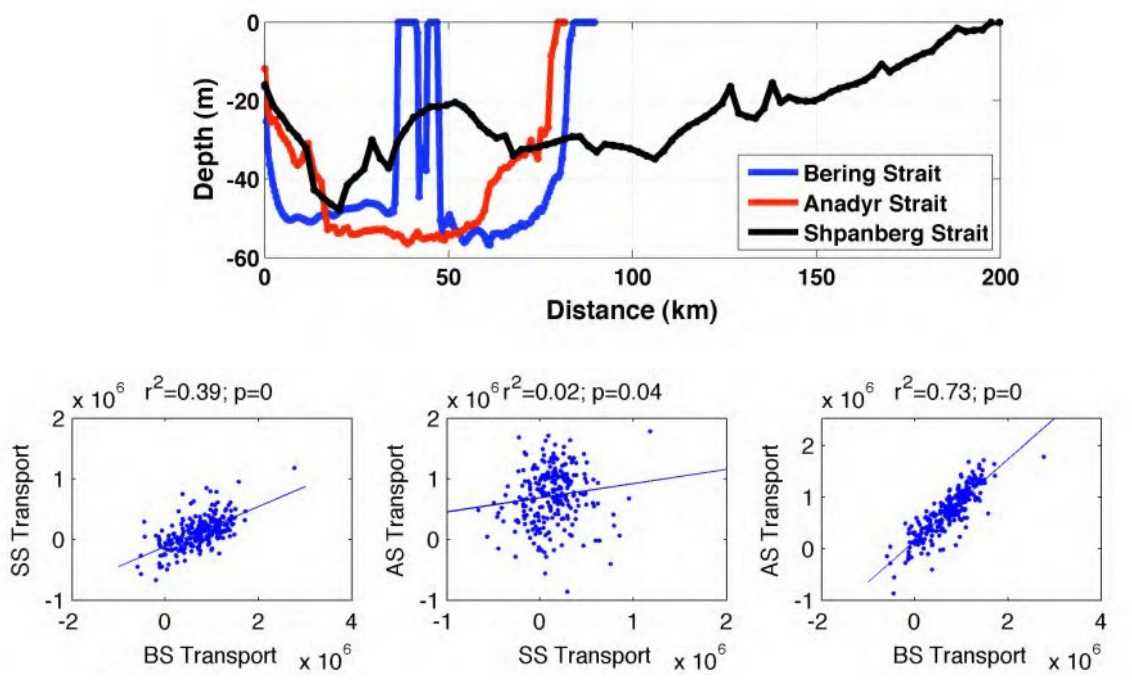

Figure 2. Top: bottom depth profiles in Anadyr (AS), Shpanberg (SS) and Bering Straits (BS). There exists little relation between the transport through Anadyr and Shpanberg straits (middle panel) even though the transport through these two straits are each significantly correlated with flow variability in Bering Strait.

Hence, in this paper we seek to analyze data and model results that will better inform our understanding of the regional flow pathways that feed Chirikov Basin, the associated heat, nutrient and carbon fluxes, and how some of these aspects have changed over time. We place the oceanographic measurements into a framework that describes linkages and co-variability between the environmental conditions, the phytoplankton, the zooplankton and fishes. The

Methods Section provides a summary of the data and numerical models used in our analyses. The Results Section examines the seasonal cycle as recorded by moored conductivity-temperature-depth (CTD) instruments. We next examine the flow field under the influence of different wind conditions, and then characterize the distributions of nutrients and full-water column conditions as measured by a suite of profiling instruments. The final Section will provide a summary and discussion of results.

Methods

Hydrography

We deployed a SeaBird 9/11 CTD at all ASGARD process and survey stations to collect water column profiles of temperature, salinity, chlorophyll-a fluorescence, dissolved oxygen, beam attenuation and photosynthetically available radiation (PAR). CTD was processed to 1- dbar pressure levels following the manufacturer's recommended automated procedures and a cast-by-cast manual inspection for removal of anomalous readings that can be caused by biofouling, deployment irregularities and various instrument problems.

We towed an undulating Acrobat ® CTD system along select transects for full water column high resolution profiles of the physical hydrography. The Acrobat ® also carried an EcoTriplett optical sensor with channels for chlorophyll a fluorescence, colored dissolved organic matter (CDOM) and optical backscatter.

Underway data

Continuously-collected underway data from the ship's science systems was archived, despiked, and compiled into 1-minute averages. These data streams include flow-through sensors connected to the seawater intake (temperature, salinity, NO_3), meteorological data streams (wind speed, wind direction, relative humidity, air temperature, surface PAR, longwave downwelling irradiance, shortwave downwelling irradiance), and ship's navigational data (heading, speed-over-ground, course-over-ground, speed- through-water, depth, latitude, longitude).

We collected and processed water column profile data from the ship's dropkeel-mounted Teledyne-RDI 300-KHz Workhorse ADCP, which provided water speed, direction, and acoustic backscatter signal strength in 4 m depth bins. The ship's EK-80 acoustic backscatter transducers and transceivers provided measurements of water column backscatter at five discrete frequencies.

Moorings

Seven bottom-anchored biophysical moorings were deployed as shown in Figure 1. All moorings had subsurface taut-wire configurations. The uppermost float on the taut-wire moorings was located at about 25 m depth to avoid drifting ice keels. All moorings had 307-KHz Teledyne-RDI Workhorse Sentinel ADCPs with bottom-tracking to measure ice motion and SeaBird SeaCat CT data-loggers with fluorometers. Including the NE Chukchi mooring at the

CEO site, select moorings were outfitted with specialized geochemical instrumentation: nitrate sensors, sediment traps, discrete water samplers, and optics (chlorophyll-a fluorescence, optical backscatter and CDOM).

We also make use of past mooring data from deployments in the 1970s and 1980s in order to help demonstrate how some aspects of the system have changed over time.

Numerical Models

We use integrations of the Alaska Region Vertically Integrated (ARVI) model, an idealized ocean circulation model that has realistic bathymetry but no density variations and forced only by wind, and the Northeast Pacific model version 6 (NEP6), a fully 3-d ice and ocean circulation model. Both models are integrated using the Regional Ocean Modeling System (ROMS) and are described, discussed and analyzed by Danielson et al. (2014) in application to the Bering-Chukchi flow field.

Results

The June 2017 to June 2018 Annual Cycle, and Comparison to the Past

Moorings N1 (east) and N2 (west) were deployed on either side of St Lawrence Island; Mooring N3 was in the Alaska Coastal Current just west of Nome, and mooring N4 was in northwestern Chirikov Basin. The annual cycle of water conditions near the seafloor at these four sites (Figure 3) helps delineate Anadyr Waters (N2 and N4: very saline) from Alaska Coastal Waters (N3: fresh) and Bering shelf waters (N1: intermediate salinity). We see that the two eastern-most moorings reached the winter freezing-point temperature in mid-January and began to warm again in mid-April. The two western moorings never stayed at the freezing point for more than a couple of weeks in a row (March) and mostly remained 1-2 degrees above the freezing point.

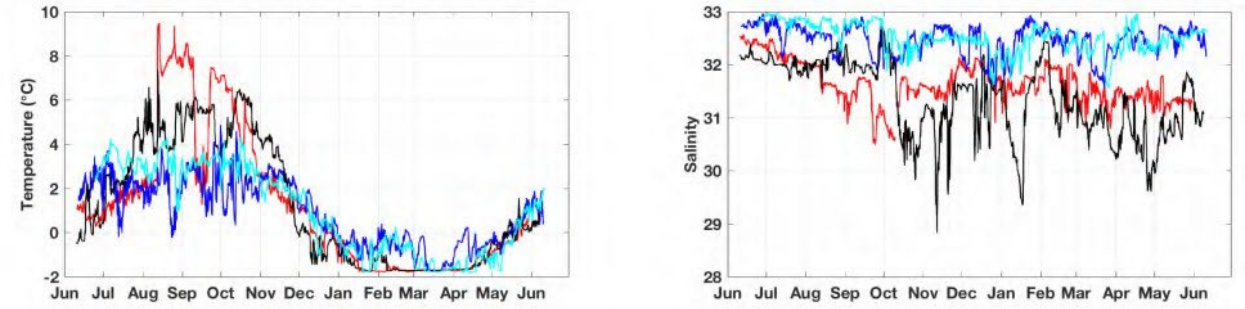

Figure 3. Near-bottom measurements from June 2017 to June 2018 at moorings N1 (red), N2 (blue), N3 (black) and N4 (cyan).

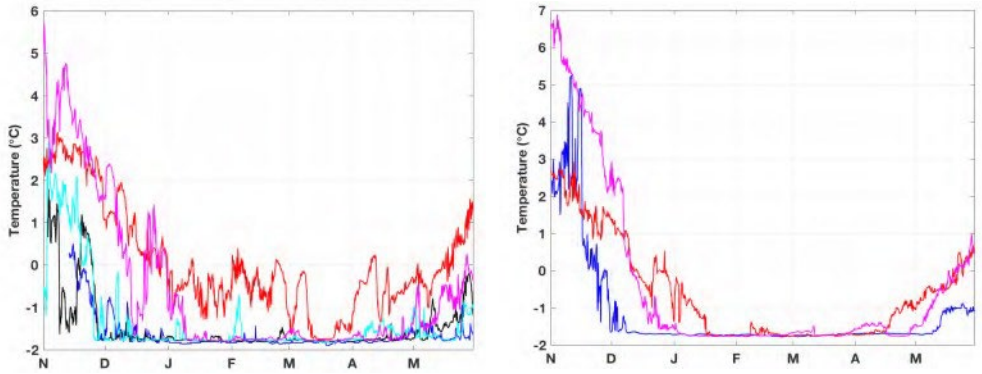

Figure 4. Left: Near-bottom temperature measured in Anadyr Strait from November (N) through May (M) in the winters of 1980-81 (blue), 1981-82 (black), 1984-85 (cyan), 2017-18 (red) and 2018-19 (magenta). Right: Near-bottom temperature measured in Shpanberg Strait from November (N) through May (M) in the winters of 1979-80 (blue), 2017-18 (red) and 2018-19 (magenta).

How has the system has changed thermally relative to past decades? Figure 4 shows fall, winter and spring temperatures measured at our mooring site N2 in Anadyr Strait (red and magenta) along with temperature records from moorings deployed in 1980, 1981 and 1984 (Schumacher et al., 1983; Muench et al. 1988). In the 1980s, the near-bottom waters had cooled to the freezing point by the end of November, and mostly remained close to freezing from mid-December until mid-May. The temperature in fall 2018 briefly cooled to near-freezing in mid-December, but did not remain near the freezing point until a week into January. Most notably, the data show that the 2017-2018 winter stands out with temperatures remaining 1-2 degrees above the freezing point for most of the winter (although March did reach the freezing point for a couple of weeks).

The Regional Flow Field

Integrations of the idealized ARVI ROMS model (Figure 3) reveal the basic change in sea level set-up and associated current fields under the conditions of 1 Sv (10^6 m3 s^{-1}) northward flow through Bering Strait for the no-wind situation (center middle panel of Figure 3) and steady, spatially invariant winds applied over the entire integration domain. We find that winds blowing to the east, southeast and south tend to enhance the eastward-flowing Anadyr Current extension on the south side of St Lawrence Island, while winds blowing to the northwest tend to reverse this flow and retard the magnitude of the Anadyr Current all along its path. We note that under all wind-forced scenarios the current velocities in Shpanberg Strait are largest near the Alaskan coastline offshore of the Yukon-Kuskokwim delta, but under the unforced wind scenario the largest currents in Shpanberg Strait are closest to the island.

Also of note is that the geochemical makeup of waters entering Chirikov Basin from the Anadyr and Shpanberg sides is not identical. Anadyr Water dominates in Anadyr Strait, while Bering

shelf water masses and even Alaskan Coastal Waters comprise those entering Chirikov Basin from Shpanberg Strait and Norton Sound.

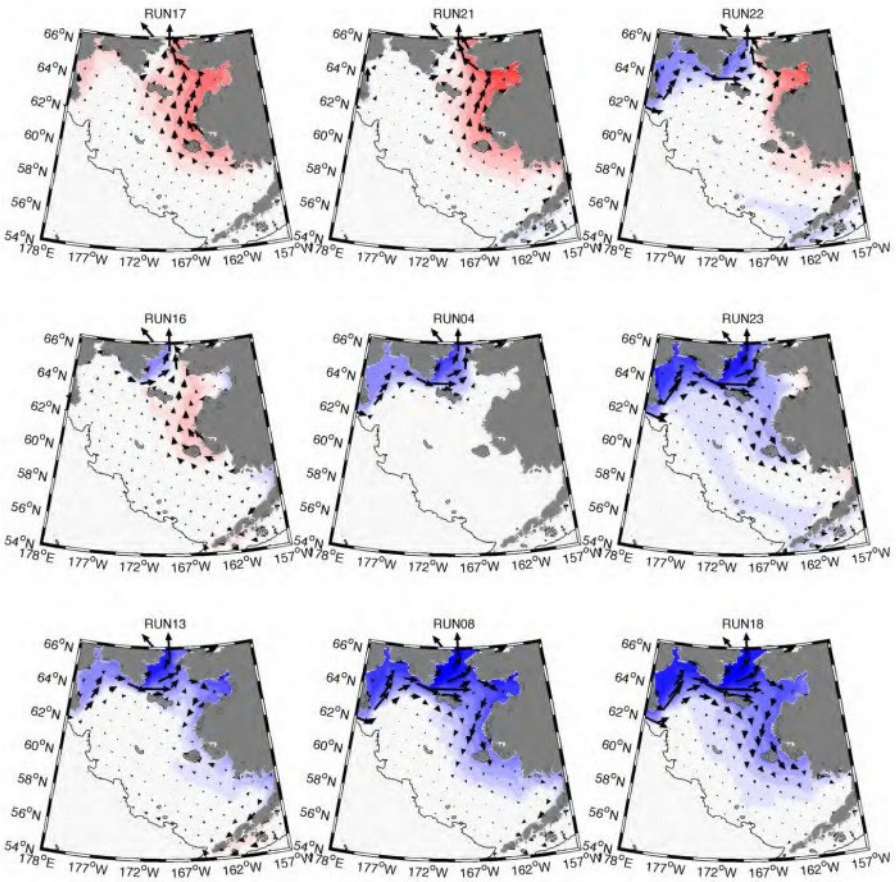

Figure 5. Steady-state circulation patterns (vectors) and associated sea surface heights (color contours) for a Bering Strait transport of 10^6 m^3 s^{-1}. Top row, left to right: wind blowing to the NW, N and NE, respectively. Middle row: wind blowing to the W, no wind, and wind blowing to the E, respectively. Bottom row: wind blowing to the SW, S and SE, respectively.

Linking physical conditions with the biogeochemistry and biology

Underway measurements of nitrate from the ASGARD cruises show that central Chirikov Basin is a zone at which high levels of NO_3 are found each time the vessel transits through. This, of course, is the signature of the Anadyr Water being mixed to the surface after its passage through Anadyr Strait, where the energetic flow is strongly turbulent. Phytoplankton productivity measurements show that Anadyr and Shpanberg Straits are regions in which the fraction of "new" nitrate fuels a large proportion of the primary productivity.

A high-resolution transect across Chirikov Basin from approximately mooring N3 to mooring N4 (Figure 7) reveals a number of key features of this region. These include the following. We note the very warm and very fresh waters adjacent to the Alaskan coast, with a strong pycnocline at less than 10 m depth. The fresh plume is associated with an elevated CDOM signal, a potential tracer of humic riverine-origin waters. The near-bottom coastal waters show the influence of the ACC, with salinities below 31. Salinities increase progressing westward, with a series of frontal systems having steeply sloping isopycnals that intersect both the surface and the bottom. In the eastern portion of the transect a subsurface chlorophyll bloom is evident but the largest bloom is

a surface-intesified peak that extends more than 20 m into the water column. Both of these chlorophyll *a* peaks are associated with dense aggregations of scatterers in the 200 kHz frequency band, a signal that was shown elsewhere on the cruise to correspond to net samples with many euphausiids.

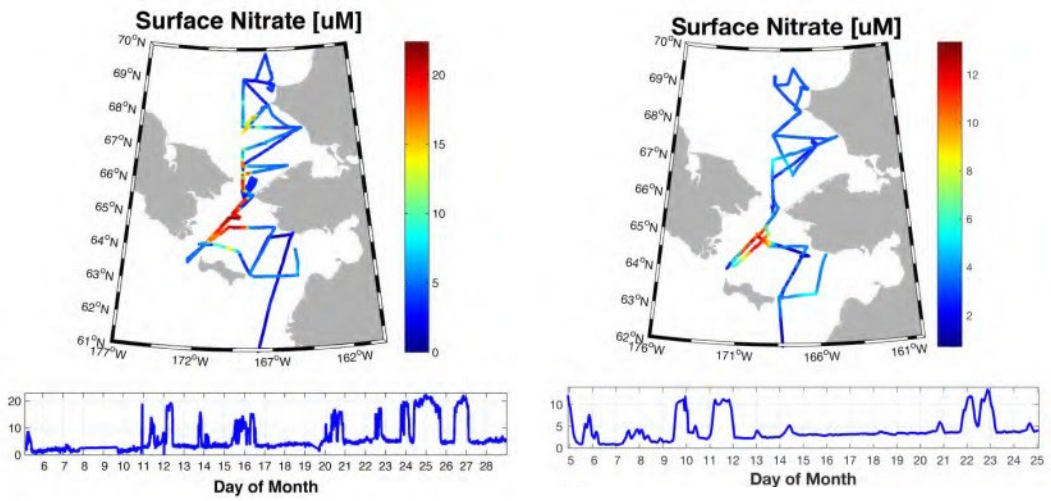

Figure 6. Underway measurements (need final calibrations) of NO_3 from the Sikuliaq's underway system in June 2017 (left) and June 2018 (right). Note elevated levels of NO_3 especially downstream of Anadyr Strait, but also north of Shpanberg Strait and Bering Strait.

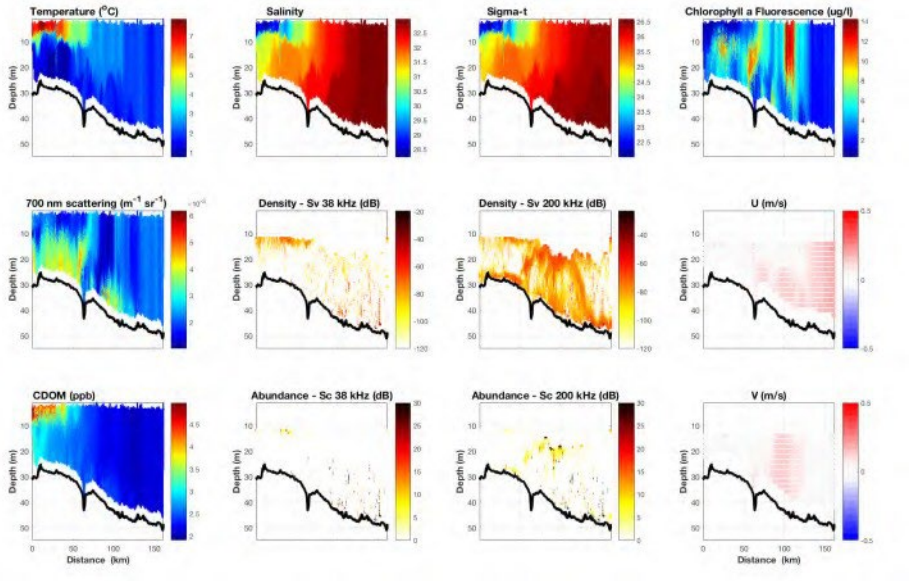

Figure 7. Water column profiles for a transect between mooring N3 (left side of panels) and N4 (right side of panels). Top row: temperature, salinity, density and chlorophyll a fluorescence. Middle row: optical backscatter, 38 kHz acoustic backscatter density, 200 kHz acoustic backscatter density, and eastward velocity. Bottom row: colored dissolved organic matter, 38 kHz acoustic abundance, 200 kHz acoustic abundance density and northward velocity.

Discussion

In contrast to prior observations that showed near-freezing waters in Anadyr Strait for many winter months, we show that 2017-2018 winter near-bottom waters advecting into Chirikov Basin were 1-2 degrees above the freezing point for all but a few weeks of time (Danielson et al., in prep.). This stark contrast in thermal flux conditions clearly was a major factor in keeping the 2017-2018 winter sea ice at such a low extent overall, and as shown by Stabeno and Bell (2019), the atmospheric conditions were favorable in this winter for maintaining these conditions.

We can identify a variety of factors that are helping set the character of the Chirikov Basin ecosystem. Chirikov Basin is a region of great ecological importance. It supports a zone massive biological productivity due to the delivery of nutrient-rich waters by the Anadyr Current, and the energetic mixing that allows this water to be brought up to the euphotic zone. This productivity feeds the seafloor community across the Chirikov Basin, but especially in the DBO-2 region. Current speeds near mooring N4 abate relative to the swifter flows found closer to shore at mooring sites N1, N2 and N3. The slower currents at N4 help allow sinking phytodetritus to reach the seafloor. Resuspension events, when they occur, are able to then deliver some of this carbon farther downstream – in the direction of the DBO-3 region that is north of Bering Strait.

Key Points:

- We use in situ and salinity-based estimates of nutrient concentrations to estimate nutrient fluxes through Bering Strait.
- We estimate annually averaged fluxes of 16±6 (nitrate), 1.5±0.5 (phosphate), and 30±11 kmol/s (silicate), ~50% larger than prior studies.
- Bering Strait nutrient flux varies by season, with largest poleward fluxes occurring in April, and weakest fluxes occurring in December.

Abstract

In situ nutrient concentration data and salinity-nutrient parameterizations established at Anadyr Strait from June 2017 to June 2018 are used to estimate monthly Pacific-to-Arctic fluxes of nitrate, phosphate, and silicate through Bering Strait over 1997-2019. In most months our estimates rely on measurements made from mooring-based sensors and whole water samples, while over May-August the basis is shipboard hydrography. We find annually averaged Bering Strait fluxes of 16±6, 1.5±0.5, and 30±11 kmol/s for nitrate, phosphate, and silicate, respectively, with inter-annual variability ±30% of the mean. Maximum fluxes occur in April, exceeding the annual average by ~50%, while minimum fluxes occur in December. Annually averaged fluxes estimated here are ~50% higher than previous estimates. Significant ($p<0.05$) increasing trends in phosphate and silicate fluxes are found over 1998-2018, but not nitrate. However, it is unclear if these trend results are due to differences in draw-down or limitations of the salinity-nutrient parameterizations.

Plain Language Summary

Nutrients flowing through Bering Strait (Pacific to Arctic) regulate the growth of Arctic plankton, which form the base of the marine food web. However, because of limited nutrient data at Bering Strait, only a few studies have attempted to estimate the size of this nutrient supply. We find that nutrients and salinity are closely related at nearby Anadyr Strait. Using those relationships and long-term mooring observations of salinity and currents at Bering Strait, we are able to estimate Bering Strait nutrient concentrations and the amount carried through the strait into the Arctic. We find strong seasonal cycles as well as significant year-to-year variability. Our estimates are about 50% higher than past studies, suggesting more Pacific-Arctic nutrient delivery than previously thought.

1 Introduction

The Arctic is experiencing rapid change (Polyakov et al. 2020), including reduced sea ice extent and volume (Wang et al. 2018), and altered growing conditions for marine phytoplankton (Lewis and Arrigo 2020), affecting Arctic marine ecosystems (Huntington et al. 2020), including iconic marine mammals and seabirds, subsistence harvests vital to Indigenous communities, and biological carbon pump dynamics.

Bering Strait is the only oceanic link between the Arctic and Pacific oceans, and is relatively narrow (~85 km across) and shallow (~50 m deep) with an annual average throughflow around 1.0 Sv (10^6 m^3/s) (Woodgate 2018). The Anadyr Current (Fig. 1a) delivers approximately 80% of the Bering Strait transport through Anadyr Strait ~250 km south of the Bering Strait (Danielson et al. 2014). The advective time between them is $\geq$ 10 days (Coachman 1993). Due to typically low nutrient concentrations on the eastern Bering shelf (Danielson et al. 2011), the Anadyr Current delivers the bulk of nutrients that are advected into the Arctic through Bering Strait, supporting remarkably high levels of pelagic and benthic biological productivity in the Pacific Arctic (Grebmeier et al. 2015).

Little prior work has evaluated Arctic-bound nutrient fluxes directly at Bering Strait. Torres-Valdes et al. (2013) used a single August 2005 cross-strait transect in combination with modeled currents to estimate annually averaged fluxes into the Chukchi Sea: 9.0±0.8, 1.3±0.1, and 20.9±2.4 kmol/s for nitrate, phosphate, and silicate, respectively. Using a three-dimensional ocean-sea ice-biogeochemical model, Zhou et al. (2021) estimated an annual flux of ~10 kmol/s of nitrate. Downstream in the Chukchi Sea, Mordy et al. (2020) found inter-annual variability in winter nitrate flux of up to 10 kmol/s during 2010-2018. Here, we provide observation-based nutrient flux estimates from a year of mooring-based measurements from Anadyr Strait (2017-2018) and long term (1997-2019) mooring observations in Bering Strait.

77

78

79 **2 Data**

80 **2.1 Shipboard Hydrography**

81 Nutrient and CTD hydrographic data (>500 vertical profiles) from ship-based observation programs
82 (April-September) in the Northern Bering and Southern Chukchi seas between 2004-2018 are used to
83 characterize regional nutrient distributions (Fig. 1a, Supplementary Table S1).

84

85 **2.2 Moorings**

86 **2.2.1 Anadyr Strait Mooring**

87 Subsurface mooring N2 was deployed in 46 m of water in Anadyr Strait (Fig. 1a) from 12 June 2017 to 9
88 June 2018 at 64.1545 °N, 174.5260 °W. N2 was equipped with SeaBird conductivity-temperature-depth
89 (CTD) dataloggers, a Teledyne RDI acoustic Doppler current profiler (ADCP), a Satlantic submersible
90 ultraviolet nitrate analyzer (SUNA), and a Green Eyes LLC Aqua Monitor discrete water sampler
91 (supplementary Table A2).

92

93 Instrumentation specifics were as follows: CTDs at depths of 25 m (SBE-16, 120 minute sampling), 35 m
94 and 41 m (SBE-37s, 15 minute sampling); an upward-looking 300 kHz ADCP at 41 m depth (30 minute
95 ensembles of 1 m bins); a SUNA V2 at 35 m depth (120 minute sampling); and an Aqua Monitor at 35 m
96 depth, which over the deployment collected twenty-five 500 mL water samples in rack-mounted IV bags,
97 each primed with 400 μL of saturated mercuric chloride solution to halt microbial activity. Following
98 mooring recovery, 60 mL subsamples were filtered (0.45 mm cellulose acetate filters) and stored frozen.
99 On shore, thawed samples were analyzed for nitrate (NO_3^-), nitrite (NO_2^-), ammonium (NH_4^+), phosphate
100 (PO_4^{3-}), and silicate (H_4SiO_4) using automated continuous flow analysis (Becker et al. 2020). Quality
101 controls are described in the archived datasets. Between 30-90 minutes after deployment, the Aqua

Monitor collected four samples to estimate repeatability. Thereafter, sample spacing was between 9-31 days (more frequently in summer).

2.2.2 Bering Strait Mooring

We use monthly estimates of Bering Strait salinity and transport (Woodgate et al. 2015, Woodgate 2018) from the long-term (1997 to present) A3 mooring (Fig. 1a), which is representative of average Bering Strait through-flow properties (Woodgate 2015). These estimates do not include contributions from the Alaskan Coastal Current (ACC), which is responsible for ~10% of the net transport but is nitrate-deplete (Danielson et al. 2017).

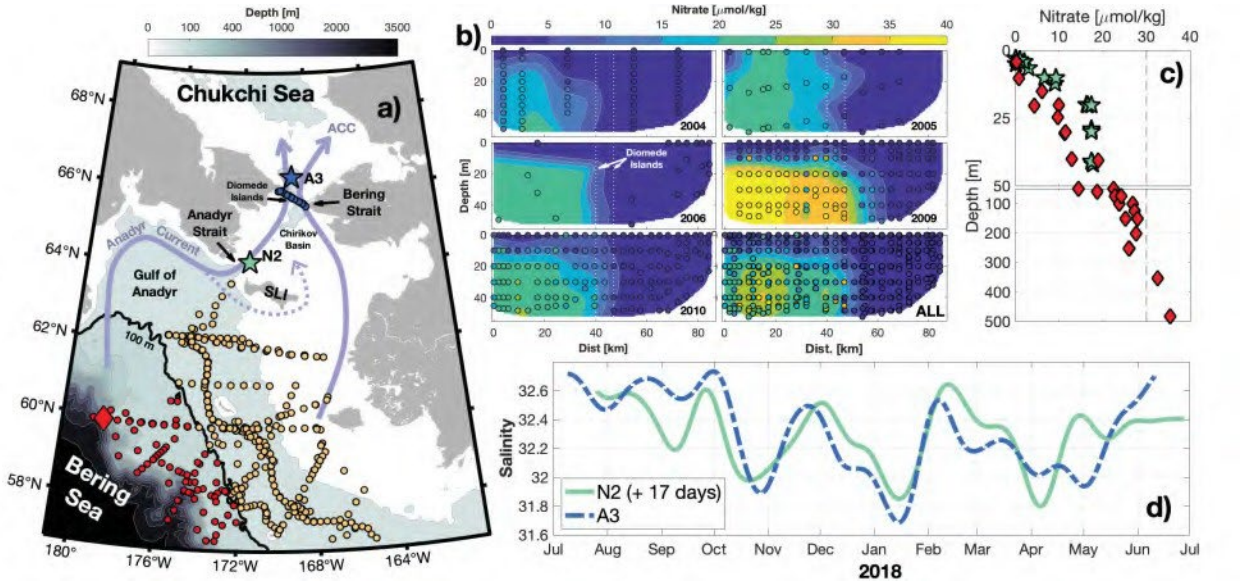

Figure 1: *a) Map of hydrography, typical flow patterns and mooring locations. Yellow/red circles are sites of hydrographic profiles collected mostly during summer from 2008-2018 (sources in Supplementary Table 1; red markers denote casts to >100 m); blue circles mark Bering Strait RUSALCA stations. Stars mark mooring sites N2 (cyan) and A3 (blue). Thick black contour is at 100 m depth. Light blue lines show nominal paths of major currents. 126
127

128 **3. Results**

129 **3.1 Nutrient Biases and Corrections**

130 Niskin bottle nutrient samples from the N2 mooring deployment and recovery cruises are used to correct
131 the SUNA and Aqua Monitor data for offsets and drift (e.g. Daniel et al. 2020). CTD profile and Niskin
132 samples (not shown) exhibit a well-mixed water column within ±10 m of the Aqua Monitor at
133 deployment, with average $NO3_{NIS}$=17.3±0.4, $PO4_{NIS}$=1.76±0.02, and $SiO4_{NIS}$=27.4±0.6 μmol/kg from 6
134 samples (± indicates 95% confidence interval hereinafter). The first four Aqua Monitor samples (from
135 just after deployment) had concentrations of $NO3_{AM}$=14.5±1.8, $PO4_{AM}$=1.94±0.11, and $SiO4_{AM}$=23.6±2.2
136 μmol/kg. These samples suggest initial Aqua Monitor biases of about -2.8, +0.18, and -3.8 μmol/kg, and
137 measurement uncertainties of 1.8, 0.1, and 2.2 (nitrate, phosphate, and silicate, respectively). Upon
138 recovery one year later, CTD profiles suggest a well-mixed water column within ±5 m of the Aqua
139 Monitor, with average $NO3_{NIS}$=12.9±0.2, $PO4_{NIS}$=1.75±0.04, and $SiO4_{NIS}$=26.8±0.8 μmol/kg from 5
140 samples, where a single Aqua Monitor sample measured $NO3_{AM}$=13.1, $PO4_{AM}$=1.92, $SiO4_{AM}$=23.6
141 μmol/kg. Aqua Monitor nutrient concentrations were adjusted assuming linear drift between deployment
142 and recovery during the yearlong occupation. The SUNA nitrate estimate bias was 4.0 μmol/kg on
143 deployment and 0.3 μmol/kg on recovery, and concentrations were again adjusted assuming linear drift.
144 Post-correction, the two measures of nitrate at mooring N2 (Aqua Monitor and SUNA) are strongly

145 correlated over the year-long deployment (root-mean-square-difference=2.3 μmol/kg, r=0.87 and p<0.01,
146 Fig. 2e).
147
148

149 **3.2 Salinity-Nutrient Relations**

150 Ship-based hydrography from across the northern Bering Sea shelf and continental slope exhibit a nearly
151 linear relationship between salinity (S_{HYD}) and nitrate ($NO3_{HYD}$) for measurements collected from >100 m
152 depth (Fig. 2a, dark grey dots), where S_{HYD}=33-34 and $NO3_{HYD}$=25-45 μmol/kg. Extrapolation of this
153 mixing line to full nitrate depletion at salinity ~31 PSU closely approximates the maximum observed
154 nitrate concentration at each salinity in the range of 31-34 (Fig. 2a), suggesting that in the absence of
155 biological nitrate drawdown, mixing between nitrate-rich slope waters and nitrate-deplete shelf waters
156 (upper 10-20 m across the eastern Bering shelf) primarily regulates nutrient concentration. While the
157 range of depths that the Anadyr Current draws its source waters from is not well known, near-bottom
158 observations of nitrate up to 30 μmol/kg in Anadyr Strait (Walsh et al. 1989) and typical vertical profiles
159 from the slope region (Fig. 1c) suggest that the core of the Anadyr Current must draw slope waters from
160 ≥100 m depth. This assumes no mixing between the region of upwelling and Anadyr Strait, so if Anadyr
161 Current waters mix with lower-salinity shelf waters during their transit to Anadyr Strait, the mean source
162 depth could be greater.
163

164 At N2, there is no significant relationship between nutrient (Aqua Monitor) and salinity (SBE37) *in situ*
165 measurements at 35 m depth (i.e., sub-pycnocline) when considering all samples together. However,
166 significant relationships emerge when data are partitioned seasonally (Fig. 2b-d). We divide mooring data
167 into three intervals that roughly map onto fall, winter and summer, respectively: September-December
168 (cooling, ice-free, decreasing light availability; magenta circles) and January-April (cold, ice-covered;

orange triangles); May-August (warming, ice-free or declining sea ice conditions, high light availability; green squares).

The moored S_{N2} data are strongly correlated with $NO3_{AM}$ from September-December (r=0.97, p< 0.01, N=5) and January-April (r=0.99, p<0.01, N=6), but are not well correlated for May-August (r=0.50, p=0.10, N=13). We attribute the difference between fall and winter regression lines to the fall season being at the end of the growing season after the nutrient inventory has experienced summer biological drawdown. The strong correlations show that for fall and winter (both weakly stratified), salinity provides a useful proxy for nitrate in the Anadyr Current.

Using SBE salinity (S_{N2}) and calibrated Aqua Monitor nitrate (Section 3.1) at mooring N2, we perform linear least squares regressions to parameterize nitrate concentration ($NO3_{EST,N2}$), i.e.,

$$NO3_{EST,N2} = C_1 S_{N2} + C_2 \qquad \text{Eq. 1}$$

C_1 and C_2 are coefficients calculated for each of the three seasonal intervals (Fig. 2b-d).

We find $NO3_{EST,N2}$ closely tracks both synoptic-scale and longer period signals captured by the SUNA nitrate sensor ($NO3_{SUNA,N2}$) during fall and winter intervals (Fig. 2f). Differences between $NO3_{SUNA,N2}$ and $NO3_{EST,N2}$ are not uniform from September-May (up to 10 μmol/kg in December). It is unclear why there is a consistent bias between $NO3_{SUNA,N2}$ and $NO3_{EST,N2}$ (average 2.5 μmol/kg), though it may point to limitations of our CTD calibrations, we note it is on the same scale as the Aqua Monitor precision (Section 3.1). The large deviation in December may be related to seasonally voluminous Alaskan river discharges in the eastern Bering Sea that subsequently advect westward (Danielson et al. 2006) carrying a different nitrate-salinity relation than found in the Anadyr Current.

194

195 As with nitrate, correlations with S_{N2} are significant ($p<0.05$) for $PO4_{AM}$ and $SiO4_{AM}$ for both September-
196 December ($PO4_{AM}$:0.92; $SiO4_{AM}$:0.91) and January-April ($PO4_{AM}$:0.92; $SiO4_{AM}$:0.99), but neither are
197 significantly correlated during May-August. Salinity-based estimates of phosphate ($PO4_{EST,N2}$) and silicate
198 ($SiO4_{EST,N2}$) are calculated in identical fashion to $NO3_{EST,N2}$ (Eq. 1).

214 **3.3 Nutrient Fluxes through Anadyr Strait**

215 Using velocity data from the N2 ADCP and the salinity-nutrient regressions (Section 3.2), we can
216 estimate nutrient fluxes through Anadyr Strait. Anadyr Strait is 73 km wide, has a median depth of 40 m,
217 and is approximately 2.7×10^6 m^2 in cross-sectional area. The major axis of sub-tidal barotropic currents
218 (from the ADCP on N2) is roughly normal to Anadyr Strait (oriented with through-flow). We take
219 currents along this axis as representative for the whole Anadyr Strait, and thus estimate volume transport
220 through the strait (T_{AS}). Our approach assumes the current is homogeneous across the strait, which seems
221 a reasonable first-order approximation given the prominent forcings of flow through Anadyr Strait are
222 large-scale (i.e. basin-scale pressure gradients). The average current current speed along the major axis is
223 39 cm/s for the year-long deployment, translating to 1.1 Sv of volume transport. This is similar to the A3-
224 based Bering Strait transport estimate for this timespan (1.3±0.3 Sv).
225
226 To estimate nutrient flux through Anadyr Strait, we combine the monthly salinity-based estimates of
227 nutrient concentration at N2 (Section 3.2) with the monthly mean volume transport, T_{AS}. Nitrate flux
228 ($F_{NO3,AS}$), for example, is defined as:
229

230 $$F_{N03,AS} = \pi_O \, T_{AS} \, N03_{est,N2} \qquad \text{Eq. 2}$$

231
232 where ρ_0 is the nominal density of Bering shelf water (1025 kg/m^3). Based on N2 ADCP measurements,
233 we further assume an unstratified water column from November-April such that salinity and nitrate

234 measurements at 35 m depth are representative of the full water column. For May-October, we assume
235 the water column is stratified and the upper 10 m of the water column is fully nitrate-deplete. Phosphate
236 ($F_{PO4,AS}$) and silicate ($F_{SiO4,AS}$) fluxes are calculated similarly.
237

238 From September, 2017 to April 2018 (when salinity-nutrient regressions are significant), average nitrate,
239 phosphate, and silicate fluxes are 17±4, 1.8±0.4, and 36±9 kmol/s, respectively. The flux uncertainties are
240 dominated by (and roughly scale with) the uncertainty of volume transport, here assumed to be ±20%,
241 since we lack sufficient *in situ* data to fully constrain Anadyr Strait transport. If summertime nutrient
242 depletion depths are 20 m (instead of 10 m assumed previously) this reduces our annually averaged
243 nutrient flux estimates by ~10%.
244

245 **3.4 Nutrient Fluxes Through Bering Strait**

246 Mooring data show that Anadyr and Bering Strait property variations are highly covariable due to their
247 strong advective connectivity (Fig. 1d). Specifically, at a 17-day lag, low-pass filtered (30-day cutoff
248 period) salinity measurements at N2 and A3 have a correlation coefficient of 0.70 and both records have
249 similar means and dynamic ranges. This modestly tight co-variability implies water is not strongly
250 modified in its transit between the straits, thus we employ the salinity-to-nutrient relationships of Section
251 3.2 to estimate nutrient fluxes at Bering Strait for past years. For this we use Woodgate 2018's estimates
252 of Bering Strait salinity and transport based on A3 mooring data (See Fig. 1a and Section 2.2.2).
253 Although monthly estimates of transport (T_{A3}) and salinity (S_{A3}) begin in 1990, early records are
254 intermittent so we focus on the continuous period of the record, starting in fall 1997.
255

256 For September-December and January-April we use the monthly salinity measured at A3 (S_{A3}) and the
257 salinity-nutrient regressions from N2 (i.e. Eq. 1) to estimate monthly concentrations for nitrate,
258 phosphate, and silicate at Bering Strait ($NO3_{EST,BS}$, $PO4_{EST,BS}$, and $SiO4_{EST,BS}$, respectively), assuming a

vertically unstratified regime. Using T_{A3} and these salinity-estimated nutrient concentrations, Eq. 2 provides nutrient flux estimates through Bering Strait ($F_{NO3,BS}$, $F_{PO4,BS}$, $F_{SiO4,BS}$). Since salinity and nutrients are not significantly correlated at N2 from May-August, we do not use salinity parameterization (Eq. 1) during these months. Instead, we use *in situ* observations from the Russian-American Long-Term Census of the Arctic Program (RUSALCA) (Crane and Ostrovskiy, 2015) to estimate the average nutrient concentrations within the strait. From a set of five separate cruises in August spanning 2004-2010, we select stations in close proximity to the strait to estimate the average Bering Strait nutrient cross-section for each year and nutrient parameter (See Fig. 1b for nitrate). For all nutrients, there is near-surface nutrient depletion across the whole strait, nutrient-rich subsurface waters from Anadyr Strait in the west, and nutrient-poor waters of the ACC in the east. We compute the mean concentration of each parameter over the entirety of the interpolated cross-sections and find averages of 10.9, 1.3, and 19.2 μmol/kg for nitrate ($NO3_{RUS,BS}$), phosphate ($PO4_{RUS,BS}$), and silicate ($SiO4_{RUS,BS}$), respectively. We use these as representative concentrations for Bering Strait from May-August. While we lack *in situ* Bering Strait data from May-July, SUNA data from N2 suggests this season is typically the least temporally variable (Fig. 2f), so averages from August (following most of the growing season's productivity) should provide a serviceable, perhaps conservative representation for the May-August interval. RUSALCA-based concentrations are subsequently coupled with A3 transports to estimate nutrient fluxes from May-August. By combining the RUSALCA-based (May-August) and salinity-based flux estimates (all other months) we construct a continuous monthly record of nutrient flux through Bering Strait from August 1997 to August 2019 (Supplementary Fig. S1). The period-of-record mean for nitrate, phosphate, and silicate fluxes are 16±6, 1.6±0.5, and 30±11 kmol/s, respectively.

Interannual variability (and uncertainty) is found to be 10-20 (~6), 1.0-1.9 (~0.5), and 18-36 (~11) kmol/s for nitrate, phosphate, and silicate, respectively (Fig. 3a-c). There are statistically significant ($p<0.05$) long term temporal trends for phosphate ($p<0.01$) and silicate ($p<0.02$), but not for nitrate ($p=0.16$) (See

manuscript submitted to *Geophysical Research Letters*

Discussion for possible bias here due to decreasing salinities in the Bering Strait). Sensitivity analysis,

where transport (T) and nutrient concentrations (C) are split into mean and anomaly terms ($T = \overline{T} + T'$, $C = \overline{C} + C'$, and nutrient flux is $T \bullet C$), shows that increasing transport is responsible for the increase in flux for phosphate and silicate ($|T' \bullet \overline{C}| > |\overline{T} \bullet C'|$), while for nitrate decreased concentrations offset the increased transport ($|T' \bullet \overline{C}| \approx |\overline{T} \bullet C|$). There is also considerable seasonal variability (Fig. 3d, Supplementary Table S2). Monthly average fluxes range between about 5±3 to 27±4, 0.7±0.3 to 2.1±0.3, and 12±5 to 50±7 kmol/s for nitrate, phosphate, and silicate respectively, with April maxima and December minima. This timing coincides with months of maximum and minimum salinity, consistent with our salinity-based parameterizations (Eq. 1).

303

304 **4. Discussion**

305 To sustain 50 g C $m^{-2}yr^{-1}$ of new production in the Chukchi Sea, MacDonald et al. (2010) estimate the
306 required Pacific inflow of dissolved inorganic nitrogen is 16.5 kmol/s, close to our estimate of 16±6
307 kmol/s. Our wintertime nitrate flux estimates at Bering Strait are also consistent with downstream
308 estimates at Icy Cape by Mordy et al. (2020), assuming ~40% of Bering Strait transport (Stabeno et al.
309 2018) reaches their central Chukchi mooring array (e.g. 6±2 kmol/s compared to 18±5 kmol/s found here
310 during February). However, our Bering Strait nutrient fluxes are significantly higher (~25-75%) than
311 those estimated by Torres-Valdes et al. (2013). The majority of the discrepancy is rooted in
312 methodological differences, with our single year, but year-round time series observations allowing a
313 seasonally-resolved approach. Torres-Valdes et al. (2013) use temporally static nutrient concentrations
314 based on one summer transect along with seasonally changing transport estimates. Torres-Valdes et al.
315 (2013) used a Bering Strait average nitrate concentration of 10 μmol/kg (August 2005), whereas our
316 annually averaged (for 1998-2018) concentration is ~16 μmol/kg, which is roughly the same fractional
317 difference between their nitrate flux estimate and that found here.
318

319 Recently, Zhou et al. (2021) used a three-dimensional ocean-sea ice-biogeochemical model to simulate
320 nitrate flux through Bering Strait from 1998-2015 and found values of ~12 kmol/s during February-May,
321 and ~8 kmol/s much of the remainder of the year. While that seasonality has loose qualitative agreement
322 with the monthly variability found here (Fig. 3d), their annual average of 9.63 kmol/s is lower than our
323 16±6 kmol/s, and we find greater seasonality (~5-25 kmol/s versus ~8-12 kmol/s). A possible explanation
324 for the discrepancy of the annual averages is that Zhou et al. (2021) found simulated nitrate

325 concentrations upstream of Anadyr Strait that were significantly lower (by ~5 μmol/kg) than *in situ*
326 concentrations, which may translate to lower Bering Strait nitrate fluxes.
327
328 We know of no long-term trends of deep water thermohaline and nutrient composition in the Bering Sea
329 basin, though the stability of the salinity-nutrient relationships over the multi-decadal period of record
330 (1998-2018) is a critical assumption for our methodology, given these relationships are only estimated
331 from the one yearlong N2 mooring deployment (2017-2018). The January-April salinity-nutrient
332 measurements from N2 are near the mixing line between deep nutrient-rich and shallow nutrient-poor
333 waters established from hydrographic data (Fig. 2a) collected up to 13 years before the N2 deployment,
334 possibly suggesting long-term stability. However, Woodgate (2018) observes a multi-decadal freshening
335 trend at Bering Strait, possibly due to glacier ablation in the Gulf of Alaska. Our salinity-nutrient
336 relationships are based on mixing between high-salinity high-nutrient Pacific Basin waters and low-
337 nutrient low-salinity shelf water, so changes over time to the shallow, low-salinity end member could
338 impact our estimates. If Bering Shelf water has become fresher (with constant nutrient content), we may
339 underestimate nutrient concentrations with our parameterizations (though we lack data to examine this).
340
341 Prominent discontinuities between estimated fluxes on either side of the summer season (Fig. 3d) mark
342 the changeover between salinity-based nutrient estimates and RUSALCA measurements used for May-
343 August, and demonstrate likely methodological limitations. There are different uncertainties associated
344 with each of the methods, but discontinuities may also partially reflect the seasonally varying nutrient
345 uptake cycle. Brown et al. (2011) estimate that 54% of the regional annual net primary production occurs
346 from May-July, so phytoplankton blooms during this interval draw down nutrient concentrations, thereby
347 reducing Arctic-bound nutrient fluxes. The northern Bering and southern Chukchi Seas are known for
348 high (250-300 g C m^{-2} yr^{-1}) phytoplankton productivity (Sambrotto et al. 1984, Grebmeier et al. 1988,
349 Springer 1988, Walsh et al. 1989). Though nutrient consumption during transit between Anadyr and
350 Bering Strait is unknown, we can crudely estimate this by assuming half the total production (~150 g C

351 m^{-2}) occurs evenly over the ~50 m deep shelf from May-July. The expected drawdown during the two-
352 week advective period from Anaydr to Bering Strait would be ~6 μmol N kg^{-1} (assuming a Redfield ratio
353 of 16N:106C), and the remainder of the year is ~2 μmol N kg^{-1}. Since our flux estimates only use Anadyr
354 salinity-nutrient relations from September-April, and nutrient concentrations during May-August are
355 based on late-summer RUSALCA observations directly at Bering Strait, we expect only modest error (~3
356 μmol N kg^{-1}) from biotic drawdown in Chirikov Basin.
357
358 The estimated nitrate, phosphate, and silicate flux in Anadyr Strait for the N2 mooring deployment period
359 over September 2017 - April 2018 was 17±4, 1.8±0.2, and 37±5 kmol/s, respectively (Section 3.3).
360 During the same interval at Bering Strait, fluxes are estimated to be higher, at 24±8, 2.5±0.8, and 52±16
361 kmol/s. Volume transport through Anadyr Strait is weaker than that through Bering Strait (~80%;
362 Danielson et al. 2014), but the nutrient delivery through Bering Strait is largely of Anadyr origin (e.g. Fig.
363 1), so the difference in nutrient flux is unlikely explained by volume transport alone. Though the
364 uncertainty ranges of the Anadyr and Bering Strait fluxes overlap, it is possible the larger mean values at
365 Bering Strait are partially due to the southern branch of the Anadyr Current, which on average flows
366 eastward along the south shore of St. Lawrence Island (Danielson et al. 2006). Thus, our Anadyr Strait
367 estimates could underestimate the total nutrient flux carried poleward from the Gulf of Anadyr. However,
368 we presently lack data to quantify this component or other sources and losses, such as benthic
369 remineralization and denitrification.
370
371 Estimates of volume transport through Bering Strait used here (Section 3.4, Woodgate 2018) do not
372 correct for ACC influences, an additional source of uncertainty. However, the fractional correction for
373 volume transport is ~10% (Woodgate, 2018), and ACC water is known for being nutrient deplete
374 (Danielson et al. 2017), so it is unlikely the ACC contributes a significant fraction of the overall nutrient
375 supply to the Arctic. These fluxes also do not include other forms of nitrogen (e.g., ammonium,

376 particulate organic nitrogen), that may be important for primary producers. While ammonium
377 concentrations are higher on the Bering Shelf (Mordy et al. 2008, 2010), they may be less important for
378 slope-derived water, such as the Anadyr Current.
379

380 Woodgate (2018) described a multi-year trend of increasing transport and declining salinity. For our
381 parameterizations this introduces competing effects, as increased volume transport favors increased
382 nutrient flux, while decreasing salinity translates to lower assumed nutrient concentration and fluxes (Eqs.
383 1, 2). Using salinity-nutrient parameterizations established at N2, we find silicate and phosphate fluxes
384 have likely increased significantly from 1998-2018, while nitrate has a weak, insignificant positive trend
385 ($p=0.16$). Though nitrate, phosphate, and silicate are all well correlated with salinity during non-summer
386 months ($r \geq 0.89$), changes in salinity correspond to a larger fractional change in $NO3_{EST,BS}$ than either
387 $PO4_{EST,BS}$ or $SiO4_{EST,BS}$ (Fig. 2 b-d). Thus, long term decreases in salinity at Bering Strait drive a decrease
388 in computed nitrate, which when combined with the increase in volume flux means $F_{NO3,BS}$ remains
389 relatively steady. Salinity variability causes less fractional change in $PO4_{EST,BS}$ and $SO4_{EST,BS}$, such that the
390 increased transport is the determining factor in long term changes of $F_{PO4,BS}$ and $F_{SiO4,BS}$ (Section 3.4).
391

392 **5. Conclusions**

393 Though we calculate significant decadal trends for phosphate and silicate, but not for nitrate, we caution
394 that these results are built upon the assumption that salinity-nutrient reletionships are static across years.
395 Verifying this is vital for validating our trend conclusions. Independent of potential decadal trends, we
396 also find that nutrient flux through Bering Strait is considerably higher than previous estimates. Torres-
397 Valdes et al. (2013) found that Bering Strait is a substantial source of annual nutrient supply to the
398 broader Arctic Ocean (21±4%, 35±6%, and 61±11% for nitrate, phosphate, and silicate, respectively).
399 Our analysis suggests Bering Strait may be a proportionally more significant source of Arctic nutrients
400 than previously appreciated.

ABSTRACT

The northern Bering and Chukchi Seas are productive high latitude ecosystems supported by tight benthic-pelagic coupling. However, warmer waters in Arctic and sub-Arctic regions are expected to alter phytoplankton community composition in the future, with unknown consequences for this critical ecosystem. Here we present the first large-scale metabarcoding survey of 18S rRNA gene diversity in this region, covering the summer of 2017 --- the warmest on record, with sea surface temperatures rising to 10°C. This report focuses on diatoms and "picophytoplankton" (operationally defined here as Chlorophyta, Haptophyta, and Chrysophyceae), which averaged 39% and 10% of the relative sequence abundance, respectively. In total, 201 diatom taxa and 227 picophytoplankton taxa were detected as exact sequence variants (ESVs) and categorized into 7 distinct diatom assemblages and 11 distinct picophytoplankton assemblages by hierarchical clustering. Investigating the potential to predict phytoplankton community composition using shipboard CTD data alone, we found that predictions of individual ESV abundance were poor, but predictions of community assemblage were somewhat better, with environmental variables explaining 44% of assemblage variability for diatoms and 32% for picophytoplankton. Among diatoms, the genera *Chaetoceros* and *Thalassiosira* combined to make up 80% of the diatom relative abundance and 43% of the diatom ESVs, while among picophytoplankton the genera *Micromonas* and *Phaeocystis* combined to make up 57% of the relative abundance and 6% of the ESVs. Based on their biogeographical distributions, we identified ESVs of *Chaetoceros*, *Pseudo−nitzschia*, *Micromonas*, and *Phaeocystis* as abundant taxa that may be negatively affected as the region warms.

INTRODUCTION

Due to an increase in anthropogenic carbon emissions, the sub-Arctic and Arctic are warming at a fast pace (Held and Soden 2006; Zelinka and Hartmann 2011), resulting in sea ice retreat, increased areas of open water, more light, and changing patterns of productivity as the Arctic shifts from a light-limited to a nutrient-limited system (Henson et al. 2013). Presently, diatoms are the dominant primary producers in the Bering and Chukchi Seas, contributing as much as 470 g C m^{-2} $year^{-1}$ (Springer and McRoy 1993), playing an essential role in Arctic biogeochemical cycles. Diatoms in the Arctic are typically large chain-forming taxa falling within microplankton (20--200 μm) size ranges or larger, which are typically associated with food webs dominated by larger copepods and an increase in biological pump efficiency due to sedimentation (Pomeroy 1974; Azam et al. 1983; Laws et al. 2000). However, because the Arctic shelves are so shallow (the Chukchi Sea shelf has a mean depth of about 40m), the amount of carbon that reaches the seafloor leads to some of the highest densities of benthic biomass in the world.

While large-celled diatoms are currently the most important primary producers in the Arctic, recent studies suggest that phytoplankton communities may shift towards mixotrophy (single cells capable of both photosynthesis and phagotrophy or osmotrophy) in response to climate change (Stoecker et al. 2017a; Stoecker and Lavrentyev 2018). Should these predictions prove correct, the decreased presence of diatoms could result in a reduced flux of carbon to the benthos. Other studies speculate that regional productivity could increase on the Chukchi shelf (Arrigo et al. 2008; JM Grebmeier 2012), with the potential to offset some excess CO_2 emissions.

Diatoms have been the dominant phytoplankton of the Bering and Chukchi seas for millennia (Moran et al. 2012; Giesbrecht et al. 2019), as shown by the presence of diatom-dominated siliceous seafloor sediment (Ran et al. 2013) dating back to the late Quaternary, when

sea level rise flooded the area (Sancetta et al. 1984). In today's ocean, Pacific waters transported northwards into the Bering Sea from depth have relatively high nutrient concentrations (Harrison et al. 2004; Pisareva et al. 2015), spurring diatom productivity (Walsh et al. 1989; Codispoti et al. 2005). Large-celled diatom taxa like *Thalassiosira* and *Chaetoceros* bloom at retreating sea ice edges in spring and early summer (Sukhanova et al. 2009) and tend to be prominent along the coast (Hill et al. 2005). In one study on the Bering Sea shelf, microplankton-sized diatoms made up about 80% of the organic carbon (Moran et al. 2012). High diversity within *Chaetoceros spp.* has been observed in the Chukchi and Beaufort seas (Balzano et al. 2017) with four distinct genetic clades reported within *C. neogracilis* using 18S and 28S rRNA gene sequencing. *Thalassiosira* and *Pseudo−nitzschia* were also prevalent throughout that study region, although *Chaetoceros* was the dominant genus. Phytoplankton blooms have also been observed under and around sea-ice, where *Chaetoceros*, *Thalassiosira*, and *Fragilariopsis* were the dominant diatoms, forming unique seawater assemblages (Arrigo et al. 2012).

Picoplankton, typically defined as plankton between 0.2 and 2.0 μm in size, (Sieburth et al. 1978), were once thought to be exclusively bacterioplankton (Platt et al. 1983). Now, many clades of (mostly) flagellated eukaryotic protists are recognized as important members of the picoplankton (Vaulot et al. 2008), and are commonly referred to as picoeukaryotes. Picoeukaryotes may be phototrophic (i.e. picophytoplankton), heterotrophic (Worden and Not 2008), or mixotrophic (McKie-Krisberg and Sanders 2014). Picophytoplankton can account for up to 90% of primary production in other marine environments (Worden et al. 2004; Jardillier et al. 2010), but in the Arctic they currently play a smaller role (McKie-Krisberg and Sanders 2014).

Prominent picophytoplankton taxa in the Arctic belong to flagellated groups including Chrysophyta, Cryptophyta, Haptophyta (Prymnesiophyta), and Chlorophyta (Stoecker and

Lavrentyev 2018). Among chrysophytes, the genera *Ochromonas* and *Dinobryon* are common and both are known to be mixotrophic (Estep et al. 1986; Andersson et al. 1989; Keller et al. 1994; McKenzie et al. 1995). In addition, *Dinobryon* forms colonies important to particle flux (Olli et al. 2002; Stoecker and Lavrentyev 2018). Cryptophytes have been identified, e.g. in the southeastern Bering Sea (Olson and Strom 2002), but rarely down to genera and species (Stoecker and Lavrentyev 2018). An exception is *Teleaulax amphioxeia*, a mixotroph (Yoo et al. 2017). The most common haptophyte in the Arctic is *Phaeocystis* (Stoecker and Lavrentyev 2018). These colonial picophytoplankton can form massive blooms, spurring seasonal production and affecting marine carbon cycling (Smith et al. 1991). Another group that is becoming increasingly recognized as important in the Arctic are the Chlorophytes, especially the genus *Micromonas*. Once thought to comprise a single species, *Micromonas* is now known to contain a diverse array of taxa (Simon et al. 2017). Laboratory experiments have also found high rates of bacterivory by *Micromonas* under oligotrophic conditions similar to those found in polar seas in the summer (McKie-Krisberg and Sanders 2014).

This study aims to establish a robust baseline of phytoplankton community composition at the molecular level, in the midst of changing sub-Arctic and Arctic environments, with a focus on diatom and picophytoplankton communities. This study is the first molecular analysis to cover such a large area over the Bering and Chukchi seas and includes hundreds of samples collected over the course of three spring and summer months (June, August, and September). To describe latitudinal changes within these communities over the Bering and Chukchi seas, we selected sites within the Distributed Biological Observatory (DBO), an established set of monitoring stations designed to study biodiversity and productivity shifts in response to global climate change (Grebmeier et al. 2010; Grebmeier 2012). Phytoplankton size, biomass, and composition are core

standardized ship-based sampling parameters of the DBO; our study adds genetic analyses for taxonomic identification of phytoplankton over time and large environmental gradients, providing insights into fine-scale seasonal community shifts of phytoplankton that are not captured by microscopy and pigment analyses.

MATERIALS AND METHODS

Sampling Sites

Seawater samples were collected during June, August, and September 2017. June sampling took place aboard *RV Sikuliaq* as part of the Arctic Shelf Growth, Advection, Respiration and Deposition Rate Experiments (ASGARD) project. August sampling took place aboard *RV Norseman II* as part of the Arctic Marine Biodiversity Observing Network (AMBON). September sampling took place aboard *USCGC Healy* as part of the DBO-Northern Chukchi Integrated Study (DBO-NCIS). ASGARD covered transects in the northern Bering Sea, across the Bering Strait, and into the southern Chukchi Sea, AMBON covered study sites in the southern and northern Chukchi Sea, and DBO-NCIS covered sites in the Chukchi Sea (Fig 1). The DBO3 line was visited on each of the three cruises, the DBO4 line was visited by the DBO-NCIS and AMBON cruises, and lines DBO1 (DBO-NCIS), DBO2 (ASGARD), and DBO5 (DBO-NCIS) were visited on one cruise each.

Fig 1: Map of sampling sites with bathymetric lines at depths of 20, 40, and 60 meters. Stations sampled during each cruise are demarcated by symbol: ASGARD (●), AMBON (▲), and DBO-NCIS (▼). Sampling type is shown in color: Hydrographic (CTD-only; *red*), Process (size-

fractionated filtering; *green*), and Survey (0.2µm filtering only; *blue*). DBO lines 1 through 5 are shown in colored boxes.

Seawater was generally collected from a subset of standard sampling depths (e.g. surface, 10, 20, 30, 40, 50, 75, 100, 125, 150, 250, 500, 1000, 2000, 3000 m) and, if present, from oceanographic features (chlorophyll maxima, pycnocline, thermocline, halocline, etc.). A median of 3 depths were sampled per station, and the modal depths per station were 5 m, 20 m, and 40 m. Seawater was collected using Niskin bottles on a rosette with an attached Sea-Bird CTD (Sea-Bird Electronics Inc., Bellevue, WA, USA).

Nutrients and Chlorophyll

For each cruise, nutrients were collected immediately after recovering the CTD with 60 mL syringes, filtered through 0.45 µm Nuclepore filters, and kept frozen below −20 °C until processed colorimetrically by autoanalyser post-cruise (Gordon, Jennings and Krest 1993). ASGARD nutrient samples were collected June 9–28, 2017, with concentrations of nitrate, nitrite, phosphate, and silicate provided. AMBON nutrient samples were collected August 7–22, 2017. DBO-NCIS nutrient samples were collected from August 28 to September 13, 2017.

Microbe and Particle Filtration

Seawater was drained from Niskin bottles into 20 L Cubitainers and stored at 4 °C until filtration using a peristaltic pump within six hours of collection. No pre-filter was used to exclude

151 macroscopic plankton. At “Survey” stations, a single 1–5 L seawater sample per depth was filtered
152 directly onto 0.2 µm-pore size Sterivex cartridge filters to collect microbes. Seawater from selected
153 “Process” stations was sequentially filtered based on size, first through a 47 mm-diameter 20 µm-
154 pore size nylon net filter, then a 47 mm-diameter 3 µm-pore size membrane filter, and finally
155 through a 0.2 µm-pore size Sterivex cartridge filter (all filters from Millipore Sigma, Burlington,
156 MA, USA). The 20 µm and 3 µm filters were folded cells-in using forceps cleaned with ethanol
157 and then placed in 2 mL microcentrifuge tubes with approximately 1 mL of RNAlater (Life
158 Technologies Corporation, Carlsbad, CA, USA). Approximately 1 mL of RNAlater was injected
159 directly into Sterivex filters prior to sealing. Filters were stored in freezers (below −20 °C) until
160 lab processing and sequencing.

161 ***CHN and SPM Analyses***

162 Precombusted 25 mm-diameter Whatman GF/F filters were used to collect particulate
163 matter for carbon, hydrogen, nitrogen (CHN) analysis and suspended particulate matter (SPM),
164 following established methods (Knap et al. 1996; Neukermans et al. 2016). For both CHN and
165 SPM samples, 500 to 1000 mL of seawater was filtered from each target depth. After filtration,
166 CHN and SPM filters were rinsed with fresh Milli-Q water to remove salts, dried at 60 °C for 12
167 hours, and stored in petri dishes until analysis. CHN filters were acidified with 10% hydrochloric
168 acid for 6 hours to remove inorganic carbon and then exposed to a standard high temperature
169 combustion technique to determine levels of carbon, hydrogen, and nitrogen in each sample at the
170 Alaska Stable Isotope Facility at University of Alaska Fairbanks’ (UAF) Water and Environmental
171 Research Center. SPM filters were massed and the original weight of the filter was subtracted and
172 divided by the volume of seawater filtered to obtain in situ concentrations.

DNA Sequencing

DNA was extracted from filters using the DNeasy PowerWater kit (Qiagen, Hilden, Germany) following the manufacturer's instructions, with the exception that prior to extraction, RNALater was expelled from the thawed Sterivex filter cartridge and the filter was rinsed with 1 mL ultrapure water. PCR-amplification of 18S rRNA genes was used for analysis of phytoplankton communities. The KAPA HiFi HotStart PCR Kit (Kapa Biosystems, Wilmington, MA, USA) was used for PCR-amplification of 18S rRNA genes. Thermocycling parameters were: one cycle at 98 °C for 1-min, 26 cycles at 98 °C for 30 s, 55 °C for 30 s, 72 °C for 30 s, and one cycle at 72 °C for five minutes. Primers used in PCR to target the eukaryotic V4 hypervariable region were TAReuk454FWD1 5'-CCAGCASCYGCGGTAATTCC-3' and TAReukREV3_modified 5'-ACTTTCGTTCTTGATYRATGA-3' (Stoeck et al. 2010). Amplified DNA was dual-indexed using unique adapters (Glenn et al. 2016) before TruSeq library preparation and sequencing on an Illumina MiSeq in the UAF DNA Core Lab. Sample counts and mean reads per sample are shown in Supplementary Table 1. DNA sequences have been submitted to GenBank under accession number SUB8918463.

Data Analysis

Oceanographic data was visualized in Ocean Data View (Schlitzer 2016) and in R (R Core Team 2013). Water mass definitions (Pisareva et al. 2015) were used with the addition of an extra water mass extending from 6 °C to 14 °C, denoted "WACW" here for "Warm Alaska Coastal Water". For some analyses and visualizations, samples were grouped by depth, with all samples taken between 0 and 7 m considered 'surface', all samples taken within 10 m of the seafloor considered 'bottom', and samples from depths in between denoted 'midwater'.

195 Bioinformatics and statistical analyses were carried out in R. After sequencing, samples
196 were demultiplexed and primers were removed using cutadapt v2.8 (Martin 2011). Exact sequence
197 variants (ESVs) were called using DADA2 (divisive amplicon denoising algorithm 2), an open
198 source R package (Callahan et al. 2016) that performs quality control, error correction, merging,
199 chimera checks, and taxonomic classification using SILVA database v132 (Quast et al. 2012).
200 Samples with less than 3000 quality-controlled reads were omitted, resulting in the removal of
201 about 12% of samples. For taxonomic group analyses, "diatoms" were defined as all ESVs that
202 were classified to the class Diatomea, and "picophytoplankton" were operationally defined as all
203 ESVs that were classified to the groups Chlorophyta, Haptophyta, or Chrysophyceae. Open source
204 scripts implementing sequence analysis and visualization are available at
205 https://github.com/rec3141/microscape, and scripts to generate the plots and tables found in this
206 manuscript are available at https://github.com/rec3141/rml_thesis.
207 Diatom and picophytoplankton relative abundance tables were subjected to fourth-root
208 transformation before clustering (using 'ggplot2', 'gplots', and 'heatmap.plus' packages for R). A
209 table of Bray-Curtis dissimilarities was calculated from the transformed relative abundance matrix,
210 and samples were hierarchically clustered using Ward's minimum variance method.
211 Canonical Correspondence Analysis (CCA) finds response variables that are maximally
212 related to linear combinations of the explanatory variables provided. In this study we used taxa
213 relative abundances as response variables and the following metadata and environmental
214 parameters as explanatory variables: day of year, depth, bottom depth, distance to shore, latitude,
215 longitude, temperature, salinity, fluorescence, and dissolved oxygen. These parameters were
216 chosen because they can be obtained in situ via shipboard data streams and during a CTD cast.
217 Using the R package 'vegan' (Oksanen et al. 2019), CCA was performed across taxonomic subsets

of the relative abundance tables. In addition to ESVs, diatom and picophytoplankton communities were analyzed after aggregation to the taxonomic levels of genus and family to explore patterns of community composition at higher taxonomic levels.

RESULTS

Environmental Conditions

During the ASGARD expedition in June 2017, sampled surface water temperatures ranged from 1.1 °C to 10.9 °C, with the warmest water consistently above 6 °C appearing south of Nome (Fig 2). Beneath the surface, sampled water temperatures ranged from −1.4 °C to 7.3 °C. Water masses present at the time of sampling included Alaskan Coastal Water (ACW), Bering Shelf Water (BSW), and Remnant Winter Water (RWW; Fig 3). Concentrations of chlorophyll a were highest during June, with an average across sampled stations of 2.8 mg m^{-3}; surface waters averaged 2.8 mg m^{-3}, midwater depths 3.8 mg m^{-3}, and bottom depths 1.7 mg m^{-3}. The highest concentration observed was 26.2 mg m^{-3} at 3 m depth at station DBO3.6.

Fig 2: Sea surface temperature (°C) at each sampling site for each cruise in the northern Bering and Chukchi seas during the spring and summer of 2017. Values were gridded using weighted-average gridding in ODV. From left to right: ASGARD (June 9–29), AMBON (August 7–22), and DBO-NCIS (August 28–September 13)

Fig 3: Temperature-Salinity plots of water sampled in the northern Bering and Chukchi seas during the 2017 cruises overlaid with environmental metadata: (A: upper left) water mass designations; (B: upper right) total nitrate (μM; NO_3^{2-} + NO^-); (C: lower left) dissolved oxygen (μmol/kg); (D: lower right) chlorophyll fluorescence (mg m^{-3}; from the CTD fluorometer).

During the AMBON cruise in August, sampled surface seawater temperatures ranged from 3.8 °C to 10.1 °C, with subsurface temperatures ranging from −0.2 °C to 9.9 °C (Fig 2). Water masses encountered were the ACW, BSW, and RWW (Fig 3). Concentrations of chlorophyll a were lower during August sampling, averaging 1.4 mg m^{-3} across all samples and depths, 1.1 mg m^{-3} at the surface, 1.6 mg m^{-3} at midwater depths, and 1.2 mg m^{-3} at bottom depths. The highest concentration observed was 7.9 mg m^{-3} at 32 m depth at station DBO4.6.

During the DBO-NCIS cruise in late August–early September, sampled surface seawater temperatures ranged from 1.8 °C to 7.5 °C, with subsurface temperatures ranging from −1.7 °C to 8.6 °C (Fig 2). Water masses encountered included ACW, Atlantic Water (AW), ACW, BSW, Melt water/river water (MWR), RWW, and Winter water (WW; Fig 3). Across the Chukchi shelf, strong winds from the east drove upwelling through Barrow Canyon and even reversed the ACW, detectable at lines DBO3, DBO4, and DBO5. Concentrations of chlorophyll a were the lowest of the three cruises, averaging 0.8 mg m^{-3} across all samples and depths; mean values of 1.1 mg m^{-3}

were observed at the surface, 0.7 mg m^{-3} at midwater depths, and 0.9 mg m^{-3} at bottom depths. The highest concentration observed was 5.8 mg m^{-3} at 33 m depth at station W-4.

Taxonomic Diversity

Overall Structure

Eukaryotic microbial communities in the Bering Strait and Chukchi Seas during the open water season of 2017 were assigned (bootstrap support > 60%) to 35 Phyla and 58 Classes. The 7 most abundant Phyla (as classified using SILVA) made up 93% of the relative sequence abundance across all samples: Ochrophyta (39.8%, primarily Diatomea and Chrysophyta), Dinoflagellata (24.6%, mostly mixotrophic taxa), Ciliophora (8.0%), Protalveolata (6.4%, primarily Syndiniales), Chlorophyta (5.2%, primarily *Mamiella*les), Chytridiomycota (4.8%), and Prymnesiophyceae (4.4%). Overall, the groups we defined as "picophytoplankton" made up 10.0% of the relative sequence abundance across all samples.

Despite an opportunistic sampling scheme that resulted in spatiotemporal heterogeneity of sampling sites and little direct overlap among cruises, the dominance of diatoms was particularly consistent over the course of the season, with mean relative abundances of 36.0 ± 0.1% across cruises. Chlorophyta also remained fairly consistent over the summer at 4.8 ± 0.7% across cruises. Prymnesiophyceae (i.e. Haptophytes) reached maximal relative abundances in June (8.2%) but were nearly absent in September (0.5%). The dominant mixotrophs and heterotrophs (Dinoflagellata and Ciliophora, respectively) reached maximal relative abundances in August (27.6% and 11.3%, respectively). Among parasites, *Sydiniales* represented 1.0% of the mean relative abundance in June and 9.6% in September (with high spatial variability), while the Chytridiomycota exhibited the opposite pattern with maximal relative abundances in June (6.5%) and minimum in September (1.1%).

278

279 *Size Structure*

280 Picophytoplankton, generally defined as single-celled eukaryotes that are less than 2.0 μm
281 in diameter, were operationally defined here as all taxa that were classified to the taxonomic groups
282 Chlorophyta (green algae), Haptophyta, or Chrysophyceae (golden algae, with the Ochrophyta).
283 While size does not necessarily correlate with taxonomy, we found that these flagellated cells
284 generally fell into the expected size range, with the prominent exception of *Micromonas* ESV 20,
285 which was found frequently on 20 μm filters (Supp Fig 1). This abundant organism may have
286 fallen prey to larger protists that were captured on the large filter. Some picophytoplankton taxa
287 are known to be able to form colonies (e.g. *Phaeocystis*), but these taxa were quite rare on 20 μm
288 filters, suggesting they were free-living (or easily disaggregated) in the study region. The
289 remainder of this manuscript will focus only on results from the "Survey" stations, which were not
290

291 size-fractionated prior to filtration onto 0.2 μm filters.

292

Diversity within Genera

293 A significant positive correlation was observed between genus relative abundance and ESV
294 richness for diatoms ($N=25$, $p<<0.001$, Spearman correlation) but not for picophytoplankton
295 ($N=16$, $p>0.05$, Spearman correlation). In diatoms, the genera with the highest relative abundances
296 (*Chaetoceros*, *Thalassiosira*) also had the highest diversity at the ESV level (43 and 44 ESVs,
297 respectively).

298

Diatoms

Diatom taxa were classified to 5 families, 25 genera, and 201 unique ESVs, which were used as molecular proxies for species (or lower) level taxonomy (Table 2). The most prominent family was Mediophyceae (88% diatom relative abundance) with the other families contributing from <1% to 6% of the diatom relative abundance. Multiple genera represented the families Mediophyceae (9), Bacillariophyceae (9), and *Fragilaria*les (3), while only 2 genera each were found within the Melosirids and Rhizosolenids (Table 2). The distribution of diatom proportions was highly skewed, with only 14 ESVs making up 80%, 26 ESVs making up 90%, and 99 ESVs making up 99% of the cumulative relative abundance (Supp Fig 2).

Chaetoceros was the most common diatom genus across all depth bins (48–71%) followed by *Thalassiosira* (15–26%). Other genera ranged from <1–6% at all depths. Some prominent diatom ESVs were putatively identified to species using best BLAST hits, including ESV 2 (*Chaetoceros socialis* complex) and ESV 19 (*Chaetoceros diadema*).

317 Table 2: Diatom taxonomy list for the northern Bering and Chukchi seas cruises during 2017 using
318 a taxonomic bootstrap cutoff of 60%. Taxonomy follows SILVA v132.

320

321 *Picophytoplankton*

322 Picophytoplankton taxa were classified to 3 kingdoms and 16 genera, with 227 unique
323 ESVs (Table 3). Multiple genera represented Chlorophyta (8) and Haptophyta (7), while only 1
324 was identified in Chrysophyceae. The most prominent ESVs (Table 3) were within the
325 Chloroplastida (52% picophytoplankton relative abundance), followed by Haptophyta (42%), and
326 Chrysophyta (6%). The distribution of picophytoplankton proportions was highly skewed, with

only 9 ESVs making up 80% of the total, 23 ESVs making up 90%, and 99 ESVs making up 99% of the cumulative relative abundance (Supp Fig 3).

Among the picophytoplankton were well-known genera like *Bathycoccus*, *Micromonas*, *Mamiella*, *Chrysochromulina*, *Phaeocystis*, and *Nannochloris* (Lovejoy et al. 2006; McKie-Krisberg and Sanders 2014). *Micromonas* was the most common genus in the picophytoplankton assemblage, comprising 36% of the picophytoplankton sequences at the surface, 36% in midwater depths, and 24% at the bottom. *Phaeocystis* was the second most common genus with 20% relative abundance at the surface, 19% at midwater depths, and 38% at the bottom, followed by *Chrysochromulina* which comprised 11%, 10%, and 8% of picophytoplankton sequences in the surface, midwater, and bottom, respectively. All other identified genera varied from <1 to 3% across all depths. Prominent picophytoplankton ESVs that were putatively identified to species level using best BLAST hits included ESV 20 (*Micromonas pusilla*), ESV 31 (*Phaeocystis pouchetii*), and ESV 188 (*Bathycoccus prasinos*).

While many of the top ESVs for diatoms and picoeukaryotes were easily identified, numerous others did not have good matches to sequences in the database used for taxonomic identification. Future studies should work to identify these sequences using cultured representatives that might also be identified in older studies based on morphological data.

Community Clustering

Diatom Assemblages

Samples were categorized into seven assemblages (D1–D7) based on hierarchical clustering of diatom community composition, with 32–140 samples per cluster (Table 4). The sample assemblages separated into two major branches, defined primarily by the relative abundance of *Chaetoceros* ESV 2, which was singularly dominant in clusters D1 and D2, while of varying importance in D3–D7 (Fig 4). Of the clusters with abundant *Chaetoceros* ESV 2, its relative abundance increased from D4 (16%) to D6 (23%) to D7 (31%) to D2 (58%) to D1 (96%). Cluster D3 was highly diverse, with no single dominant ESV. Compared to other clusters, D3 had relatively high proportions of unknown taxon ESV 56 (8%) and *Skeletonema* ESV 336 (4%).

Fig 4: Hierarchical clustering of samples based on diatom community composition from the northern Bering and Chukchi seas cruises during 2017. (a) The dendrogram shows the relationships among the clusters (D1—D7) and number of samples categorized to each. (b) Barplots show the relative abundance of the top 90% most abundant ESVs in each assemblage. (c) The color legend shows the taxonomic identification of each ESV, with numbers in brackets indicating taxonomic bootstrap support for the genus label, and numbers in parentheses indicating the mean relative abundance of that ESV across all samples in parts per thousand.

Cluster D6 was the only cluster to have a majority of *Thalassiosira*, dominated by ESV 85 (27%), unknown taxon ESV 453 (12%), and unknown taxon ESV 389 (8%). Cluster D2 had a higher proportion of *Thalassiosira* ESV 104 (16%) compared to any other cluster. Cluster D4 was distinguished by higher concentrations of unknown taxon ESV 323 (12%; tentatively assigned to *Nitzschia*) and *Chaetoceros* ESV 27 (12%) than any other cluster. Cluster D5 was characterized by high proportions of *Chaetoceros* ESV 19 (27%), which was commonly found throughout the study region, and ESV 246 (20%; tentatively assigned to *Helicotheca*), and ESV 56 (5%; tentatively assigned to *Guinardia*), which were not.

Table 4: Hierarchical clustering of samples based on diatom community composition (D1-D7) from the northern Bering and Chukchi seas cruises during 2017. Numbers of samples per cluster are shown for each cruise and depth bin. Within each cruise and depth bin, the most frequent cluster is shown in bold.

Project	Depth Bin	D1	D2	D3	D4	D5	D6	D7
ASGARD	surface	2	2	3	12	0	7	**32**
ASGARD	midwater	3	3	1	10	0	16	**32**
ASGARD	bottom	0	1	3	10	0	9	**34**
AMBON	surface	1	1	**33**	1	14	0	1
AMBON	midwater	3	4	**66**	6	18	0	17
AMBON	bottom	1	5	**22**	0	1	0	13
DBO-NCIS	surface	**11**	10	1	0	0	0	1
DBO-NCIS	midwater	47	**55**	6	2	0	0	5
DBO-NCIS	bottom	**22**	1	1	0	0	0	5

Each cluster was composed of samples originating from a range of environmental conditions, with D3 standing out as having a particularly high median temperature (7 °C), D1 having relatively high nutrient concentrations, and D4 and D5 having relatively low nutrient concentrations (Fig 5). Cluster D3 was found in the largest range of environmental conditions, from –1 to 11 °C and from salinities of 25 to 35. Cluster D6 had the lowest temperature range, from 2 °C to 5 °C.

394

395 Fig 5: Distribution of temperature (above) and silicate concentrations (below) from samples in
396 each diatom assemblage cluster (D1–D7), colored by water mass for the northern Bering and
397 Chukchi seas cruises during 2017.

398

399 D7 was the most frequently observed cluster during the ASGARD cruise (54% of samples;
400 Table 4; Fig 6), followed by D4 and D6 (18% each). D7 was prominent throughout the Bering
401 Strait region, with the exception of the DBO3 line off the coast of Point Hope, AK, where
402 *Thalassiosira*-rich cluster D6 was common. A surface bloom was apparent at the western-most
403 station of that transect, indicated by elevated chlorophyll fluorescence (>12 mg m^{-3}). D7 was again
404 common along the northernmost transect sampled during June (Fig 6), where fluorescence values
405 were lower (<3 mg m^{-3}).

406

407 Fig 6: Spatiotemporal trends in diatom community assemblages from the northern Bering and
408 Chukchi seas cruises during 2017.

409

410 D4 and D6 occurred overwhelmingly in June (87% of all occurrences) and were mostly
411 confined to the Bering Strait region (Fig 6), where chlorophyll fluorescence values were relatively
412 high; they appeared proportionally across surface, midwater, and bottom depths (Fig 6). D4
413 appeared in coastal zones both north and south of the Bering Strait, whereas D6 appeared only in
414 a patch in the central channel offshore of Point Hope (Table 4; Fig 4; Fig 6).

415 During the AMBON cruise in August, D3 was the most common cluster, occurring 58%
416 of the time (Table 4), followed by D5 (16%), and D7 (15%). Cluster D5 was observed exclusively

during the AMBON cruise, primarily in surface waters of an offshore transect crossing Hanna Shoal (Fig 6). Cluster D7 was still common, but found almost exclusively at midwater and bottom depths, potentially indicating a sinking *Chaetoceros* bloom (Table 4; Fig 5; Fig 6).

During the DBO-NCIS cruise in late August and September, clusters D1 (48%) and D2 (40%) were most prominent. Both the overall diversity and chlorophyll fluorescence values were lower during this cruise, with most samples dominated by *Chaetoceros* ESV 2 (Table 4; Fig 5; Fig 6).

Picophytoplankton Assemblages

Samples were categorized into eleven assemblages (P1–P11) based on hierarchical clustering of picophytoplankton community composition, with 16–86 samples per cluster (Table 5, Fig 7). The sample clusters split first between P1–P3 and P4–P11, followed by a second major split between P4–P7 and P8–P11; these divisions roughly reflect the seasonality/cruise schedule.

Clusters P1 and P4 were both characterized by very low diversity (Fig 7), dominated by *Micromonas* ESV 20 (78%) and *Phaeocystis* ESV 31 (81%), respectively. *Micromonas* ESV 20 also made up major portions of the picophytoplankton diversity in P2 (36%), P3 (32%), P5 (35%), P6 (15%), P7 (15%), P9 (29%), P10 (49%), and P11 (14%). *Phaeocystis* ESV 31 was also an important contributor to P5 (43%), P7 (37%), P10 (6%), and P11 (28%).

Fig 7: Hierarchical clustering of samples based on picophytoplankton community composition from the northern Bering and Chukchi seas cruises during 2017. (a) The dendrogram shows the relationships among the clusters (P1—P11) and number of samples categorized in each. (b) Barplots show the relative abundance of the top 90% most abundant ESVs in each assemblage. (c) The color legend shows the taxonomic identification of each ESV, with numbers in brackets indicating taxonomic bootstrap support for the genus label, and numbers in parentheses indicating the mean relative abundance of the ESV across all samples in parts per thousand.

Other taxa that contributed to distinguishing clusters include *Bathycoccus* ESV 188 (P8: 17%), *Nannochloris* ESV 277 (P3: 54%), *Chrysochromulina* ESV 297 (P10: 17%), *Chrysochromulina* ESV 307 (P11: 18%), ESV 659 (P9: 37%; possibly *Uroglena*), ESV 665 (P7: 15%; possibly *Chrysochromulina*), ESV 748 (P6: 19%; possibly *Chrysolepidomonas*), ESV 760 (P8: 15%; unidentified), *Chrysochromulina* ESV 840 (P9: 12%), and *Prasinoderma* ESV 1381 (P2: 23%).

Each cluster was composed of samples originating from a range of environmental conditions, with P8 standing out as having a particularly high median temperature, P2 and P6 for having relatively high nutrient concentrations, and P8 and P9 for having relatively low nutrient concentrations.

Table 5: Hierarchical clustering of samples based on picophytoplankton community composition (P1-P11) for the northern Bering and Chukchi seas cruises during 2017. Numbers of samples per cluster are shown for each cruise and depth bin. Within each cruise and depth bin, the most frequent cluster is shown in bold.

Project	Depth Bin	P1	P2	P3	P4	P5	P6	P7	P8	P9	P10	P11

DBO-NCIS	midwater	34	13	**37**	5	7	0	1	3	1	1	1
DBO-NCIS	bottom	1	**11**	4	2	3	1	0	0	0	0	0

Picophytoplankton spatiotemporal distributions

The three primary splits in the picophytoplankton assemblage clustering roughly reflected the seasonality of the cruise that the samples were collected on (Table 5), with P1–P3 composed primarily of samples from DBO-NCIS (90%), P4–P7 mostly from ASGARD (63%), and P8–P11 mostly from AMBON. However, P6 was an exception to this trend (95% collected on AMBON), as was P11 (74% collected on ASGARD).

During the ASGARD cruise in June, *Phaeocystis*-rich clusters P4, P5, P7, and P11 occurred 94% of the time (Table 5). Cluster P11 was prominent throughout the Bering Strait, while P4 and P7 appeared more frequently at the edges of P11 along the central channel, and P5 appeared more often closer to the Alaskan coast

During the AMBON cruise in August, picophytoplankton communities were *Phaeocystis*-poor (Table 5), with diverse clusters P8 (38%) and P6 (20%) becoming common (Fig 8), along with *Micromonas*-rich P10 (15%). Clusters P8 and P10 were widely distributed across the Chukchi Shelf, and about 10 times as common at surface and midwater depths than at the bottom (Table 5; Fig 8; Fig 9). Cluster P10 was particularly prevalent in the channel between Wainwright and Hanna Shoal, and was not found at the warm, fresh coastal sites, which were primarily affiliated to P8. While cluster P6 was common across the central Chukchi Shelf, it was never observed near shore, and was found at midwater and bottom depths 94% of the time (Table 5; Fig 8; Fig 9).

Fig 8: Distribution of temperature (*above*) and phosphate concentrations (*below*) from samples in each picophytoplankton assemblage (P1–P11), colored by water mass, from the northern Bering and Chukchi seas cruises during 2017.

Fig 9: Spatiotemporal trends in picophytoplankton community assemblages for the northern Bering and Chukchi seas cruises during 2017.

During the DBO-NCIS cruise in late August and September, the *Phaeocystis*-rich clusters were again absent, as were the diverse clusters P8 and P10 (Table 5). In their place were clusters

P1 (28%, rich with *Micromonas* ESV 20), P3 (33%, rich with *Nannochloris* ESV 277), and P2 (17%), similar to P1 with the addition of *Prasinoderma* ESV 1381 (Table 5; Fig 8; Fig 9).

Environmental Drivers of Community Variability

The ability to predict microbial communities in Arctic seawater in real time while aboard ships would be a valuable tool. To test our current ability to make such predictions, we restricted the analysis of environmental drivers to those parameters that are readily available at sea, i.e. those available during a CTD cast: day of year, sampling depth, bottom depth, distance to shore, latitude, longitude, temperature, salinity, fluorescence, and dissolved oxygen. Exploratory analyses including additional explanatory variables (e.g. SPM, CHN, nutrients) did not display marked improvements in predictions (not shown).

Aggregation by Taxonomy

In general, diatom and picophytoplankton relative abundances were not easily predictable based on metadata or environmental variables available at the time of sampling (Fig 10). After aggregating at the ESV, Genus, and Family levels, no linear combination of environmental parameters explained more than 12.6% of variability within diatom communities or 19.7% in picophytoplankton (Table 6).

Fig 10: Diatom (*left*) and picophytoplankton (*right*) sample assemblages overlaid on temperature-salinity plots for the northern Bering and Chukchi seas cruises during 2017.

Table 6: Proportion of constrained variability captured by selected environmental variables for the northern Bering and Chukchi seas cruises during 2017.

	Diatoms	**Picophytoplankton**
Family	11.6%	19.7%
Genus	12.6%	14.2%
ESV	12.5%	7.4%
Cluster	43.6%	32.5%

For diatom ESVs, the first two CCA axes contributed 47% of the inertia (Supp Fig 4), driven primarily by day of year and salinity, respectively. At the genus level, the first two axes contributed 61% of the inertia, driven primarily by temperature and day of year, respectively. At the family level, the first two axes contributed 99% of the inertia, driven primarily by temperature and distance to shore, respectively.

For picophytoplankton ESVs, the first two CCA axes contributed 44% of the inertia (Supp Fig 4), driven primarily by day of year and temperature, respectively. At the genus level, the first two axes contributed 59% of the inertia, driven primarily by day of year and dissolved oxygen, respectively. At the family level, the first two axes contributed 68% of the inertia, driven primarily by day of year and distance to shore, respectively.

Analysis of variance (ANOVA) was used to determine the significance of each environmental parameter in explaining the variability in relative abundance of taxa (Supp Fig 4). For diatoms, the number of significant ($p < 0.05$) parameters decreased from ESV (9/10) to genus

(8/10) to family (5/10). For picophytoplankton, 9/10 parameters were significant at each taxonomic level.

Aggregation by Cluster

CCAs were also performed on communities that were aggregated by community assemblage. To aggregate by sample cluster (D1–D7 in diatoms, P1–P11 in picophytoplankton), the relative abundance of each taxon in each sample was replaced by the mean relative abundance of that taxon in the samples within the sample cluster prior to CCA analysis.

Significant improvements in explaining community variability were detected after aggregating by cluster: 43.6% in diatoms and 32.5% in picophytoplankton (Table 6). For diatom clusters, the first two CCA axes contributed 83% of the inertia, driven primarily by day of year and temperature, respectively. For picophytoplankton clusters, the first two axes contributed 73% of the inertia, also driven primarily by day of year and temperature, respectively. Cluster aggregation resulted in 9/10 significant parameters for both diatoms and picophytoplankton.

Temperature Effects on Community Structure

Using CCA, temperature was repeatedly identified as an important factor structuring the microbial communities in our study region. The clustering analyses (Fig 5; Fig 8; Fig 10) also suggested that a shift in community structure may have occurred around 5–7 °C, so we used Student's t-tests to identify breakpoints in ESV relative abundance as a function of temperature (Table 7).

The three most abundant diatoms (all *Chaetoceros*) showed a clear preference for waters colder than 7 °C (Table 7; Fig 11), as did the two most abundant picophytoplankton: *Micromonas*

549 ESV 20 and *Phaeocystis* ESV 31 (Table 7; Fig 12). Among diatoms, about 70% of ESVs had a
550 maximal relative abundance in waters colder than 7 °C (Fig 11); among picophytoplankton, it was
551 over 80% (Fig 12). Some taxa preferred warmer waters, however, including *Skeletonema* ESV 336
552 and *Pseudo−nitzschia* ESV 274 (Fig 13), as well as *Bathycoccus* ESV 188 and *Nannochloris* ESV
553 277.

563 relative abundance (each column is an ESV).
564

565 Fig 13: The relative abundances of two ESVs corresponding to the genus *Pseudo−nitzschia* as a
566 function of temperature.

Table 7: Breakpoints in preferred water temperature identified for some abundant ESVs for the northern Bering and Chukchi seas cruises during 2017. The t-tests tested the hypothesis that the relative abundance of an ESV was significantly different (two-sided, alpha = 0.05, Bonferroni-corrected) in samples collected in warm water (> breakpoint) compared to cold water (< breakpoint). For each ESV, the test statistics were computed for every unique temperature in the dataset and breakpoints were identified as local minima of the test p-values, all of which were $p<<0.0001$.

	ESV	**Breakpoint (°C)**	**Prefers warm/cold**
Diatoms	*Chaetoceros* ESV 2	6.7	cold
	Chaetoceros ESV 19	7.0	cold
	Chaetoceros ESV 27	7.0	cold
	Skeletonema ESV 336	5.2	warm
	Pseudo−nitzschia ESV 274	4.5	warm

DISCUSSION

This study is the first synoptic, high-throughput molecular phylogenetic investigation of phytoplankton diversity in the Bering and Chukchi Seas based on hundreds of samples collected from June to September in 2017 (Fig 1). We use this unique opportunity to describe the seasonal diversity and geographic distributions of phytoplankton communities in the Chukchi and Bering Seas using metabarcoding. We focus primarily on diatoms and picophytoplankton, both prominent primary producer groups in this region. We also highlight the diversity within these groups and explore the environmental and biological drivers of phytoplankton community structure. These results will help in determining how sub-Arctic and Arctic microbial communities might respond to changes in their environment resulting from anthropogenic global warming.

Diversity, Community Resilience, and Potential Impacts of a Warmer Arctic

The expeditions described here were conducted during the warmest temperatures on record in the Bering and Chukchi Seas, a harbinger of a "new normal" in the warmer Arctic Ocean expected in the future. Paleoecological reconstruction of marine microbial community structure during past periods of climatic change has shown that, even at the species level, communities can be resilient to large changes in environmental conditions (Moritz and Agudo 2013); here we explore the baseline variability in microbial community structure across space and time in this region. While numerous studies have characterized phytoplankton bloom timing (Kahru et al. 2011; Sigler et al. 2014), there are few studies that characterize and identify the diversity of the Bering and Chukchi Sea phytoplankton communities at the molecular level. Here we focus on the 18S rRNA gene as a marker of diversity to examine the ecological mechanisms of resilience to changes in environmental conditions in modern biological communities (Tesson et al. 2014; Sjöqvist and Kremp 2016).

Diatom and picophytoplankton assemblages each consisted of over 200 ESVs, but differed in their relative abundances, with diatoms making up a large fraction (36.0 ± 0.1% mean relative abundance across all sampling seasons), as expected to result from the influx of nutrients through Bering Strait. Among diatoms, 90% of the relative abundance was contributed by the most abundant 26 ESVs, including genera that are well known from the Pacific Arctic like *Chaetoceros*, *Fragilariopsis*, *Navicula*, *Nitzschia*, *Pseudo−nitzschia*, and *Thalassiosira* (Sakshaug 2004; von Quillfeldt 2005). Here we compared diatoms and picophytoplankton to provide baseline estimates for future comparisons to a coming "new Arctic" (Overpeck et al. 2005; Carmack et al. 2015), which is expected to feature increased temperatures and stratification levels, limiting nutrient turnover in surface waters, and possibly causing a shift towards picophytoplankton (Li et al. 2009) resulting from regenerated production (Ardyna et al. 2011). Additionally, diatoms are better adapted to lower light availability, provided nutrients are sufficient (Siemering et al. 2016), another indicator that diatoms as a whole may be negatively affected with less ice coverage throughout the year and with stratification limiting nutrient turnover.

Diatoms and picophytoplankton were sensitive to a temperature transition zone observed at around 5–7 °C (Table 7). One of these, *Chaetoceros* ESV 2, was cosmopolitan, found in nearly every sample in the study, across all seasons, temperatures, and salinities. However, this taxon reached its highest relative abundances in waters colder than 6.7 °C, and declined precipitously above that temperature. *Chaetoceros* ESV 2 was most closely related to *Chaetoceros socialis*, a species complex already known to have high intraspecific diversity (Degerlund et al. 2012; Gaonkar et al. 2017). *Skeletonema* ESV 336 was found almost exclusively in waters warmer than 5.2 °C, consistent with literature descriptions as a genus of temperate, coastal diatoms (Thornton and Thake 1998; Kooistra et al. 2008). Among the picophytoplankton, *Bathycoccus prasinos* ESV

188 appeared almost exclusively in waters warmer than 5.9 °C, while *Phaeocystis pouchetii* ESV 31 and *Micromonas pusilla* ESV 20 appeared predominantly in waters colder than 6.9 °C and 6.2°C, respectively. The clear temperature preferences for some of the most relatively abundant taxa in this region presage changes for these communities as the Arctic and sub-Arctic continue to warm.

In addition to a decline in some common diatoms, the Alaskan Arctic could see shifts in taxa related to known harmful algal bloom-forming species (HABs). *Pseudo−nitzschia* is a genus containing HAB-forming diatoms in which about 50% of species are known to produce domoic acid, a neurotoxin that has recently been identified in Alaskan waters (Lefebvre et al. 2016; Huntington et al. 2020). We found two prominent ESVs classified as *Pseudo−nitzschia* to the genus level in our dataset, with *Pseudo−nitzschia* ESV 518 predominant at lower temperatures, and *Pseudo−nitzschia* ESV 274 predominant at higher temperatures (Fig 13). While it was not possible to identify these to the species level, about 50% of *Pseudo−nitzschia* species have been shown to produce the toxin domoic acid (Bates et al. 2018); this genus may persist and increase in abundance with warming temperatures (Hallegraeff 2010). The picophytoplankter *Phaeocystis pouchetii* ESV 31, detected prominently throughout our study region but especially in early summer, is also a known toxin producer (Eilertsen and Raa 1995); however it's prominence in the Alaskan Arctic may decrease as temperatures rise (Table 7). Nonetheless, changing conditions in the Arctic are still expected to lead to increases in certain HAB-forming taxonomic groups that stand to affect higher trophic levels (Walsh et al. 2011).

These strong temperature preferences are exhibited by taxonomic groups that, combined, contributed a high proportion of the relative abundance. Climate change has occurred cyclically throughout Earth's history (Sarmiento and Bender 1994), though the current pace of

anthropogenically driven climate change is unprecedented (Jeffries et al. 2014). Despite the evidence of diatoms persisting through past climatic events, a rapidly warming Arctic today signals change for numerous prominent taxa. While salinity, nutrients, and temperature each have influence on community structure (Lozupone and Knight 2007), our results imply that temperature plays a greater role than other environmental factors in driving structural changes. This finding is in agreement with a comprehensive TARA Oceans metagenomic study (Sunagawa et al. 2015) examining prokaryotes and picoeukaryotes across temperate, tropical, and polar latitudes, which also concluded that temperature is one of the primary drivers of marine microbial community structure.

Our identification of key groups with strongly preferred temperature ranges allows us to confidently state that primary producer communities will change in the face of climate change, with ramifications felt throughout the Bering and Chukchi Sea ecosystem. Specifically, we expect to see a loss of *Chaetoceros* (especially ESV 2) and *Phaeocystis* ESV 31 (Fig 11, Fig 12). Diatoms with a preference for warmer conditions could still be outcompeted if temperature-driven stratification suppressed the upwelling of nutrients to the surface (Cermeño et al. 2012), which diatoms rely on to outgrow other phytoplankton early in the growing season (Litchman 2007). *Chaetoceros* and *Thalassiosira* both rely on high nutrient concentrations to bloom, and form large chains that contribute significantly to the carbon cycle. The combination of high nutrient requirements and strong temperature preferences of some taxa (Fig 11) could lead to a decrease in their abundance in the future, and a subsequent increase by other taxa. If the replacement taxa are smaller, solitary diatoms, or picophytoplankton like *Micromonas*, this could have significant effects on the carbon cycle, leading to a reduced flow of particulate carbon to the benthos. In the present ecosystem, this flow drives the tight benthic-pelagic coupling observed over the Bering

and Chukchi shelves (Grebmeier and Barry 1991; Dunton et al. 2005); rapid changes could cause significant stress to those animal communities.

In general, we observed a spectrum of generalist to specialist diatom ESVs: some taxa were found to thrive in a range of environmental conditions while some were found only in specific and narrow environmental conditions. The CCA analysis captured only a rough summary of this diversity, making it difficult to distinguish specialist from generalist taxonomic groups, and illustrating that this type of analysis may be more meaningful for picking informative variables to investigate than in finding the root causes of community variability (Thaler and Lovejoy 2014). To better understand how these communities change with environmental conditions, collecting samples from the same area over a long period of time may be more useful than collecting samples at sites just one time during the year. Because ship-based observations are limited in temporal scope, long-term mooring deployments like the Chukchi Ecosystem Observatory (Hauri et al. 2018) will be critical for understanding the seasonal changes in planktonic community structure, and future deployments of the Chukchi Ecosystem Observatory are expected to include sampling of microbial communities for this purpose.

Biogeography

Clustering the samples by community assemblage revealed cases where sample clusters dominated by chain-forming diatoms (e.g. *Chaetoceros* and *Thalassiosira* in clusters D1, D2, and D7) were more prevalent in midwater and bottom depth bins, suggestive of a bloom in the process of sinking as also indicated by low chlorophyll concentrations. Alternatively, these diatoms could be indicative of sustained production due to higher nutrient concentrations found deeper in the water column since the vast majority of sampling depths fell within the euphotic zone.

A similar phenomenon was observed for *Phaeocystis*, another important group in the carbon cycle. After blooming, *Phaeocystis* can aggregate, sink, and carry large quantities of organic carbon to the seafloor, supporting the benthos and potentially sequestering carbon. Two *Phaeocystis*-rich clusters, P4 and P5, were more prevalent at midwater and bottom depth bins, again suggesting a sinking bloom or sustained production at the bottom due to nutrients and suitable conditions at depth.

Similarly, clusters were also useful in identifying temperature preferences for certain taxa, allowing the prediction of certain ESVs that may be more sensitive to a warming Alaskan Arctic. Each of these putatively sinking communities (clusters D1, D2, P4, and P5) was substantially more prevalent in waters colder than 6 °C compared to waters warmer than 6 °C, suggesting that these sinking communities may indeed be negatively affected by warmer waters in the future Arctic.

We found several *Micromonas* ESVs to be prominent members of the picophytoplankton community, though the most abundant, *Micromonas* ESV 20, was most commonly found at temperatures below 6.2 °C, replaced by *Bathycoccus* ESV 188 in warmer coastal waters. Future studies could investigate the different physiologies of *Micromonas* and *Bathycoccus* to predict potential changes in biogeochemical cycling or primary or secondary productivity in the case that *Bathycoccus* expanded further into the *Micromonas* niche. While this pattern may hold at the large scale, in more localized settings, factors like currents, wind direction, advection of water from off shelf, or upwelling of nutrients may provide stronger indications of community composition due to mixing water masses, or the growth of opportunistic taxa when certain conditions are met, e.g. increased nutrient loads.

Top-Down and Bottom-Up Controls on Community Structure

Our study focused primarily on environmental variables that are bottom-up controls on primary producers. Top-down controls were not explored in this study, however grazing by heterotrophic protists has been demonstrated to impact phytoplankton community structure. Changes in phytoplankton bloom development has been shown to impact food web structure and top-down and bottom-up control of marine ecosystems in polar waters (Arrigo and van Dijken 2004). The PCR primers used in this study also amplify heterotrophic protist DNA (e.g. dinoflagellates and ciliates), but their analysis was outside of the scope of this work at this time. Future studies should include them as potential drivers of phytoplankton community composition in this region.

Top-down and bottom-up controls have long been debated in the field. Results from this study suggest that bottom-up controls may influence diversity in terms of ESVs, but do not appear to drastically reshape communities at the family level and above. We suggest that top-down controls are more likely to drive community structure in terms of broad shifts in diversity. Our results also suggest that top-down and bottom-up controls may oscillate as environmental conditions shift over time and space, a trend demonstrated in another coastal sea (Mozetič et al. 2012). If shifts in community structure are more likely, climate change may not have the detrimental effects predicted, i.e., resilience in diatoms means the efficiency of the biological carbon pump to the seafloor will be maintained. As seawater temperatures continue to rise in the Arctic, some studies have suggested that a shift to more mixotrophic plankton could also occur, altering biogeochemical cycling (Ward and Follows 2016). Common throughout temperate oceans (Hartmann et al. 2012; Flynn et al. 2013), mixotrophs are multifunctional protists that photosynthesize when nutrient concentrations are high, and assume an osmotrophic or

734 phagotrophic lifestyle in nutrient deplete conditions (Ward and Follows 2016). Diatoms, in
735 general, are relatively large and heavy, meaning they sink quickly, raising the efficiency of transfer
736 of carbon to the seafloor. In contrast, mixotrophic picophytoplankton are much smaller, and are
737 expected to increase in abundance in a warmer Arctic due to the advantages that mixotrophy brings
738 in conditions of high resource variability (Mitra et al. 2016; Stoecker et al. 2017b).

739 Hypothesized changes as a result of increased mixotrophy in the Arctic include increased
740 carbon fixation but decreased vertical carbon flux (Stoecker and Lavrentyev 2018), which would
741 be expected to increase trophic transfer, possibly raising planktonic production at higher trophic
742 levels (Mitra et al. 2014; Ward and Follows 2016). An increase in mixotroph abundance could
743 reduce carbon flux to the benthos, which could have long-lasting repercussions all the way up the
744 food web to humans. Our study observed a relatively high abundance of *Micromonas* ESV 20 (not
745 identified to species), a prominent genus of picophytoplankton found throughout the world ocean
746 that has been identified as mixotrophic. Recent studies (Lovejoy et al. 2007; McKie-Krisberg and
747 Sanders 2014) have demonstrated that this genus has dispersed widely throughout the Arctic
748 Ocean, and has been observed to be particularly sensitive to temperature (Demory et al. 2018).
749 The strain found in the Arctic differs from the clades found in other oceans by notably thriving at
750 6–8 °C due to its adaptations to cold and low-light conditions (Lovejoy et al. 2007). Our study
751 found the peak abundance of *Micromonas* ESV 20 occurred at 6.2 °C and this taxa preferred colder
752 waters (Table 7). As a mixotroph, *Micromonas* could impact production in the Arctic if it were to
753 displace phytoplankton that rely solely on photosynthesis. Combined with its strong temperature
754 preferences and numerous studies from across the global ocean, *Micromonas* is a key genus to
755 watch and monitor in the face of a changing Alaskan Arctic.

Taxonomic Resolution and Environmental Influence

Our results suggest that over broad scales (multiple sampling seasons and regional sites), taxonomic genera provide a suitable level to understand general impacts of environmental variables on community structure. However, higher taxonomic resolution is needed to observe more subtle shifts not detectable at higher taxonomic levels (e.g. *Chaetoceros* ESV 2 and different temperature preferences of *Micromonas* ESVs). Not only is high taxonomic resolution the most useful for studying community changes, it also adds to our understanding of diversity in a rapidly changing ocean environment. When possible, it is best to identify organisms to the highest taxonomic resolution possible, underscored by numerous studies demonstrating the importance of microdiversity (Allison and Martiny 2008; Needham et al. 2017; García-García et al. 2019).

In our study we used primers targeting the V4 hypervariable region of the 18S ribosomal RNA gene, which is often specific enough to identify taxa to species level but often not specific enough to identify intraspecific diversity. Because many cultured representatives of Arctic phytoplankton remain missing from sequence databases, and we did not collect morphological data, we deferred from making strong claims to species identifications and focus instead on ESVs as indicators of taxonomic diversity. Future studies should consider the use of more sensitive primers in order to quantify microdiversity within these communities. Even with these limitations, it was still possible to identify several specific ESVs that stand to be the most affected in the face of a warming Arctic, as well as build a comprehensive taxonomic dataset in conjunction with environmental data across the late spring and summer in the Bering and Chukchi Seas. We have clearly demonstrated specific taxonomic groups that stand to be most affected in a new and warming Alaskan Arctic.

Drivers of Community Structure

Statistical analyses suggested that, overall, environmental parameters measured at the time of sample collection (e.g. temperature, salinity, chlorophyll, dissolved oxygen) were not the primary drivers of phytoplankton community structure at broad spatial and temporal scales. While the composition of individual samples across all cruises were not well characterized using these measured variables, the amount of variability explained (i.e. the quality of predictions) increased somewhat when samples were clustered by community assemblage. Environmental parameters accounted for only 12.5% of variability for diatoms at the ESV level and 7.4% for picophytoplankton, but accounted for 43.6% and 32.5% of the variability across clustered sample assemblages for diatoms and picophytoplankton, respectively (Table 6). This suggests clustering samples based on similarity improves the ability to anticipate community composition from environmental data.

During the summer of 2017, environmental parameters measured at the time of sampling held little value for predicting phytoplankton community structure. Many studies have debated which parameters are most important to driving community structure (Krug et al. 2013; Sunagawa et al. 2015; Neeley et al. 2018), with a lack of clear consensus. However, our findings consider these communities at the ESV-level (genus, species, and, when possible, subspecies taxonomic resolution), while prior studies characterized to genus and species. Our higher taxonomic resolution allowed us to determine temperature as having more of a measurable effect on certain taxonomic groups, and especially those ESVs that are most prevalent (Table 7). Water mass has previously been attributed to shaping Arctic phytoplankton communities with some water masses observed to hold distinct communities—including diatoms, chlorophytes, and haptophytes—specifically within Pacific Halocline Water (originating through the Arctic Ocean) and deep

801 Atlantic Water (Fehling et al. 2012; Kalenitchenko et al. 2019). The mixing of these distinct water
802 masses, separated by global thermohaline circulation, may explain the high degree of community
803 dissimilarity observed there, whereas in our study many communities originated from closely
804 related water masses flowing northward from the Pacific Ocean and into the Bering and Chukchi
805 Seas. However, some mixing of water masses appeared to have an impact on our samples. At
806 midwater and bottom depths at AMBON's furthest northeast transect, an inflow of water through
807 Barrow Canyon, suggested by ADCP and nutrient profiles from the area, may have introduced
808 deep Arctic water onto the shelf, with its own unique community, consistent with other
809 observations of distinct communities between on- and offshore environments (Siemering et al.
810 2016). Other instances of community introduction via advection of water have been documented
811 with significant differences attributed to hydrography (Hamilton et al. 2008; Kalenitchenko et al.
812 2019).

813 While our study did not identify any diatom and picophytoplankton taxa found exclusively
814 in temperate waters, our results confirm temperature shifts are likely to affect the distribution of
815 taxa. Changes in temperature have driven poleward shifts of numerous temperate taxa, including
816 phytoplankton, across the globe (Poloczanska et al. 2013). On the Atlantic side of the Arctic, the
817 fronts of Atlantic water masses have moved further north due to sea temperature warming, bringing
818 with it phytoplankton communities characteristic of warmer Atlantic waters (Neukermans et al.
819 2018). While our study did not find strong correlations with water mass, the local trends observed
820 in combination with previous studies indicate water movement is important to communities on a
821 regional level. Highly different water masses in conjunction with increased water masses have a
822 potential to bring in their own distinct communities, creating conditions more suitable for taxa not
823 traditionally found in the Arctic. A clear understanding of the physical environment is needed to

824 understand the context of changes within communities across all oceans, and future studies could
825 usefully incorporate backtracing of water parcels using models of current flow to better predict the
826 origins of sampled water.
827

828 **CONCLUSIONS**

829 Objectives of this study were to explore the spatial and temporal distributions of eukaryotic
830 phytoplankton communities in the Pacific Ocean inflow to the Arctic, covering the Chukchi Sea
831 and Bering Strait regions. This project aimed to determine whether reproducible patterns of
832 occurrence were present within community assemblages of diatoms and picophytoplankton, and
833 the role of environmental conditions in structuring these communities. The sampling coverage
834 attained in this study in both the spatial and temporal domains was much larger than typical studies
835 of its kind, allowing for unique insights into the structuring of microorganisms at the base of the
836 Alaskan Arctic food web.
837 Overall, the low predictability of community composition based on measured
838 environmental variables suggests that more explanatory variables exist that were not considered
839 in this study. However, our most notable finding is identifying temperature as a driver for certain
840 taxa, especially ones that make up a high proportion of the primary producers (e.g. *Chaetoceros*
841 ESV 2). Other integrative, bottom-up forcing factors that could contribute to phytoplankton
842 community structure, such as historical light availability, cloud cover, weather patterns,
843 stratification levels, mixing, ice extent, and freshwater input (e.g., ice melt, precipitation, rivers,
844 runoff), were beyond the scope of this study, so we cannot comment on their utility in predicting
845 microbial community structure at this time. Future studies should incorporate remote sensing

observations or seascape predictions to include these additional parameters as explanatory variables.

Our study also captured the diversity of these communities, all the more important considering diversity is a key buffer in rapid environmental changes (especially as the Arctic warms in response to climate change). Our study identified key genera and ESVs of diatoms and picophytoplankton. While we did identify hundreds of ESVs, more work is needed to determine both abiotic and biotic drivers of community assembly, and more specific genetic studies are needed to delineate microdiversity within the primary producer communities of the Alaskan Arctic. Our work does begin to fill in the gaps, allowing us to contribute more genetic information to existing databases. Monitoring of changes in zooplankton grazer abundance and distribution (e.g. copepods, ciliates, dinoflagellates) will also be important to understand how top-down controls could change and affect the phytoplankton. However, we did reaffirm the importance of temperature in structuring many key members of the diatom and picoeukaryote communities. Connecting certain taxa with temperature allowed for some insights into the future primary producer community of the Bering and Chukchi seas.

Our study highlights the diversity of primary producers and demonstrates that these communities are driven by a variety of environmental and biological parameters that are difficult to fully quantify. We observed a weaker influence of nutrients, water mass, water depth, and geography on diatom and picophytoplankton communities as a whole compared to other phytoplankton community studies (Sunagawa et al. 2015; Neeley et al. 2018; Kalenitchenko et al. 2019). However, we have demonstrated some key taxonomic groups are sensitive to temperature and these same taxonomic groups influence the structure of the communities. The taxonomic groups' responses to temperature are consistent with predictions of shifts to smaller celled

mixotrophs and away from larger celled phytoplankton (Ward and Follows 2016). Since the biological carbon pump in the Arctic is currently driven primarily by the sinking of large (>10 μm) diatom cells and chains, we can expect to see declines in benthic-pelagic coupling and seafloor productivity and higher trophic levels. However, this is also dependent on the resilience provided by biodiversity, especially microdiversity within primary producers, an area which is in need of more study. A shift to small-celled phytoplankton in a freshening Alaskan Arctic could have disruptive implications for primary productivity that supports the seafloor (Li et al. 2009).

Our analyses, conducted on almost a thousand samples collected across four months and three cruises, has established a baseline of microbial communities in the Bering and Chukchi seas and identified prominent taxa that are the most vulnerable to climate change. Already we can see the impacts of climate change on the lowest trophic levels that support the entire Alaskan Arctic ecosystem. Long-term monitoring along our study sites, especially the DBO and Chukchi Environmental Observatory, will be imperative to continue increasing our understanding of photoautotrophs and other microbes in the warming Bering and Chukchi seas.

ACKNOWLEDGEMENTS

We gratefully acknowledge the dedication and skillfulness of the captains, crews, and chief scientists aboard the R/V Sikuliaq, CGC Healy, and R/V Norseman II, without which this work could not have been completed. Funding for this work was provided by the National Oceanic and Atmospheric Administration (NA14OAR0110266, NA15OAR0110208), and the North Pacific Research Board (1802). This work was also funded through a National Ocean Partnership Program (NOPP Grant NA14NOS0120158) by the National Oceanographic and Atmospheric

Administration (NOAA), the Bureau of Ocean Management and Shell Exploration & Production, under management of the Integrated Ocean Observing System (IOOS).

Key words: Phytoplankton, Bering Sea, Chukchi Sea, Synechococcus

Intended Journal: Oceans

Abstract:

Size structure of phytoplankton populations has been shown to be an important determinant of the flow of carbon and energy to higher trophic levels in Arctic ecosystems. Phytoplankton populations dominated by small (<10um) pico- and nanophytoplankton cells are generally dominated by eukaryotic flagellates that are tightly grazed by microzooplankton leading to increases in trophic length. General dogma suggests that the picocyanobacteria *Synechococcus* is detectable but comprises a negligible fraction of phytoplankton carbon in Arctic ecosystems. As part of the Arctic IERP sampling program, we quantified the abundance of the *Synechococcus*, and other picophytoplankton, during the spring to fall period between 2017-2019 in the Northern Bering and Chukchi Seas. *Synechococcus* abundances increased from <500 cells/ml in spring to >50,000 cells/ml in the fall around Kotzebue Sound. Furthermore, the spatial extent of regions with elevated *Synecococcus* abundances in late summer/fall, as well as the absolute abundances, increased from 2017 to 2019, coincident with increasing late summer/fall water temperatures. When integrated over the euphotic zone, *Synechococcus* contributed up to 40% of estimated total phytoplankton carbon during late summer/fall in Kotzebue sound and the region near Icy Cape. These observations support an increased importance of a previously marginal phytoplankton group during a warming period in the Chukchi Sea. The full implications of these changes in the phytoplankton community remain to be resolved.

Introduction:

Arctic and subarctic seas are facing many stressors that may lead to significant changes in its function in the future (IPCC 2021). An important change is sea ice loss that when coupled with intensification of the hydrological cycle (Peterson et al., 202; Serreze et al., 2006) will likely lead to increases in stratification in near shore shelf systems, a key controlling factor of the productivity, through negative impacts on nutrient inputs, and structure of marine ecosystems of the Arctic Ocean (Carmack et al., 2006, Carmack 2007). The impact(s) of these changes on phytoplankton at the base of marine food chains is not completely resolved, particularly changes in phytoplankton community size structure (Tremblay and Gagnon, 2009).

Globally picophytoplankton (<2um) are well known and dominate in the major oligotrophic ocean gyres, but dogma is that they are not quantitatively important in the sub/arctic systems (Buitenhuis et al. 2011, Flombaum et al. 2013). In contrast, numerous measurements of size-fractionated chlorophyll have shown that the picoplankton size fraction can dominate phytoplankton biomass in sub/arctic systems during oligotrophic periods (e.g., summer) and regions (e.g., off-shelf) (e.g., Booth and Horner, 1997; Brugel et al., 2009; Legendre et al., 1993; Li et al., 2009; Odate, 1996). Given that picophytoplankton have a much higher carbon to chlorophyll ratio than microphytoplankton, it is likely that their importance to both carbon cycling and quality as a food source has been further underestimated (Lee et al., 2013). Within the picophytoplankton size class there is a wide diversity of both eukaryotic (e.g., prasinophytes and cryptophytes, Lovejoy et al., 2007; Sergeeva et al., 2010) and prokaryotic (e.g., Cottrell and Kirchman, 2009; Not et al., 2005) organisms. More recent studies have used flow cytometry as a more efficient tool to numerically quantify these <2um cells into operational categories (i.e., pico- and nanophytoplankton; Laney and Sosik, 2014), although some organisms do contain unique pigment signatures that allow them to be distinguished from other similar cells. For example, *Synechoccocus* and cryptophytes both contain

the orange pigment phytoerythrin, and thus can be identified as specific groups within the pico- and nanophytoplankton.

In the region between the eastern Beaufort Sea and Baffin Bay picophytoplankton numerically dominate in deeper water stations off shelf, and particularly in the SCM (e.g., Ardyna et al., 2011, Schlooss et al. 2008). In the Chukchi and western Beaufort Seas, it has also been shown that small prasinophytes, other flagellates (e.g., cryptophytes) and non-colonial phaeocystis (<5um) dominated in the deeper basin sites during summer and fall, while diatoms dominated on the shallow shelf (Gosselin et al 1997, Booth and Horner, 1997; Hill et al., 2005; Sergeeva et al., 2010; Sherr et al., 2003). Based upon a few stations in the southern Bering Sea, Liu et al. (2002) observed that picophytoplankton abundance, both *Synechococcus* and eukaryotes decreased from the basin to the shelf. Some eukaryotic picophytoplankton strains have been shown to persist through the winter maintaining growth rates that exceed grazing losses, and have been suggested to represent unique temperature controlled biogeographical clades (Lovejoy et al., 2007). Representatives of this eukaryotic psycrophillic clade are pan-Arctic, with some representatives having maximum growth temperatures of ~12.5ºC, so there may be problems in the future, and could cause disruptions in the food web. In contrast, the picocyanobacteria *Synechococcus,* has been found to be associated with slightly warmer and saltier water than eukaryotic picoplankton (Cottrell and Kirchman, 2009; Not et al., 2005; Tremblay and Gagnon, 2009, Waleron et al., 2007, Gradinger and Lenz 1989). Interestingly, Waleron et al. (2007), using eDNA analysis, identified 6 OTUs similar to *Synechoococcus* from the Mackenzie River system. These OTUs were linked to freshwater *Synechococcus* and it was concluded that they flushed into the system and implied they survived but were not actively growing.

The distributions of picophytoplankton around the sub/Arctic are important to understand, in particularly their contributions to total biomass (not just numbers), as well as the environmental variables that they correlate with to understand the niches that they currently occupy and when those niche boundaries might be exceeded. In this study we address the following questions. 1) what are the large spatial (i.e., cross shelf) and seasonal patterns of *Synechococcus* abundance and biomass in the Northern Bering and Chukchi Seas; 2) what are the environmental parameters associated with patterns in *Synecococcus* biomass; and 3) is there evidence of long term trends in *Synechococcus* biomass.

Methods:

Sample collection: Physical, chemical and biological measurements were made as part of the Arctic Integrated Ecosystem Research Program (AIERP, 4 cruises, and one cruise of opportunity) within the Northern Bering and Chukchi Sea region (Table 1, Figure 1). Samples were collected in clean Niskin bottle at roughly 10m spacing throughout the water column. At each station and depth a range of discrete phytoplankton samples were collected including size-fractionated chlorophyll a (Chl-a), picoplankton and nanoplankton counts by quantitative flow cytometry (e.g., Lomas et al., 2010), microplankton counts by inverted microscopy and FlowCAM, and seston particulate organic carbon (POC). Only flow cytometry data data are reported in this study.

Phytoplankton cell counts and carbon biomass estimates: Samples for picoplankton enumeration were generally collected at four to seven depths throughout and just below the euphotic zone, fixed with paraformaldehyde (0.5% final concentration), stored at ~4ºC for 1-2 h, before long-term storage at -80ºC.

Samples were analyzed on a Becton Dickinson (formerly Cytopeia Inc.) Influx or Jazz cytometer using a 488 nm blue excitation laser, appropriate Chl-*a* (692 ± 20 nm) and phycoerythrin (580 ± 15 nm) bandpass filters, and was calibrated daily with 0.53-µm and 3.0-µm fluorescent microbeads (Spherotech Inc. Libertyville, Illinois, USA). Each sample was run for 4-6 min (~0.3-0.5 mL total volume analyzed), with log-amplified Chl-*a* and phycoerythrin fluorescence, and forward and right-angle scatter signals recorded. Data files were analyzed from two-dimensional scatter plots based on Chl.-*a* or phycoerythrin fluorescence and characteristic light scattering properties (e.g., DuRand and Olson, 1996) using FCS Express 3.0 (DeNovo Software Inc. Los Angeles, California, USA) or SortWare (Becton Dickenson, East Rutherford, New Jersey, USA). Picophytoplankton, operationally defined as cells <3.0-um, were identified as *Synechococcus* cells based upon cell size and the presence of phycoerythrin. Based upon these gating criteria, the number of cells in each identified population was enumerated and converted to cell abundances by the volume-analyzed method (Sieracki et al., 1993). Precision of triplicate samples was <10% for cell concentrations >200 cells mL^{-1}. Carbon per cell was estimated for flow cytometrically identified phytoplankton using a calibration curve that related cellular particulate organic carbon (POC) to normalized geometric mean cellular forward scatter (proxy for cell size) (e.g., DuRand et al., 2001, Casey et al. 2013, data specific to the flow cytometer used in this study). Carbon content of each identified population was estimated by multiplying volumetric cell abundance and POC per cell derived from the calibration curve.

Chlorophyll: Sample volumes varied depending upon the cruise, but ranged from 0.1 - 1L, and in all cases were gently vacuum filtered (≤5 mm Hg) for total chlorophyll (Chl-a) analysis onto Whatman GFF (or equivalent) filters (nominal 0.7 µm pore size). At selected stations, size-fractionated chlorophyll concentrations were estimated by filtered paired samples sequentially through a 5 µm Whatman Track Etch polycarbonate filters and then a Whatman GFF filter. After filtration, samples were stored frozen at -80°C until extraction and analysis. For analysis, samples were extracted in 5 ml of 90% acetone for 24 h at -20°C. Samples were analyzed on a calibrated fluorometer, either Turner Designs TD-700 or 10-AU, with day-to-day performance of the fluorometer tracked using a commercially available solid standard. Fluorescence readings were taken before and after the addition of 75 µl of 1.2M HCl and concentrations calculated using standard equations (Parsons et al., 1984).

Table 1. Summary details associated with cruises included in this analysis.

Cruise ID	**Dates**	**Latitude (°N) (min-max)**	**Longitude (°W) (min-max)**	**Stations (>/< 50m)**
SKQ-2017-09S	5th June – 26th June 2017	56.4 to 69	-172.6 to -169	
OS-1701	6th Aug – 27th Sept 2017	67.0 to 72.5	-169.0 to -152.3	
SKQ-2018-13S	7th June – 23rd June 2018	63.3 to 69	-171.5 to -164.4	
HLY-1801	8th Aug – 23rd Aug 2018	64.7 to 71.8	-170.0 to -153.8	
OS-1901	1st Aug – 2nd Oct. 2019			

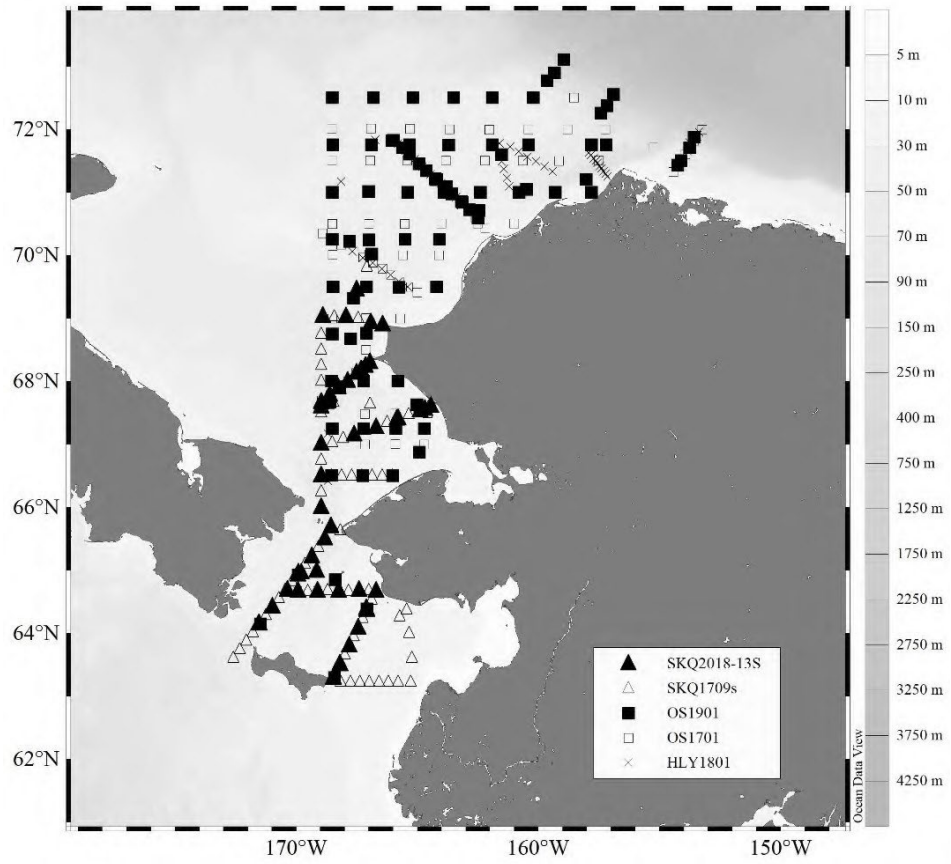

Figure 1. Map of station locations included in this analysis. There are a total of 494 discrete stations, although some are sampled multiple times over multiple cruises within the same program.

Dissolved nutrients: Samples for nutrient analysis were collected at the same depths as Chl-a and rate process incubation samples. Samples were syringe filtered using 0.45µm cellulose acetate membranes, and collected in 30ml acid washed, high-density polyethylene bottles after three rinses. On the BASIS and EcoFOCI cruises, samples were stored frozen at -80ºC and analyzed later at the shore-based facility, while samples from the BEST cruises were stored at 4ºC until analysis at sea, usually within 12 hrs of collection. Phosphate, nitrate, nitrite, and ammonium concentrations were determined using a combination of analytical components from Alpkem, Perstorp and Technicon. WOCE-JGOFS standardization and analysis procedures (Gordon et al., 1993) were closely followed including reagent preparation, calibration of lab glassware, preparation of primary and secondary standards, and corrections for blanks and refractive index. Nutrient data from the Bering Sea program cruises were accessed from the Bering Sea Project Data Archive (Stabeno et al., 2013a, b), and data from the BASIS and EcoFOCI cruises were provided by co-author CWM.

POC analysis: [to be written]

Data analysis: [to be written]

Results:

Spatial and temporal distribution of Synechococcus. *Synechococcus* cell abundance showed a clear seasonal variation in each major region (Figure 2). Cell abundance in the spring period were generally low (<1000 cells/ml), with the highest concentrations in the Northern Bering Sea/Bering Strait region. In stark contrast, in late summer/early fall, cell abundances could exceed 100,000 cells/ml. In summer/fall periods highest abundances were in Kotzebue Sound, although between years in the study the spatial extent of high cell abundances increased substantially.

Synechococcus abundances were found to have a seasonal vertical distribution pattern (Figure 3). During spring periods (e.g., June 2018), *Synechococcus* abundances were greater at depth, whereas in late summer/early fall (e.g., Aug/Sept. 2019), greatest *Synechococcus* abundances were restricted to the upper 20m of the water column over the broader spatial range where they were observed.

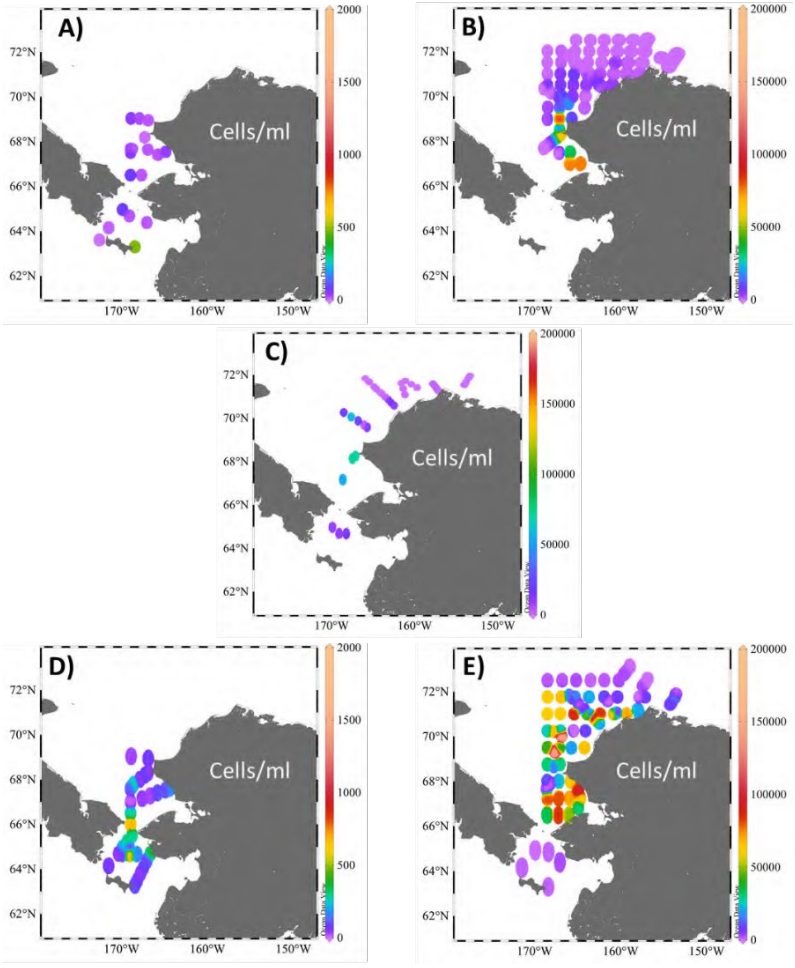

Figure 2. Seasonal patterns of *Synechococcus* abundance in the Northern Bering and Chukchi Seas. A) spring 2017 (SKQ-2017-09S), B) late summer/early fall 2017 (OS1701), C) summer 2018 (HLY1801), D) spring 2018 (SKQ-2018-13S), and E) late summer/early fall 2019 (OS1901). Note the 100x different in scales between the spring and late summer/early fall cruises.

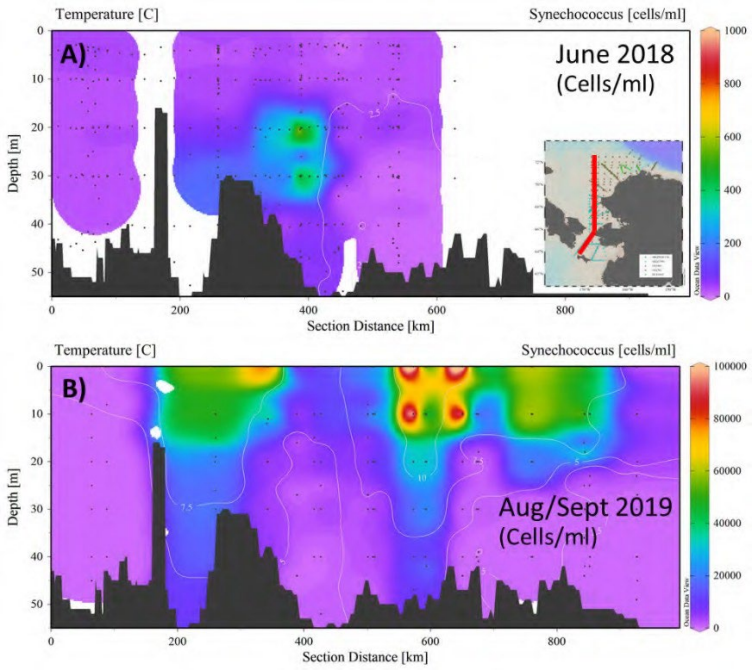

Figure 3. Latitudinal section plot of *Synechococcus* abundance through the study region.

Relationships to environmental parameters. *Synechococcus* cell abundances were highest in waters with temperatures >7oC and salinities <30.5 (**Figure 4a**). The T/S region where *Synechococcus* cell abundances were highest is classified as the warm coastal water (Danielson et al. 2020), although elevated abundances can also be found in the warmer/fresher regions of the warm shelf water. These waters are also depleted in inorganic nitrogen concentrations (**Figure 4b**).

Multiple linear regression (Model 2) analysis suggests that the only environmental variable that is significantly related to *Synechococcus* cell abundance is Temperature (Table 2). Interestingly there are two other nanophytoplankton populations, size-defined nanoeukaryotes, and the specific nanoeukaryote group of the cryptophytes, that are significantly related to *Synechococcus*.

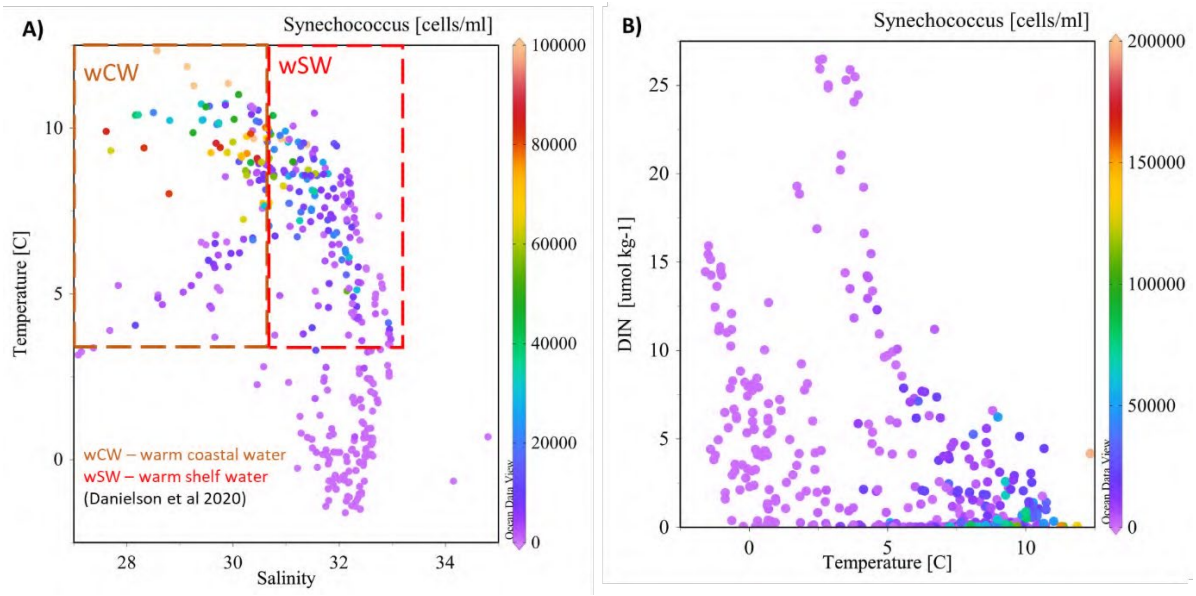

Figure 4. Relationships between *Synechococcus* abundance and environmental variables. A) temperature/salinity plot. Dashed lines bound the warm coastal water (orange) and warm shelf water (red) domain as defined by Danielson et al. 2020. B) temperature/dissolved inorganic nitrogen (DIN) plot. DIN is defined as the sum of NO3, NO2 and NH4.

Table 2. Results of multiple linear regression (Model 2) analysis between *Synechococcus* abundance and environmental and biological variables. Variables significantly related to *Synechococcus* abundance are shown in italic font.

Parameter	**Coefficient**	**Std. Error**	**t-statistic**	**P-value**

Contributions to total biomass. Cell abundances were converted to carbon biomass values using the relationship between normalized forward light scatter and cellular carbon (Casey et al., 2013). Total phytoplankton carbon was estimated by multiplying total chlorophyll-a by the slope of the particulate organic carbon to chlorophyll-a ratio. *Synechococcus* carbon, as a percentage of total phytoplankton carbon, increased as total phytoplankton carbon decreased, reaching values as high as 40% of total phytoplankton carbon (**Figure 5**). At chlorophyll-a concentrations ≤2ug/L, a value commonly used to denote a 'bloom', *Synechococcus* could contributed >20% of total phytoplankton carbon and increased to >40% at <1ug/L chlorophyll. Samples from the shallowest depths and warmest temperatures consistently contributed higher fractions of total phytoplankton biomass.

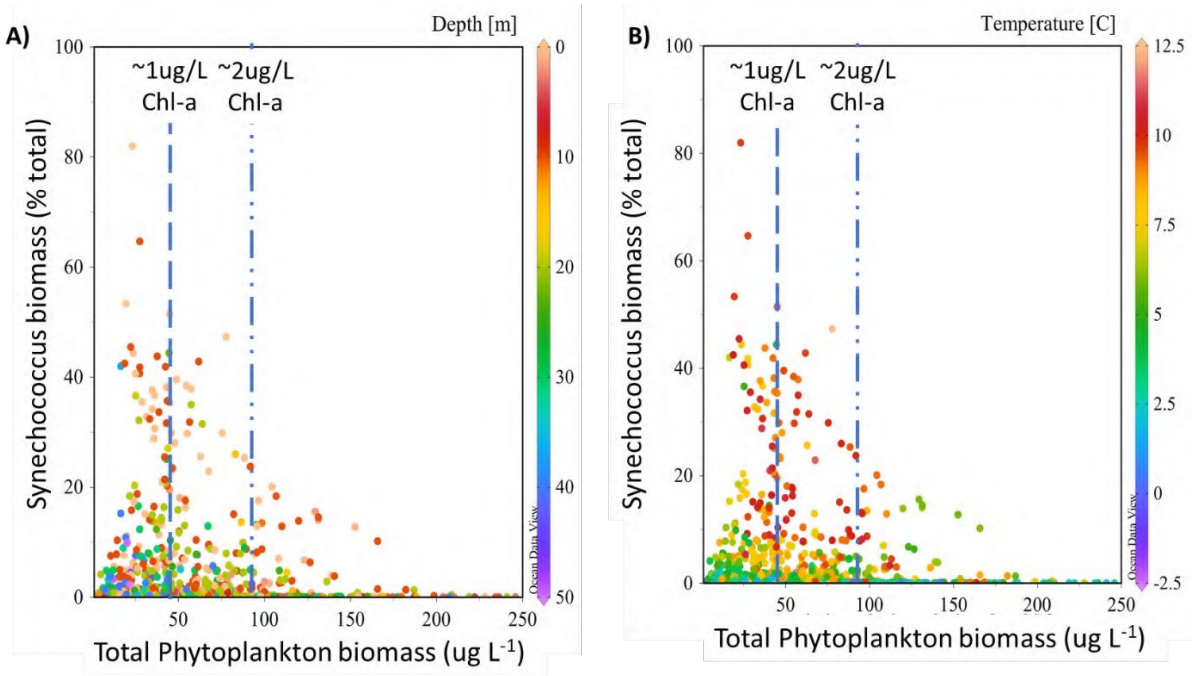

Figure 5. Contributions of *Synechococcus* to total phytoplankton carbon as function of A) depth and B) temperature. Dashed lines denote phytoplankton carbon associated with 1ug/L and 2ug/L chlorophyll.

Discussion

Highly productive systems like the Bering and Chukchi Seas are generally characterized by strong seasonal blooms of large phytoplanktonic diatoms that are rich in fatty acids and serve as an important food source for higher trophic levels. Seasonality of phytoplankton blooms, in particular the 'fall bloom' are gaining increasing recognition as being important in the trophic transfer of carbon and energy (Sigler et al., 2014). In the eastern Bering Sea shelf system, while *Synechococcus* has been observed (e.g., Liu et al., 2002; Moran et al., 2012) their abundances are generally low and represent a minor contribution to total phytoplankton carbon. The data presented in this study suggest that in the Chukchi Sea there is a very different pattern, with a much stronger seasonal amplitude in the abundance of *Synechococcus* and contribution to total phytoplankton carbon. Given the niche that *Synechococcus* fills globally (Flombaum et al., 2013; Visintini et al., 2021), our observations are consistent with *Synechococcus* growing into waters that are warm and nutrient deplete. In other ocean regions, *Synechococcus* abundances are tightly controlled by grazing (e.g., Worden and Binder, 2003), unfortunately there are not *Synechococcus*-specific grazing rates in the Northern Bering and Chukchi Seas. In the Northern Bering and Chukchi Seas, the picoplankton size fraction is tightly controlled by grazers, however, observations were at a time when *Synechococcus* abundances were low (Krause et al., 2021). The extensive net growth of *Synechococcus* during the late summer/fall period suggests a potential disruption to in this grazing control. The ecological impact of the observed increase in *Synechococcus* abundance remains to be fully understood.

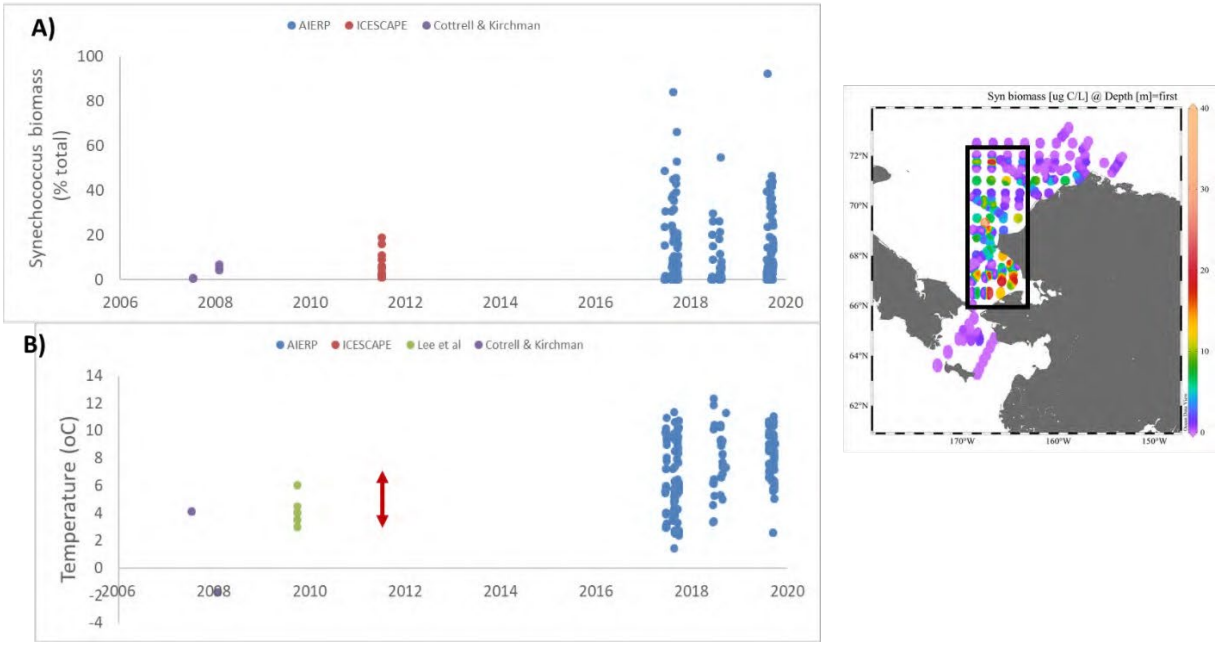

Figure 6. Changes in A) *Synechococcus* biomass and B) sample water temperature from published studies over time. Map inset shows the bounding box (black line) from which our data and those of previously published studies are used for this analysis.

Increasing Synechococcus *in a warming Arctic.* As *Synechococcus* has generally been considered a trivial component of the Arctic phytoplankton community, there are relatively few studies that have

quantified their abundance and from which carbon biomass can be estimated. *Synechococcus* biomass increased over the past decade in the region of Kotzebue Sound and north (Cottrell and Kirchman, 2009; Laney and Sosik, 2014, this study; **Figure 6a**). During this time, water temperatures in this same region increased significantly (Cottrell and Kirchman, 2009; Laney and Sosik, 2014; Lee et al., 2013, this study; **Figure 6b**). This observation is consistent with our environmental analysis from this study where temperature was the only variable that was significantly related to *Synechococcus* abundance. Zhuang et al. (2021) observed that pigments associated with picoplankton, and potentially cyanobacteria, increased from 2008-2016 on a transect in the Chukchi Sea along Icy Cape, consistent with our observations.

KEYWORDS: Fatty acid analysis, Arctic, Chukchi Sea, northern Bering Sea, phytoplankton

ABSTRACT

Arctic and subarctic ecosystems are transitioning due to ocean warming, resulting in conditions that will lead to shifts in phytoplankton communities, their nutritional compositions, and production of fatty acids (FA). FA biomarkers are useful indicators of changing phytoplankton community composition and provide insight into basal resource quality for higher trophic level consumers such as zooplankton, fish, birds and marine mammals, yet phytoplankton FA information is largely lacking from the Bering and Chukchi Sea region. Therefore, we analyzed suspended particulate matter (seston) fatty acids (FA), chlorophyll-a (Chl-a) and environmental data collected from four surveys in the North Bering and Chukchi Seas, two during June of 2017 and 2018 and two during August and September of 2017 and 2019. Our objectives were to determine 1) whether, seston FA composition was correlated with phytoplankton taxonomic composition analyzed using imaging microscope (FlowCAM) techniques, 2) seasonal differences in seston FA concentrations, and 3) how FA concentrations vary with environmental parameters. We found significant seasonal differences in seston FA compositions, with diatom biomarkers more prevalent in spring, followed by a community shift to dinoflagellate and small flagellate FA biomarkers in late fall. These results were overall confirmed by FlowCAM analyses. FA seston concentrations were correlated with total and large size-fractioned Chl-a concentrations, nitrogen concentration and temperature. Lastly, we used a model framework to predict availability of the diatom-associated essential FA, eicosapentaenoic acid (EPA, 20:5n-3). Combined our analysis provide new information on FA phytoplankton dynamics and the important nutritional role of phytoplankton for higher trophic level consumers in the Northern Bering and Chukchi Sea regions.

1. INTRODUCTION

The Bering and Chukchi Seas are some of the most productive areas of the Arctic (Hill et al., 2018). A pronounced diatom spring bloom commonly associated with the timing of ice breakup (Fujiwara et al., 2016; Laney and Sosik, 2014) fuels pelagic and benthic secondary production (Grebmeier et al., 2006; Sigler et al., 2014). Later in the season, once the ocean stratifies, a majority of the large size-fractioned phytoplankton biomass is often present in subsurface water layers (Martini et al., 2016) while smaller sized plankton occur in the surface waters (Giesbrecht et al., 2019). Arctic and subarctic ecosystems, including the Bering and Chukchi Seas are transitioning (Huntington et al., 2020) due to rapid ocean warming. This scenario is projected to continue in the coming decades (Hermann et al., 2019) with changes already affecting sea ice phenology, spring bloom timing and phytoplankton production (Clement Kinney et al., 2020; Song et al., 2021). These changes also influence the production of fatty acids (FA) synthesized by phytoplankton which play a key nutritional role for the growth and functioning of marine consumers. More baseline data on phytoplankton nutrition, including their FA compositions is needed for tracking potential short and long-term changes in the quality and quantity of basal resources in the Bering and Chukchi Sea food webs.

Phytoplankton play a crucial nutritional role in marine ecosystems due to their ability to synthesize dietary FA required by higher trophic level organisms (Budge et al., 2014; Dalsgaard et al., 2003). Marine consumers generally lack the ability to synthesize several essential FA at a sufficient rate to meet their metabolic demand (Helenius et al., 2020), and therefore require FA preformed in their diets (Bell and Tocher, 2009). Several essential polyunsaturated FA (PUFA), including eicosapentaenoic acid (EPA, 20:5n3) and docosahexaenoic acid, (DHA, 22:6n3), are central compounds that regulate cell membrane fluidity, neurological functioning, localized

47 hormones and growth (Bell and Tocher, 2009; Helenius et al., 2019; Tocher et al., 2019). Dietary
48 limitation of essential PUFA directly influence zooplankton fecundity and growth rates (Leiknes
49 et al., 2016; Pond et al., 1996), survival of larval (Copeman and Laurel, 2010) and juvenile fishes
50 (Bell et al., 1995), and lower overall ecosystem productivity (Litzow et al., 2006).
51 The relative amounts of specific FA vary among phytoplankton taxa (Cañavate, 2019;
52 Parrish, 2013), thus changes in phytoplankton community compositions induce shifts in the
53 dietary FA pool available for consuming organisms (Galloway and Winder, 2015). The
54 association between specific FA and certain taxonomic groups also make FA useful biomarkers
55 (Dalsgaard et al., 2003). Yet, the utility of FA biomarkers to partition phytoplankton taxa is
56 known primarily from monoculture experiments (Cañavate, 2019; Dunstan et al., 1993;
57 Jónasdóttir, 2019). Using FA biomarkers to distinguish phytoplankton taxa in field samples is
58 more challenging (Reuss and Poulsen, 2002), variable and less studied (Galloway and Budge,
59 2020; Marmillot et al., 2020). Nonetheless, field studies in other high latitude systems, such as
60 the Beaufort Sea (Connelly et al., 2016; Marmillot et al., 2020), West Greenland Sea (Reuss and
61 Poulsen, 2002), and Barents Sea (Falk-Petersen et al., 1998) have highlighted that changes in
62 phytoplankton compositions, including seasonal shifts from diatoms to flagellates, can be visible
63 in the seston FA pools. Beyond the primary association with a specified phytoplankton
64 taxonomic group, individual FA biomarkers vary with environmental conditions (Sushchik et al.,
65 2004). Although FA provide valuable information about food quality, they are often not
66 diagnostic or species-specific but should rather be viewed as indicative of dominance from broad
67 taxonomic groups (i.e., predominance of diatoms versus flagellates; (Jónasdóttir, 2019),
68 particularly when analysis field data. Therefore, additional species information from microscopy

imaging techniques are also beneficial to validate observed FA biomarker patterns (Marmillot et al., 2020).

Here we use FA biomarkers as indicators of changing phytoplankton community compositions, and of basal resource quality for higher trophic level consumers. We analyzed suspended particulate matter (seston) FA, chlorophyll-a (Chl-a), phytoplankton taxonomic data, and environmental data from four surveys spanning the northern Bering-Chukchi Sea region, two during spring (June) in 2017 and 2018 and two during late summer (August/September) in 2017 and 2019. More specifically, we examine:

1) Seasonal and annual patterns in both absolute FA concentrations and percent FA composition;

2) the relationship between phytoplankton taxonomic data (dinoflagellates and diatoms) determined from imaging microscope analyses (FlowCAM) compared to specific FA biomarkers;

3) the relationship between individual FA biomarkers and physical, chemical, and biological variables; and

4) show how a simple model framework to predict concentrations of the diatom-sourced essential fatty acid, EPA, can provide a measure of consumer nutritional quality at an increased spatial resolution.

2. METHODS

2.1. Data collection

Four surveys were conducted in northern Bering-Chukchi Sea region as part of the Arctic Integrated Ecosystem Research Program (AIERP), during June of 2017 and 2018 (Arctic Shelf

Growth, Advection, Respiration, and Deposition Rate Experiments [ASGARD]) and during August and September (hereafter Aug/Sep) of 2017 and 2019 (Arctic Integrated Ecosystem Survey; Fig. 1). All data are publicly available in the DataONE repository (https://doi.org/10.24431/rw1k5a0). Water samples were collected from 5-12 L Niskin bottles attached to the CTD rosette. At every sampling station, total and size-fractioned (<5, 5-20, >20 μm) Chl-a (mg m^{-3}) samples were collected. Total Chl-a samples were collected at 10 m intervals (~5-6 depths) and filtered through 25 mm Whatman GF/F filters (nominal pore size 0.7 μm). Size-fractionated samples were collected at 2-3 depths using a stacked filtration unit, using 47 mm Whatman GF/F filters for <5 μm, and 47 mm polycarbonate filters with a pore size of 5 and 20 μm, to sample the 5-20 and >20 μm large size fractions. Filters were stored frozen (−80 °C) and analyzed within 6 months with a bench top fluorometer following standard methods (Parsons, 1984). Samples for dissolved inorganic nutrients (nitrate, nitrite, ammonium, phosphate, and silicic acid; μmol kg^{-1}) were collected from each Niskin bottle, filtered through 0.45 cellulose acetate filters, and frozen. Samples were analyzed on a Seal AA3 or Seal AA500 continuous segmented flow analyzer following methods in (Gordon et al., 1993). Ammonium was analyzed using the OPA method (Holmes et al., 1999). At every other station, seston was sampled at 1-2 depths for FA analysis (n =167). Vertical profiles of temperature and salinity were collected from surface to near-bottom at each station using a Sea-Bird Electronics (SBE) 9+ CTD, data processed and averaged into 1-m bins.

Phytoplankton community samples were analyzed for cell abundance using Fluid Imaging Technologies VS Series benchtop FlowCAM (hereafter referred to as FlowCAM) using a 10× objective and 200 μm flow cell in autoimage mode (Álvarez et al., 2014). Samples were counted from surveys in June 2017 and Aug/Sep 2017. Images were grouped into diatoms or

115 dinoflagellates. Diatoms were imaged in both June and Aug/Sep 2017, while dinoflagellates
116 were imaged only in Aug/Sep 2017. Biovolumes of cells were estimated from images using the
117 biovolume estimation function (cylindrical shape) in the VisualSpreadsheet (Scarborough, ME)
118 software provided with the instrument. These estimates compared well with manual estimates of
119 biovolume using standardized shapes and appropriate geometric equations (Menden-Deuer and
120 Lessard, 2000). FlowCAM biovolumes of diatoms and dinoflagellates were compared to
121 concentrations of the FA biomarkers of diatoms and dinoflagellates, and the ratio of DHA: EPA.
122
123 2.2. Fatty acid analyses
124 We collected FA seston samples, which comprise all living and non-living material
125 between 0.7-200 μm, such as phytoplankton, heterotrophic protists, bacteria, mesozooplankton
126 eggs and nauplii, and detritus. During sampling in June and Aug/Sep, phytoplankton commonly
127 constitute the majority of the seston material (Connelly et al., 2016; Hama, 1999) and thus the
128 majority of the seston FA can be attributed to phytoplankton FA. Water samples ranging in
129 volume from 2 L to 6 L were collected for seston fatty acid analysis on each of the four Arctic
130 surveys. Samples were collected from the surface, Chl-a maximum, or at near-bottom depths.
131 Seawater was prescreened through a 200 μm Nitex mesh into 2L sample bottles (1-3 bottles per
132 sample). Each bottle was filtered onto a pre-combusted Whatman 47 mm GF/F filter (0.7 μm
133 nominal pore size), and sample filters were stored aboard the ship at -80°C. Samples were
134 shipped frozen on dry ice to the Hatfield Marine Science Center (HMSC) in Newport, Oregon,
135 and analyzed at the Marine Lipid Ecology Laboratory. To obtain sufficient material, some filters
136 were combined for each sampling depth (1-3 filters), placed into lipid-clean glass tubes and
137 stored in chloroform under nitrogen for less than 3 months prior to extraction. Lipids were

138 extracted using a modified Folch procedure (Folch et al., 1957) using 2:1 chloroform: methanol
139 as described by Parrish et al. (1999). A total of 167 seston samples were processed for FA
140 analyses. An internal standard (23:0 methyl ester) was added to all samples at approximately
141 10% of the total FA concentration, and total lipid extracts were derivatized into their fatty acid
142 methyl esters (FAMEs) using sulphuric acid-catalyzed transesterification (Budge et al., 2006).
143 Resulting FAMEs were analyzed on an HP 7890 GC FID equipped with an autosampler
144 and a DB wax+ GC column (Agilent Technologies, Inc., U.S.A.). The column was 30 m in
145 length, with an internal diameter of 0.25 mm and film thickness of 0.25 μm. The column
146 temperature began at 65 °C and held this temperature for 0.5 min. Temperature was increased to
147 195 °C (@ 40 °C min^{-1}), held for 15 min then increased again (@ 2 °C min^{-1}) to a final
148 temperature of 220 °C, where it was held for 1 min. The carrier gas was hydrogen, flowing at a
149 rate of 2 ml min^{-1}. Injector temperature was set at 250 °C and the detector temperature was
150 constant at 250 °C. Peaks were identified using retention times based upon standards purchased
151 from Supelco (37 component FAME, BAME, PUFA 1, PUFA 3) and in consultation with
152 retention index maps performed under similar chromatographic conditions as our GC-FID
153 (Wasta and Mjøs, 2013). Column function was checked by comparing chromatographic peak
154 areas to empirical response areas using a quantitative FA mixed standard, GLC 487 (NuCheck
155 Prep). Chromatograms were integrated using Chem Station (version A.01.02, Agilent). Select
156 samples were run in triplicate and the coefficient of variation for peaks >1% of the sample, were
157 less than one.
158
159 2.3. Statistical and data analyses

Absolute FA concentrations, the amount of seston FA per volume seawater (reported as mg m^{-3}), were used to infer overall availability of FA as basal resources for consumers. FA data were calculated as percent of total fatty acids, which is a useful metric for quantifying phytoplankton compositional changes in the seston. FA were classified as C:Bn-P, where C is the number of carbon atoms, B the number of double bonds and P the position of the first double bond from the methyl group end (Budge et al., 2006). We considered two aspects of phytoplankton FA composition. Firstly, we focused on phytoplankton biomarkers, such as those indicative of diatoms: 16:1n-7, 16:4n-1, EPA (20:5n-3) and a composite diatom biomarker based on the ratio of 16:1n-7/16:0 (Budge and Parrish, 1998; Dalsgaard et al., 2003). Flagellates are a diverse group, including small autotrophic flagellates, heterotrophic flagellates and dinoflagellates. Therefore, we refer to the biomarkers 18:4n-3, 18:5n-3 and DHA (22:6n-3) as a combination of flagellate and dinoflagellate (dino+flag) FA biomarkers, due to the difficulty in partitioning among these groups using FA biomarkers alone. Secondly, we focused on long-chain PUFA (C_{20+22}) such as EPA and DHA, that are essential in the diet of secondary consumers. In addition, we assessed the ratio of DHA to EPA to denote relative dino+flag: diatom biomarkers in the samples, and a bacterial biomarker, here the sum of all odd carbon FA and branched FAs (Kaneda, 1991).

Type II regressions using $\log_{10}$-transformation were used to assess pairwise relationships between FA seston concentrations, and biological and physical variables including temperature, salinity, nutrients, and total and size-fractioned Chl-a concentrations. One-way Analysis of Variance (ANOVA) with associated post-hoc Tukey Honestly Significant Difference (HSD) was used for group comparisons, such as between seasons, years, depth category (above, below or in the mixed layer) and water mass designations (warm shelf water, cool shelf water, Anadyr water,

183 modified winter water and warm coastal water, Danielson et al., 2020). ANOVA models were
184 assessed for normality and homogeneity of variances of the residuals and variables were log_{10}-
185 transformed when necessary. Non-metric multidimensional scaling (nMDS) using Bray-Curtis
186 distances was used to assess multivariate patterns of the FA percent data, using all FA that
187 constituted more than 1% of the total FA, and the groups saturated FA (SFA), monounsaturated
188 FA (MUFA), PUFA and Bacterial FA.

189 Linear mixed effects models (Zuur et al., 2009) were used to assess how multiple
190 physical and biological parameters influence the FA composition of seston samples, and then to
191 develop a simple model framework that allows prediction of water column (0-50 m) integrated
192 EPA (mg m^{-2}) concentrations over broader spatial or temporal scales. For each FA biomarker a
193 full linear mixed effects model included the following predictor variables: total Chl-a,
194 temperature, nitrogen (sum of nitrate and ammonium), salinity and depth (a categorical variable
195 as described earlier) parameters that are all known to influence FA compositions (Budge et al.,
196 2014; Galloway and Winder, 2015). The different surveys were included as a random effect
197 because we expected that relationships between FA and environmental variables were likely to
198 be independent among years and season. For all models, inspections of residual plots did not
199 reveal obvious deviances from normality or homoscedasticity after log-transformation of
200 variables. In cases of multicollinearity (variance inflation factor (VIF) > 5), we retained only one
201 of those values in the final analysis.

202 Mixed effects models were performed for the following biomarkers: the ratio of DHA:
203 EPA, the ratio of PUFA: SFA, and FA percentage data for diatom biomarkers 16:4n-1 and EPA,
204 and dino+flag biomarkers 18:5n-3 and DHA. We followed the recommendations in (Zuur et al.,
205 2009) for fitting FA mixed effects models. First, the optimal random effect structure (which

206 could be no random effect) was fitted for the full model using restricted maximum likelihood
207 estimation. Second, we used maximum likelihood estimation to determine the most parsimonious
208 fixed effect model structure, with the optimal random structure as determined in step one.
209 Finally, the most parsimonious model for each FA, which included the optimal random and fixed
210 effect structures, was re-fitted with restricted maximum likelihood estimation. Determination of
211 the most parsimonious model in each step was decided using Akaike Information Criterion
212 corrected for small sample sizes (AICc, Burnham and Anderson, 2002). In the instances where
213 more than one model had similar AICc scores (<1 AICc), we chose the model with the lower
214 number of explanatory variables. For simplicity, we report only the final parsimonious model for
215 each FA biomarker in the results.
216 To predict integrated EPA (mg m^{-2}) concentrations, we used a mixed effects model to the
217 EPA concentration data. Because the biological, chemical and physical survey data was sampled
218 at a higher vertical and spatial sampling resolution compared to the FA sampling, these models
219 allowed for predicting integrated water column EPA concentrations for all survey stations.
220 Predictive models were computed using natural log-transformed data, thus a correction was
221 applied to re-convert predicted FA concentrations (Duan, 1983). All analyses were done using R
222 version 3.6 (R Core Team, 2018). Mixed effects models were fitted using the "*nlme*" package
223 (Pinheiro et al., 2017), AICc using the "*AICcmodavg*" package (Mazerolle and Mazerolle, 2019),
224 and type II regressions were computed using the "*smatr*" package (Warton et al., 2012).
225
226 **3. RESULTS**
227 3.1. Spatial patterns of Chl-a and FA concentrations.

228 Generally, areas of higher than average Chl-a were spatially associated with higher total
229 FA concentrations. Average water column (0-50 m) Chl-a measurements were higher in June
230 2017 and 2018 compared to Aug/Sep 2017 and 2019, though high variability existed among
231 stations and across all surveys (Fig. 1). Elevated water column average Chl-a concentrations (>6
232 mg m^{-3}) were present north of St. Lawrence Island within and north of the Bering Strait in both
233 June 2017 and 2018, areas that similarly showed elevated (> 15 mg m^{-3}) concentrations of total
234 FA. Total Chl-a concentrations had significant positive correlations with both the ratio of large
235 (> 5 μm) to small (< 5 μm) particle Chl-a, and the > 20 μm size-fractioned concentrations (Table
236 S1), indicating that communities were comprised of large phytoplankton in areas with high
237 concentrations of total Chl-a.
238
239 3.2. Seasonal dynamics of FA biomarkers
240 Total FA concentrations (mean±SD) in June 2017 were significantly higher than all other
241 surveys (average across stations: 28.2±21.1 mg m^{-3}, $p<0.05$, Tukey HSD, Figs. 1, 2A), followed
242 by FA concentrations in June 2018 (22.2±16.9 mg m^{-3}), Aug/Sep 2019 (18.8±16.5 mg m^{-3}), and
243 Aug/Sep 2017 (12.1±5.4 mg m^{-3}). Overall SFA, and MUFA concentrations were higher in June
244 compared to Aug/Sep (Fig. 2A), however percent PUFA levels were highest in Aug/Sep 2019
245 (Fig. 2D). The diatom biomarkers 16:1n-7, 16:4n-1, and EPA all varied significantly among
246 season and year (Tukey HSD, $F(3,163) = 10.6$, 4.2, and 4.3, respectively, $p< 0.05$, Fig. 2B).
247 Concentrations of 16:1n-7 and 16:4n-1 and EPA were significantly higher in June than in
248 Aug/Sep except for EPA, were values in Aug/Sep 2019 were similar to values in June. The
249 diatom biomarkers (percentage of 16:1n-7, 16:4n-1 and EPA, Fig. 2E) showed similar patterns to
250 the concentration data.

The concentration of dino+flag-associated biomarkers 18:5n-3(0.8± 1.0 mg m^{-3}) and DHA (1.5± 1.6 mg m^{-3}) were significantly higher in Aug/Sep 2019 compared to all other surveys (Tukey HSD, $p<0.05$, Fig. 2C). The dino+flag biomarker 18:4n-3 was significantly higher in Aug/Sep 2019 than in Aug/Sep 2017 (Tukey HSD, $p<0.05$), but otherwise showed no difference among seasons and years. The dino+flag percent FA data and the sum of n-3 PUFA showed overall similar patterns to the concentration data, with Aug/Sep 2019 values being the highest (Fig. 2F). Resultant DHA: EPA ratios were significantly higher in Aug/Sep compared to June (Tukey HSD, $p<0.05$, Fig. 2C). The diatom biomarkers of EPA, 16:1n-7, and 16:4n-1 were all correlated positively for both the concentration (Table S1) and percentage data (Table S2). Similarly, DHA correlated well with the dino+flag biomarkers 18:4n-3 and 18:5n-3 for both the concentration and percentage data (Table S1-S2).

Multivariate nMDS analysis of the FA percentage composition data similarly showed clear differences among seasons and years (Fig. 3). FA biomarkers most responsible for the separation of seasons were diatom biomarkers (i.e., 16:1n-7, 16:2n-4, 16:4n-1 and EPA), which appeared to be more highly associated with the June 2017 and 2018 samples. In contrast, dino+flag markers (i.e., 18:3n-3, 18:4n-3, 18:5n-3, and 22:6n-3) were more closely associated with the Aug/Sep 2017 and 2019 samples. However, substantial variability of the FA compositions within each survey also indicate clear spatial differences in phytoplankton communities across years and seasons.

3.3. Taxonomic comparison of FA biomarkers and FlowCAM images

FlowCAM-measured diatom and dinoflagellate biovolumes correlated positively with their taxa-associated FA biomarkers. Significant positive correlations were observed between

$\log_{10}$-transformed diatom biovolumes and FA concentrations of EPA (Fig. 4A, $r^2 = 0.41$, $p < 0.01$, df = 38), 16:1n-7 (Fig. 4C, $r^2 = 0.45$, $p < 0.01$, df = 38), and 16:4n-1 (Fig. 4E, $r^2 = 0.46$, $p < 0.01$, df = 38) in June 2017 and Aug/Sep 2017. However, when analyzing only the Aug/Sep 2017 diatom data, correlations were not significant ($p > 0.05$, df = 20). Dinoflagellate biovolumes correlated positively with FA concentrations of DHA (Fig. 4B, $r^2 = 0.51$, $p < 0.01$, df = 20) and 18:5n-3 (Fig. 4D, $r^2 = 0.55$, $p < 0.01$, df = 20) in June 2017. Additionally, the ratio of DHA to EPA correlated positively with the FlowCAM-measured ratio of dinoflagellate to diatom biovolumes (Fig. 4F, $r^2 = 0.45$, $p < 0.01$, df = 20) in June 2017.

3.4. Associations between FA biomarkers and environmental variables

Next, we analyzed associations between the individual environmental variables and the FA concentration and percentage biomarkers using $\log_{10}$-transformed data from discrete samples. Some of the main primary pairwise correlations shown in Figure 5 and highlighted below, while all regressions are presented in Table S1 and Table S2.

Overall, the majority of the concentrations of individual FA correlated positively and significantly with total and size-fractionated (<5 µm, 5-20 µm, >20 µm) Chl-a data (Fig. 5A-F, Table S1). The strongest relationship for total FA was with total Chl-a and >20 µm fraction ($r^2 = 0.52$, $p<0.01$), which in turn were highly correlated ($r^2= 0.90$, $p<0.01$) (Fig. 5A, Table S1). Significant correlations were also found for PUFA concentrations, common diatom biomarkers 16:1n-7, and EPA with total and >20 µm Chl-a concentrations (Fig. 5B-D, $r^2 = 0.37$ to 0.52, $p<0.01$, Table S1). In contrast, dino+flag biomarkers 18:5n-3, 18:4n-3 and DHA had the highest correlations with small size fractions of Chl-a (< 5 um) ($r^2 = 0.36$ to 0.67, $p<0.01$, Table S1); positive but weaker correlations were also found with total Chl-a (Fig 5.E, $r^2 = 0.05$ to 0.23,

297 $p<0.05$). Nutrients correlated negatively with temperature and positively with salinity (Fig. 5G,
298 Table S1). We found few significant relationships between FA concentrations and temperature,
299 salinity, and nutrient concentrations and those were weak (Table S1). DHA: EPA ratios were
300 lowest in cold, high salinity waters (Fig. 5H) and correlated negatively with nitrate
301 concentrations (Fig. 5I, $r^2 = 0.31$, $p<0.01$, Table S1).

302 Overall, the percentage FA results suggested that diatoms are higher in relative biomass
303 in colder, high salinity waters and in areas of higher nitrate (Table S2). dino+flag FA biomarker
304 percentages were higher in warmer waters, shallower depths, and in areas with low nutrient
305 concentrations (Table S2). Total and large (>20 μm) size-fractioned Chl-a correlated positively
306 with the percentage diatom biomarkers (16:1n-7, 16:4n-1, 16:2n-4, and EPA) but negatively with
307 the percent contribution of dino+flag-associated FA biomarkers (18:4n-3, 18:5n-3, and DHA)
308 and the ratio of DHA to EPA (Fig. 5F, Table S2). Percentage diatom FA biomarkers associated
309 negatively with the dino+flag and SFA. The percentage contribution from bacterial FA
310 biomarkers correlated positively with the diatom biomarkers, >20 μm, and 5-20 μm and total
311 Chl-a, but negatively with several dino+flag biomarkers. For both the percentage and
312 concentration data, the patterns observed for all 4 surveys combined were generally also visible
313 within each survey (data not shown).

314 Mixed effects models using the FA percentage data showed that several environmental
315 variables influence FA phytoplankton dynamics. The most parsimonious mixed effects models
316 consistently included survey as a random effect. All statistical values are reported in Table S3;
317 below we report the main findings. Percent EPA contribution correlated positively with total
318 Chl-a concentrations and with vertical depth position (Table S3). EPA values were higher below

319 the mixed layer and though the effect of vertical position was included in the final model, its
320 influence was minor (i.e., delta AICc with the vertical position included or not, was small).
321 The diatom biomarker 16:4n-1 showed a significant positive relationship with total Chl-a
322 and nitrogen concentration but a negative relationship with temperature. Percent DHA was
323 positively related to total Chl-a, but negatively related to nitrogen concentrations (Table S3). The
324 dino+flag marker 18:5n-3 was negatively related to both total Chl-a and nitrogen concentrations.
325 DHA: EPA ratios also were negatively related to Chl-a and nitrogen concentrations, while
326 relating positively with salinity and temperature. The ratio of PUFA: SFA increased with Chl-a
327 concentrations, but decreased with nitrogen concentrations and temperature (Table S3).
328 Lastly, we used a mixed effects model to enable predictions of absolute EPA
329 concentrations (Fig. 6). The most parsimonious model, assessed using AICc, included log-
330 transformed total Chl-a and log-transformed nitrogen (sum of nitrate and ammonium) as the
331 fixed effect and a random structure consisting of an interaction of Chl-a and survey (Table S4).
332 Model prediction of EPA correlated overall strongly with measured EPA concentrations (r^2 =
333 0.63, $p < 0.01$, df = 151, Fig. S1A). Variability and thus uncertainty of EPA model predictions
334 were highest in samples with total Chl-a concentrations >5 mg m^{-3} (Fig. S1B). Water column
335 integrated EPA concentrations differed significantly among all four surveys (Fig. 6, Tukey HSD,
336 $p<0.05$), with average values highest in June 2018 (93 ± 60 mg m^{-2}), followed by June 2017 (66
337 ± 46 mg m^{-2}), Aug/Sep 2019 (54 ± 30 mg m^{-2}), and Aug/Sep 2017 (30 ± 8 mg m^{-2}). Throughout,
338 there was high spatial variation in the predictions with the highest concentrations reaching levels
339 of 264 mg m^{-2} and 241 mg m^{-2} in June 2017 and 2018, while highest values in Aug/Sep 2017
340 were 54 mg m^{-2} and 198 mg m^{-2} in Aug/Sep 2019.
341

4. DISCUSSION

Seston FA biomarkers reflected phytoplankton community shifts from diatoms dominating in spring followed by late summer increases of dinoflagellates and small flagellates. High total FA and PUFA concentrations in late spring (June) primarily synthesized by diatoms suggest that phytoplankton FA from this time period provide important dietary subsidies for consumers (Grebmeier et al., 2006). Diatom and dinoflagellate biovolume measurements from FlowCAM images correlated positively with their respective FA biomarkers, confirming that in general FA compositional data can provide reliable information on phytoplankton community dynamics. Measured phytoplankton FA composition (concentrations and percentages) varied with changes in temperature and nutrients, likely due to a combination of species-specific changes in physiology as well as changes in the phytoplankton community composition (Grosse et al., 2019; Jiang and Gao, 2004). Lastly, derived EPA concentrations based a model using commonly sampled survey data (e.g., temperature, nitrogen, and Chl-a) may provide broad-scale water column integrated estimates of dietary EPA availability for consumers in the northern Bering and Chukchi Sea ecosystems.

4.1 FA biomarker and FlowCAM estimates of diatoms and dinoflagellates

Taxonomic information from microscopy imaging techniques generally confirmed that observed FA biomarker patterns can be associated with major phytoplankton taxa groups. Although FlowCAM-measured diatom and dinoflagellate biovolumes correlated positively with diatom and dinoflagellate FA biomarker concentrations, these data also revealed substantial unexplained variance. The combined June and Aug/Sep 2017 data yielded significant trends for diatom biovolumes and their FA biomarkers (16:1n-7, 16:4n-1 and EPA) however, similar

365 diatom trends were insignificant when using only samples from Aug/Sep 2017. Whether the lack
366 of clear correlation was due to variable FA concentrations among diatoms species, less
367 dominance of this taxa compared to spring samples, variable environmental conditions (Sushchik
368 et al., 2004), or FA contributions from other phytoplankton groups is unclear. For example,
369 *Synechococcus,* which can contain 16:1n-7 (Jónasdóttir, 2019), were observed in up to 20% of
370 the phytoplankton carbon biomass during Aug/Sep 2017 (data not shown). Similarly,
371 chlorophytes containing 16:4n-1, or chlorophytes and cryptophytes containing EPA (Jónasdóttir,
372 2019), could have contributed to the FA pools of the diatom associated biomarkers.
373 Differentiating between dinoflagellates, heterotrophic flagellates and flagellates using FA
374 biomarkers alone is challenging. The observable trends between 18:5n-3 and DHA with
375 dinoflagellate identified from the FlowCAM suggest that noticeable FA contributions at least
376 partially originated from dinoflagellates, however, small flagellates, not measured with the
377 FlowCAM analysis, may also be important. Dinoflagellate and small flagellates often co-occur.
378 Higher percentages of 18:1n-9 and 18:0 in some Aug/Sep 2017 samples could indicate increased
379 contributions from smaller flagellates (Reuss and Poulsen, 2002), but these quite ubiquitous FAs
380 that are also present in several other taxa (Cañavate, 2019). The significant association between
381 dinoflagellate biovolumes and their specific FA biomarkers (DHA, 18:5n-3) differ from a recent
382 study by Marmillot et al. (2020) which found no significant relationships for dinoflagellates. We
383 speculate that these differences may be explained by the fact that flagellates are a diverse group
384 of organisms including auto, mixo and heterotrophic species, which can vary substantially in
385 their FA signatures depending on their diet intake and responses to environmental conditions.
386 Overall, and despite considerable variation, our results are in general agreement with previous
387 field studies (Marmillot et al., 2020; Reuss and Poulsen, 2002; Sushchik et al., 2004) and

388 highlights the utility of FA biomarkers for depicting relative contributions of major
389 phytoplankton taxonomic groups.
390
391 4.2. Factors influencing seston FA dynamics
392 Shifting environmental conditions influence seston FA dynamics through both individual
393 phytoplankton species and community composition responses (Cañavate et al., 2019; Miller et
394 al., 2017). Seasonal environmental shifts were clearly visible in the FA biomarkers, with highest
395 abundances of diatom FA in spring followed by increasing dino+flag FA in late summer. These
396 seasonal shifts agree well with phytoplankton taxonomic analysis from the northern Bering and
397 Chukchi Seas (Laney and Sosik, 2014; Lee et al., 2019; Sukhanova et al., 2009) and with FA
398 biomarker studies in other Arctic regions (Connelly et al., 2016; Falk-Petersen et al., 1998). Chl-
399 a concentration was the primary predictor variable for the concentrations of almost all FA
400 biomarkers. These linkages were particularly strong between absolute concentrations of the
401 diatom biomarkers, 16:4n-1, 16:1n-7 and EPA, and the total and the large (>20 μm) size fraction
402 Chl-a. The high positive correlation of >20 μm with total Chl-a suggests that large phytoplankton
403 primarily of diatom origin were driving changes in total Chl-a concentrations.
404 Temperature and nitrogen concentrations also influenced the percentage FA patterns.
405 Temperature correlated negatively with the ratio of PUFA to SFA, a pattern that is likely driven
406 by decreasing PUFA concentrations with warming (Hixson and Arts, 2016; Jiang and Gao,
407 2004), due to both individual species and community compositional responses to variable
408 environmental conditions (Hixson and Arts, 2016). Relative concentration of dino+flag
409 biomarkers increased with decreasing nitrogen concentrations, warmer temperatures and lower
410 salinity, supporting that dinoflagellates and small flagellates are commonly more prevalent in

411 low nutrient environments as observed during summer in the eastern Bering Sea (Moran et al.,
412 2012; Sukhanova et al., 2009). Differences in residual nutrient concentrations among water
413 masses are associated with different phytoplankton communities (Danielson et al., 2017), which
414 likely explain the higher percentages of FA diatom biomarkers in colder, more saline, nutrient-
415 rich waters. Differences in FA compositions with depth also indicate that diatoms are more
416 prevalent in deeper, higher nutrient waters near the subsurface Chl-a maximum which are
417 common phenomena in summer in these ecosystems (Lowry et al., 2015; Martini et al., 2016). In
418 contrast, higher abundance of FA dino+flag biomarkers occurred closer to the surface in waters
419 with lower nutrient concentrations, where they may have an advantage compared to, for example
420 diatoms. Higher surface area to volume ratios of small flagellates allow enhanced access to
421 nutrients at low concentrations (Edwards et al., 2012), while many dinoflagellates maintain
422 higher growth by migrating daily from deeper, nutrient rich water to the surface (Jephson and
423 Carlsson, 2009) and also engage in heterotropy.
424
425 4.3. Importance of dietary FA for consumers
426 Variation in plankton communities and their nutritional quality (i.e. lipid and essential
427 FA) influence spatiotemporal trends in food quality available to consumers (Twining et al.,
428 2016). The availability of essential EPA strongly influences copepod nauplii growth rates
429 (Leiknes et al., 2016), fish (Copeman and Laurel, 2010), juvenile crab (Copeman et al. 2021),
430 benthic organisms (Schollmeier et al., 2018) and overall ecosystem production (Litzow et al.,
431 2006). Using ancillary data from all four surveys, we calculated water column integrated spatial
432 predictions of EPA concentrations. Overall, the modeled EPA predictions compared well to
433 measured EPA concentrations. Modeled EPA data may provide a first step towards a broader

434 characterization of dietary availability of essential FA in these ecosystems. Overall, predicted
435 EPA concentrations were highest in spring with lower concentrations in late summer,
436 particularly Aug/Sep 2017. Our mixed effects model analyses also show that FA spatial
437 predictions vary between seasons and years, as "survey" was a significant explanatory variable in
438 the model. Survey should be considered a proxy for seasonal and inter-annual changes in the FA
439 pools associated with the phytoplankton community composition. Thus, predictive power
440 increases when accounting for inter- and intra-annual differences in FA composition patterns,
441 and best results are retrieved if model predictions are coupled with a smaller subset of FA
442 phytoplankton information from the specific year in question. Additional improvements of the
443 current model framework would be inclusion of data from colder years that may have noticeably
444 different phytoplankton communities (Hill et al., 2005) compared to the years 2017-2019, and
445 laboratory studies of regional zooplankton or benthic invertebrate (e.g., crabs, Copeman et al.
446 2021) growth and reproduction rate responses to dietary availability of essential EPA.
447 An expected future consequence of warming and increased stratification is a shift in
448 phytoplankton community structure towards smaller sized cells (Morán et al., 2010) and a
449 prospective decrease in PUFA concentrations (Hixson and Arts, 2016). Such shifts in FA
450 compositions are due to a combination of direct physiological effects on phytoplankton FA
451 synthesis as well as due to phytoplankton community shifts. How changing sea ice phenology
452 and the resulting effects on ice-associated phytoplankton (Clement Kinney et al., 2020), and
453 spring and summer open water blooms influences the availability of carbon and thus important
454 dietary FA in the northern Bering and Chukchi Sea ecosystems, remains an open question. Our
455 analyses and model framework provide new regional baseline information on phytoplankton FA

seasonal and inter-annual variations. Such information will increase the ability to evaluate the impacts of changing dietary lipid on higher trophic level consumers at broader spatial scales.

DECLERATION OF COMPETING INTEREST

The authors declare no known competing financial interests or personal relationships that could have appeared to influence the work reported in this manuscript.

ACKNOWLEDGEMENTS

We are grateful to Brendan Smith, Miranda Irby, Ed Farley, Anna Mounsey, Haley Cynar, Jeff Krause, Harmony Wayner, and Steven Baer for help during field sampling, for analysis of the nutrient data, and the crews of the *R/V's Ocean Star* and *Sikuliaq*. We are thankful to Lauren Rogers for help with mixed effects models and comments from Jeanette Gann and Fletcher Sewall that substantially helped improve the manuscript. We thank Carlissa Salant Michelle Stowell and Jami Ivory for general analytical assistance in the Marine Lipid Ecology Lab in Newport, OR, and the funding sources; NPRB Arctic IERP (Arctic IES LTL (A92), ASGARD, Phytoplankton Gap proposal (A96), National Science Foundation Office of Polar Programs award numbers OCE-1603460 (ML)). The findings and conclusions in this paper are those of the authors and do not necessarily represent the views of the National Marine Fisheries Service, NOAA. Reference to trade names does not imply endorsement by the National Marine Fisheries Service, NOAA. This is EcoFOCI contribution number EcoFOCI-1005 and PMEL contribution number 5325. This publication was partially funded by the Cooperative Institute for Climate, Ocean, & Ecosystem Studies (CIOCES) under NOAA Cooperative Agreement NA20OAR4320271, Contribution No 2021-1168.

Zooplankton communities of the Arctic's Bering Strait region during the spring bloom, 2017-2018

Russell R. Hopcroft & Caitlin A. Smoot

Institute of Marine Sciences, University of Alaska Fairbanks

Introduction

The Bering Strait region is an important transition zone between the Pacific and Arctic Oceans, being a significant conduit of heat, fresh water, nutrients and entrained plankton (Grebmeier and Maslowski 2014). Four decades ago, it was estimated that 1.8 million metric tons of Bering Sea mesozooplankton were carried into the Chukchi Sea annually (Springer et al. 1989), that were responsible for the higher productivity of the Chukchi Sea than any adjacent regions of the Arctic Ocean. The pronounced changes in sea ice cover that have been occurring for the past two decades (Danielson et al. 2020) are anticipated to have significant consequences on the productivity, function and biodiversity of Arctic regions (Post et al 2013), with consequences for higher trophic levels of subsistence importance (Huntington et al 2020).

Planktonic communities have been shown to serve as useful "beacons of climate change" (Richardson, 2008) due to relatively rapid response changing temperatures and their strong coupling to water mass characteristics. There is now a large body of literature for the Chukchi and Bering Seas that demonstrates the close relationship of zooplankton community structure to water mass distribution (e.g. Hopcroft et al. 2010, Questel et al. 2013, Ershova et al. 2015a, Eisner et al. 2017, Abe et al. 2020), the general occurrence of multiple waters masses within the region, and the Pacific faunal character of much of the Chukchi during late summer. It is however notable that most of these studies have occurred during late summer, when the region is largely ice-free and planktonic productivity is in decline. Thus, we have limited information on what this ecosystem looks like during the spring bloom period that occurs several months in advance of our current window of knowledge. The dynamics of bloom period, both in terms of water temperature and primary productivity, fundamentally shape the magnitude and phenology of the zooplankton community. This in turn alters the fate of phytoplankton export to the seafloor verses retention of carbon within the water column for the remainder of the seasonal cycle.

To address this deficiency, the Arctic Shelf Growth, Advection, Respiration and Deposition Rate Experiments (ASGARD) conducted a pair of cruises in June of 2017 and 2018 to examine the structure and function of communities during the bloom. The broad-scale survey of the zooplankton communities at those times provides context for the vital rates determined within those communities as summarized elsewhere within this report.

Methods

Surveys for zooplankton community assessment during June 2017 and 2018 used a similar set of stations, albeit with fewer of them occupied during the second year (Fig. 1). Smaller-bodied zooplankton were collected with a vertically-hauled 60-cm diameter twin-ring net fitted with 150-µm nets pulled at ~0.5 m s^{-1}. Larger-bodied and more mobile zooplankton were targeted with an obliquely-towed 60-cm diameter Bongo net fitted with 505-µm nets pulled at ~0.5 m s^{-1}. Both nets samples from within 3-5 m of

the seafloor to the surface. Nets were outfitted with annually calibrated flowmeters to estimate volume of water filtered, with ratcheted meters in vertical that only record flow during ascent. Samples were preserved in 10% buffered formalin and returned to the laboratory for processing.

During laboratory processing, samples were subsampled using a Folsom splitter until a given aliquot contained approximately 100 individuals of the most abundant taxa. Increasingly larger fractions were examined for less abundant taxa. Organisms were identified, enumerated, lengths measured, and when appropriate, staged to determine species composition, abundance, and biomass. Typically, 400–600 animals were examined within each sample and organisms were identified to lowest taxonomic level possible. Community similarity was assessed using the Bray-Curtis similarity, and community structure was explored with hierarchical cluster analysis and non-parametric Multi-Dimensional Scaling (nMDS) routines using PRIMER (Clarke et al. 2014).

Results

The zooplankton community was dominated by the copepods *Calanus marshallae/glacialis*, *Pseudocalanus* spp., *Oithona similis*, and *Metridia pacifica* that are best assessed with the 150-µm nets. These copepods were present at nearly all stations during both 2017 and 2018 (Figs. 2-5). The copepod *Acartia* was also present across the sampling domain in both 2017 and 2018 but had a more coastal signal (Fig. 6). We observed higher abundances of Pacific-affinity copepods (*Neocalanus* spp. and *Eucalanus bungii*) in 2017 compared to 2018 (Fig. 7). Multivariate analyses of the combined 2017 and 2018 150-µm datasets revealed five major community groupings (Fig. 8). Group 1 consisted of stations in the northern portion of the sampling domain in 2017. Group 2 consisted of stations to the northwest of St. Lawrence Island in 2017. These stations were characterized by higher abundances of Pacific-affinity copepods, such as *Neocalanus flemingeri*, compared to other groups (Fig. 9). Group 3 consisted primarily of coastal stations in the northern part of the sampling domain in 2017. Group 4 was the largest group, containing stations from both 2017 and 2018. Most stations sampled in 2018 belonged to Group 4. Group 5 also consisted of stations from both 2017 and 2018, and was composed of primarily coastal stations and stations in the southeastern portion of the sampling domain near Norton Sound. The cladocerans *Podon leuckartii* and *Evadne nordmanni* were found nearly exclusively at stations in Group 5 (Fig. 10), characteristic of freshened surface waters. The *Pseudocalanus* spp. population was composed of copepodites in all life stages in both years, but with slightly higher proportion of younger copepodites (Stages 1 & 2) in 2018 (Fig. 11). The *Calanus marshallae/glacialis* population also had a higher proportion of younger copepodites in 2018 (Fig. 12). *Metridia pacifica*, in contrast, did not show a clear dominance of younger copepodite stages (Fig. 13).

Euphausiids, composed of several *Thysanoessa* species, were present across the sampling domain in both years, with slightly higher abundances observed in 2017 (Fig. 14). The euphausiids were also primarily composed of larval calyptopsis and furcilia stages in both years (Fig. 15). Amphipods, decapods, and the predatory chaetognath *Parasagitta elegans* were present in both years across the sampling domain but did not show a particular spatial pattern (Figs. 16-18). *Aglantha digitale*, a common hydrozoan, did not display a strong spatial pattern (Fig. 19). There was often a significant biomass in other jellyfish and ctenophores present in the plankton nets. Multivariate analysis of abundance data from the 505-µm net revealed similar patterns to that of the 150-µm net, although with a few more groupings (Fig. 20). The clustering of stations northeast of St. Lawrence Island observed in the 150-µm net was also

observed in the 505-µm net. Similarly, the cluster of stations in the southeastern portion of the sampling domain in 2017 was observed in the 505-µm net as well.

Abridged Discussion

Not surprisingly, zooplankton community composition observed during the ASGARD cruises was similar to that observed several months later in the season cycle by other studies (e.g. Springer et al. 1989; Questel et al. 2013, Ershova et al. 2015, Eisner et al. 2017, Abe et al. 2020). The abundance and biomass of the crustacean components of the zooplankton fell with the bounds of prior observation, as did many, but not all, gelatinous taxa. The water-mass driven structure in the zooplankton community assemblage was consistent with previously observed patterns for 2017, but not resolved for 2018. The most notable difference between our study years and observations to north was the high abundances of *Neocalanus* copepods during 2017. High abundance of *Neocalanus* was at least partially a reflection of their seasonal occurrence in surface waters of the Gulf of Alaska (Mackas & Tsuda 1999, Coyle and Pinchuk 2003) and their proximity to that source. The individuals collected at that time were lipid-rich Copepodite Stage5 – the final stage before ontological descent – thus it is unclear if they were still actively feeding at the time of our survey. Nonetheless, the large differences in abundance between years suggest greater across-shelf transport was occurring in 2017 compared to 2018.

There were also notable differences in the distribution of developmental stages within key copepod species such as *Calanus* compared to later-season studies (e.g., Ershova et al 2015), with earlier stages being more common in this study. It is notable that the stages were more advanced during 2017 when warmer water temperatures occurred compared to 2018. Further seasonal shifts toward later stage distribution are expected for *Calanus* in this region (Kimura et al. 2020). Exceptions to such stage generalizations have however been observed in the Northeastern Chukchi with early stages sometimes dominating during August when the water over the region is replaced with that originating from the Arctic's basins (Elliot et al. 2017). Developmental stage distributipm was harder to generalize for Metridia, but early stages dominate at many stations In contrast, due to low modulation in the reproductive output of *Pseudocalanus*, seasonal difference in stage distribution were not as pronounced in this genus (Kimura et al 2020), but as observed for Calanus, younger stages were more prominent during the 2018 cruise than in 2017. Euphausiids represented another such example where abundances were high during June and dominated by larval stages. Such elevated transport following the spawning period typical for sub-arctic euphausiids (Pinchuk et al. 2003) is consistent with the belief that euphausiids populations are primarily advected into the Chukchi rather than being a fully resident species (Berline et al. 2008).

ABSTRACT

Egg production and copepodite growth rates were measured for the calanoid copepods *Pseudocalanus* spp., *Calanus marshallae/glacialis*, and *Metridia pacifica* in the northern Bering and southern Chukchi Seas during June of 2017 and 2018. For all taxa, instantaneous growth rates generally decreased with increasing copepodite stage, though the differences between most stages was not significant. The growth rates for *Pseudocalanus* spp. averaged 0.03 ± 0.002 day^{-1}, *Calanus* spp. 0.09 ± 0.004 day^{-1}, and *M. pacifica* 0.05 ± 0.03 day^{-1}. Egg production rates increased with prosome length for all species, but when standardized to body weight this trend reversed. All *Pseudocalanus* species had similar weight-specific egg production (SEP): 0.18 ± 0.01 for *P. acuspes*, 0.15 ± 0.00 for *P. newmani*, and 0.11 ± 0.02 for *P. minutus*. The SEP for *Calanus* was considerably lower, 0.09 ± 0.01, while for *M. pacifica* it was 0.11 ± 0.01. These rates suggest considerable discrepancies between growth rates and egg production weights that we propose are due to differences in life history strategies. *Pseudocalanus* reproduce nearly year round, they appear to invest less in somatic growth, preferring to quickly reach their adult stage where they invest heavily into reproduction. *Calanus* spp. have 1 or possibly 2 generations per year in this region, they invest more into somatic growth in order to ensure their population is ready for a reproductive season timed to the spring phytoplankton bloom. The more omnivorous *M. pacifica* is also likely limited to 1 or 2 generations, although their ability to thrive on a wider range of food sources than *Calanus* seems to allow for relatively higher investment in reproduction and perhaps lower investment in somatic growth. Consistent with other studies, global growth models do not match our observations particularly well, likely because they are dominated by egg production estimates at lower latitudes.

ACKNOWLEDGMENTS

I would like to thank my advisor, Russ Hopcroft, for the support throughout this project. My committee member Seth Danielson and Kenneth Coyle have provided useful feedback during all components of the project. Caitlin Smoot provided invaluable support throughout, particularly in the field and laboratory portions. Cheryl Hopcroft aided in labwork. I would like to thank the many people on the ASGARD project that aided in the setup and breakdown of my experiments, particularly Heidi Mendoza-Islas and Atsushi Yamaguchi. I would also like to acknowledge the UAF CFOS graduate student community for their support throughout this project.

GROWTH AND REPRODUCTIVE RATES OF CALANOID COPEPODS IN THE NORTHERN BERING AND SOUTHERN CHUKCHI SEAS

Formatted for: Journal of Plankton Research

ABSTRACT

Egg production and copepodite growth rates were measured for the calanoid copepods *Pseudocalanus* spp., *Calanus marshallae/glacialis*, and *Metridia pacifica* in the northern Bering and southern Chukchi Seas during June of 2017 and 2018. For all taxa, instantaneous growth rates generally decreased with increasing copepodite stage, though the differences between most stages was not significant. The growth rates for *Pseudocalanus* spp. averaged 0.03 ± 0.002 day^{-1}, *Calanus* spp. 0.09 ± 0.004 day^{-1}, and *M. pacifica* 0.05 ± 0.03 day^{-1}. Egg production rates increased with prosome length for all species, but when standardized to body weight this trend reversed. All *Pseudocalanus* species had similar weight-specific egg production (SEP): 0.18 ± 0.01 for *P. acuspes*, 0.15 ± 0.00 for *P. newmani*, and 0.11 ± 0.02 for *P. minutus*. The SEP for *Calanus* was considerably lower, 0.09 ± 0.01, while for *M. pacifica* it was 0.11 ± 0.01. These rates suggest considerable discrepancies between growth rates and egg production weights that we propose are due to differences in life history strategies. *Pseudocalanus* reproduce nearly year round, they appear to invest less in somatic growth, preferring to quickly reach their adult stage where they invest heavily into reproduction. *Calanus* spp. have 1 or possibly 2 generations per year in this region, they invest more into somatic growth in order to ensure their population is ready for a reproductive season timed to the spring phytoplankton bloom. The more omnivorous *M. pacifica* is also likely limited to 1 or 2 generations, although their ability to thrive on a wider range of food sources than *Calanus* seems to allow for relatively higher investment in reproduction and perhaps lower investment in somatic growth. Consistent with other studies, global growth models do not match our observations particularly well, likely because they are dominated by egg production estimates at lower latitudes.

INTRODUCTION

On the Bering and Chukchi Sea shelves, copepods are the primary component of mesozooplankton and provide an important link in the transfer of energy from primary production to higher trophic levels (Questel *et al.*, 2013; Ershova *et al.*, 2015). Despite this, few direct measurements of copepod production rates have been completed in this region (Vidal and Smith, 1986). Direct rate measurements of the predominant zooplankton are necessary to understand both their grazing potential on primary production and how much energy, in the form of zooplankton, may be available for higher trophic levels.

The Bering and Chukchi Sea shelves are shallow, seasonally ice covered and have extraordinarily productive spring algal blooms, fueled by the input of nutrient-rich waters of the Anadyr Current that originate on the outer Bering Sea, with general northern water transport through the region (Weingartner *et al.*, 2005; Walsh *et al.*, 1989). This region is currently experiencing rapid change, with decreasing winter ice cover, earlier break-up and generally warmer waters, particularly in the northernmost areas (Wood *et al.*, 2015). Impacts of this warming on the ecosystems are yet to be fully understood, and it is possible that the future ecosystem will become increasingly similar to the subarctic North Pacific with Arctic taxa displaced northward (Overland and Stabeno, 2004; Huntington *et al.*, 2020; Sasaki *et al.*, 2016). Due to challenges of accessibility to this region during ice breakup, most studies have occurred during summer and autumn. Thus, there is a general lack of prior observations during the bloom period, and in particular how copepod populations respond during these times.

The predominant mesozooplankton in this high-latitude region are the calanoid copepods *Calanus* spp., *Pseudocalanus* spp., and *Metridia pacifica*. The large bodied, lipid-storing *Calanus* often encompass the highest proportion of the zooplankton biomass depending on the time of the year, whereas *Pseudocalanus* are generally the most abundant zooplankter (Questel *et al.*, 2013; Hopcroft *et al.*, 2010; Eisner *et al.*, 2013). All of these copepods, particularly *Calanus*, are capable of considerable lipid storage, and therefore are important nutritional prey sources for higher trophic levels, as well as for the transfer and repackaging of carbon from primary production (Springer and Roseneau, 1985; Lane *et al.*, 2008). Therefore, *Calanus* and *Pseudocalanus* have been the genera targeted for many zooplankton studies in high latitude regions (e.g. Ershova *et al.*, 2017; Plourde *et al.*, 2005; Smith and Vidal, 1986). The diel migrator *Metridia pacifica*, although less abundant in this system, is also capable of relatively

high lipid storage and may play a role in the daily transfer of carbon within the water column (Takahashi *et al.*, 2009).

In this region there are two co-occurring and morphologically indistinguishable *Calanus* species: *C. marshallae* and *C. glacialis*. Their distributions are largely driven by water transport, with *C. glacialis* generally found in colder Arctic waters and *C. marshallae* in warmer Pacific waters (Nelson *et al.*, 2009). Both species have a life-cycle timed to take advantage of the large phytoplankton bloom that occurs during spring, when they ascend from depth and begin to produce eggs (Conover, 1988). As bottom depths on the Bering and Chukchi shelves are primarily less than 50 m, it is likely that these species overwinter elsewhere and get transported into this region as they arise from depth. *Pseudocalanus* is also a species complex, comprised of *P. minutus*, *P. acuspes*, *P. newmani* and the scarcer *P. mimus* (Questel *et al.*, 2016). These species cannot be morphologically distinguished at the copepodite stages, other than crudely by size. These species also associate well with oceanographic regions, where *P. acuspes* and *P. minutus* are circumpolar species associated with Arctic water and *P. newmani* and *P. mimus* are temperate species common in the North Pacific waters (Ershova *et al.*, 2017). This genus reproduces year round, although production peaks at times with high algal production (Napp *et al.*, 2005). The omnivorous species *Metridia pacifica* often accomplishes 2-3 generations per year in the subarctic Pacific, although due to the cold Bering Sea temperatures and short season in this region they are likely limited to one or two (Padmavati and Ikeda, 2002; Batchelder, 1985), with egg production peaking during spring and summer (Hopcroft *et al.*, 2005).

Copepods have a complex determinate biphasic life-cycle comprised of 6 naupliar stages and 6 copepodite stages, including the final adult stage. The time spent at each life stage varies by species, and can be influenced by water column temperature and food concentration (Bunker and Hirst, 2004; Hirst and Bunker, 2003; Campbell *et al.*, 2001). The vast majority of direct rate measurements for all copepod taxa are egg production measurements (Hirst and Lampitt, 1998). While egg production rates are easy to measure, they are not necessarily representative of growth rates for juvenile stages (Hopcroft and Roff, 1998). Therefore, region-specific measurements of rates specific over the entire copepod lifecycle are needed to understand secondary production within the context of a rapidly changing Pacific Arctic.

To address these gaps, we experimentally determined egg production and somatic growth rates for *Pseudocalanus* spp., *Calanus* spp., and *Metridia pacifica* in the northern Bering and

southern Chukchi Seas during June of 2017 and 2018. These rates add to our understanding of the life-history of these taxa, as well as providing valuable information as to the ecological importance of these taxa in this region during the under-studied spring bloom.

METHODS

Experiments were conducted during cruises on the R/V *Sikuliaq* during June of 2017 and June of 2018 in the northern Bering and southern Chukchi seas as part of the Arctic Shelf Growth, Advection, Respiration and Deposition (ASGARD) project (Fig. 1). Zooplankton were collected using a vertically-hauled 60-cm flow-metered twin-ring net fitted with 150-µm mesh. Nets were hauled through the entire water column (depth ranged 30-56 m) at ~0.5 m s^{-1}. Upon retrieval, only the lowest portion of the nets were lightly rinsed with seawater before removing the cod-end. Zooplankton were quickly diluted with seawater and placed in incubators set at ambient sub-surface seawater temperature until further experimental processing could occur. For community analysis, zooplankton were collected with an additional 150-µm tow, rinsed thoroughly then preserved immediately in formalin. A Seabird 911+ CTD on a 24-place rosette of 12 L Niskin bottles was deployed at each station to collect physical, and chlorophyll profiles as well as the water for incubations. For chlorophyll, 1 L water samples were drawn from CTD casts at 10m intervals. Both total and size-fractionated chlorophyll samples were filtered onto 25mm GF/F filters. Filters were immediately frozen at -80°C aboard ship and transferred frozen back to the laboratory for analysis. Filters were extracted for 24hr in 90% acetone in darkness at -20°C, with chlorophyll *a* and phaeopigment concentrations determined fluorometrically by acidification (Welschmeyer, 1994) with a Turner Designs AU-10 calibrated with purified chlorophyll *a* (Turner Designs).

Community Composition

Samples to document initial communities were processed post-cruise to determine copepod species abundance, composition and biomass. Species-specific (or morphologically similar) length-dry-weight regressions were used to estimate biomass (Questel *et al.*, 2013 - see below). Samples were divided using a Folsom splitter until the smallest fraction contained about 100 organisms. We identified each organism to the lowest taxonomic level possible then counted, staged, and measured them (Roff and Hopcroft, 1985). Increasingly larger fractions

were processed for less abundant taxa, with between 400-600 individual organisms identified from each sample. Only data for the copepods are presented here.

Artificial Cohort

Experiments were conducted to measure copepodite growth rates using the artificial cohort method (Liu and Hopcroft, 2006a; Kimmerer and McKinnon, 1987). Experiments were conducted at all 10 stations during 2018, but only 9 stations (excluding DBO 2.4) during 2017.

Zooplankton from each net tow were size fractioned to create cohorts, using gentle wet sieving, into fractions of 1000-1300, 800-1000, 600-800, 500-600, 400-500, 300-400, 200-300, and 150-200 µm (Liu and Hopcroft, 2008, 2007). A 250 µm sieve was added during 2018, creating 200-250 and 250-300 µm size classes. After creation, each size fraction was then split in two, with half being immediately preserved in formalin.

The other half was incubated for 8-10 days, dependent on available ship time. The incubations occurred within 20 L soft-sided transparent plastic cubic carboys with plankton size-classes diluted using 150-µm pre-screened seawater collected from 10 m depth, where we assumed there was sufficient chlorophyll and nutrients to sustain the incubation. Each size fraction was dispersed across multiple carboys, with the visually-estimated planktonic biomass within the fraction determining how much dilution was necessary. The three dozen carboys employed in each experiment were placed in 1 m^3 insulated commercial fish totes with a constant flow of ambient surface seawater to maintain oceanic temperatures. Water temperatures within the totes were continuously recorded during the incubations using Hobo Tidbits (Onset Inst.). At the end of the incubation the plankton were screened onto 64 µm Nitex and preserved in formalin. The target copepod species were identified and staged, and their prosome lengths (PL) were measured (Roff and Hopcroft, 1985). In addition to the cohort experiments, at 4 stations during 2017 and 7 stations during 2018 individual *Calanus* spp. were live sorted from an additional 150-µm vertical net tow, then dependent upon stage, 35-250 individuals were incubated per carboy and processed as described above.

Weights were predicted using relationships between prosome length and dry weight (DW) established for the region, with the same relationship being applied to all copepodite stages. In both years three copepod genera were numerous enough to calculate growth rates; *Calanus, Metridia* and *Pseudocalanus*. *Calanus* DW was calculated using: $\log_{10}$ DW = 4.024*log PL – 11.561 (Liu and Hopcroft, 2007), *Pseudocalanus* DW was calculated using:

$\log_{10}DW = -7.62 + 2.85*\log_{10}PL$ (Liu and Hopcroft, 2008), and *Metridia* DW calculated using $\log_{10}DW = -8.75 + 3.29*\log_{10}PL$ (Liu and Hopcroft, 2006a). The DW of the average-lengthed individual for each species from the start and end of each incubation were used to calculate the daily growth rate, using the following equation: $g = (\ln W_1 - \ln W_0)\, t^{-1}$, where W_0 is the starting weight, W_1 is the weight at the end of the incubation, and t is the number of days of the incubation. The largest size fractions often did not have an adequate number of animals and were not employed. Growth rates are only presented for experiments where there were a minimum of 30 total copepodites in both the start and end samples, and where apparent mortality was less than 50% (average mortality < 20%).

Egg Production

Egg production experiments were conducted for *Pseudocalanus minutus*, *P. acuspes*, and *P. newmani* during 2017 (n=9) and 2018 (n=10), and for both *Calanus* spp. (n=5) and *Metridia pacifica* (n=6) during 2018 only. Adult female copepods were sorted from the150-µm vertical nets. Water for the incubation was collected from 10 m depth when possible, but occasionally water from 4 m was used. All water was screened through a 150 µm mesh prior to incubation.

For *Pseudocalanus* spp., ~120 sac-less females randomly sorted from each station were placed individually into 70 ml flasks (Napp *et al.*, 2005) incubated under subdued light inside a 4° C walk-in incubator. Copepods were checked every 24 hours for 3 days. Females that had produced egg sacs by the checkpoints were removed and individually preserved with formalin. After three days, all females that had not produced were preserved as a group. All females were later identified to species, their prosome lengths were measured, and the number of eggs produced was counted.

For *Calanus* spp. (n ~ 20 per experiment) and *M. pacifica* (n = 25-48 per experiment), single adult females were placed into 70 ml egg towers within 6-place multiwell trays (Hopcroft *et al.*, 2005). The towers were fitted with a 200 µm mesh allowing eggs to fall through the mesh and be separated from the females during the incubation to prevent damage or cannibalism. Incubations were run for 24 hours, at the end of which the females were preserved in formalin. *Calanus* spp. eggs were preserved with their parent, while *M. pacifica* eggs were counted and their developmental condition noted at the termination of each incubation (Hopcroft *et al.*, 2005). Female prosome lengths were measured from all preserved animals.

Egg production rate (EPR) was calculated using: EPR = (average clutch size*percentage females producing clutch)/experiment duration (days). For *Pseudocalanus* spp., egg production was calculated for experiments with at least 10 individuals within a species. Using egg sizes/weights from previous studies in the Chukchi (Ershova *et al.*, 2017), weight specific egg production rate (SEP) was calculated by taking the ratio of the clutch weight and average weight of the females for each species.

All statistical analyses were performed with R (Version 4.0.2).

RESULTS

Community & stage distribution

During 2017 *Neocalanus flemingeri* had the highest biomass relative to the other calanoid copepods, followed closely by *Pseudocalanus*, then *Calanus, N. cristatus,* and *Metridia*, but the abundance was dominated by *Pseudocalanus* spp. (Table I). The *N. flemingeri* population was primarily composed of copepodite stage-5 (CV), a pre-diapause phase that precluded their use for growth rate or egg production studies (Mackas and Tsuda, 1999). During 2018, *Pseudocalanus* spp. had both the highest biomass and abundance of the copepods, followed by biomass for *Calanus*, *Metridia* and *Neocalanus*. The only other copepod taxa of notable abundance or biomass were *Acartia longiremis* and *Oithona similis*.

In both years the communities were primarily dominated by CI-CV of *Pseudocalanus* spp., *Metridia pacifica* and *Calanus* spp., rather than adults (Figure 2). No clear spatial patterns were observed during either year for any taxa. During 2017 there were higher proportions of CI-III, particularly for *Metridia* and *Calanus*, whereas during 2018 more CIV through adults were present. *Pseudocalanus* generally had the most variability in stage distribution, whereas *Metridia* and *Calanus* tended to have more consistent stage distribution within each cruise.

Somatic Growth Rates

For all taxa, growth rate tended to decrease as stages increased (Figure 3). For *Calanus*, mean stage duration and growth rates with their respective standard errors from the artificial cohort experiments were 8.10 ± 0.36 days and 0.09± 0.004 day^{-1}, respectively. For the stage-selected *Calanus,* mean stage duration and growth rates were 5.85 ± 0.45 days and 0.09 ± 0.006 day^{-1}, respectively, with some variability across stages (Table III). There were no significant differences between the growth rates from the artificial cohort and stage selected *Calanus*

experiments. There were relatively few experiments where *Metridia* were present in high enough abundances to obtain growth rates, however the observed mean stage duration and growth rates were 4.55 ± 0.52 days and 0.05 ± 0.003 day^{-1}, respectively, again with minor variability across stages (Table IV). The high abundance of filamentous algae at most sampling stations interfered with *Pseudocalanus* being well-sorted into cohorts having a distinct single-stage dominance. Most of their cohorts had 2-3 stages with similar abundances, therefore the rates presented reflect a greater mixture of stages for *Pseudocalanus* than for the other taxa. The mean stage duration and growth rates for *Pseudocalanus* were 8.28 ± 0.41 days and 0.03 ± 0.002 day^{-1}, respectively. For *Calanus* and *Pseudocalanus*, an ANOVA revealed significant differences between CIV and younger stage copepodites, but no differences between the CI-CIII stages, while *Metridia* had no significant difference between stages. An ANOVA showed significant differences ($p < 0.05$) between growth rates of *Calanus* and *Pseudocalanus* at all stages, and significant differences between *Metridia* and *Calanus* at all stages. There were no significant differences between *Pseudocalanus* and *Metridia* growth rates.

Growth Rate Drivers

The average temperature during the incubations ranged from 4-5.6°C. Chlorophyll concentrations from the experimental stations ranged from 0.5-6 µg/L. There was no significant relationship between growth rates and temperature or chlorophyll for either *Calanus* or *Pseudocalanus* (Fig. 4). Due to the low number of rates measured for *Metridia,* a comparison of environmental factors to the rates was not undertaken.

For *Calanus*, CI growth rates from the aritifical cohort experiments had a positive linear relationship with average prosome length from the initial experiment, and CIV growth rates from the picked stage experiments had a negative relationship (Figure 5). While such relationships for the other stages was not significant, CI and CII's tended to have a positive relationship between prosome length and growth rate, whereas CIII and CIV's had slight negative relationships.

Egg Production

Clutch size increased as prosome length increased, both within a species and across genera (Fig 6). For *Pseudocalanus* species, egg production rates generally increased with prosome length within the genus, hence *P. newmani* produced the fewest eggs per female and *P. minutus* produced the most (Figure 6). When standardized to weight (i.e. SEP), there was no statistical difference between the *Pseudocalanus* species, with a mean SEP of 0.15 ($p > 0.05$).

For *P. newmani*, mean EPR was 2.32 ± 0.40 day^{-1}, and mean SEP was 0.15 ± 0.00 day^{-1}. For *P. minutus*, mean EPR was 6.67 ± 0.77, and mean SEP was 0.10 ± 0.01. For *P. acuspes,* mean EPR was 4.64 ± 0.26, and mean SEP was 0.18 ± 0.01. *Pseudocalanus* egg production did not have any clear spatial variance, although for all taxa SEP was slightly higher in 2017 than 2018 (Figure 7). The mean EPR and SEP for *Calanus* were 39.7 ± 3.54 and 0.09 ± 0.01, respectively, and for *Metridia* 27.4 ± 1.92 and 0.11 ± 0.01. Between species the only significant difference in SEP was between *Calanus* and *Pseudocalanus*. There was no significant relationship to water column temperature or sampling site chlorophyll concentration for any of these rates.

DISCUSSION

During the 2017 and 2018 spring blooms, the northern Bering and southern Chukchi seas had low diversity copepod communities similar to those reported during summer and fall, with the highest biomass contributed by *Neocalanus flemingeri*, *Calanus* spp., *Pseudocalanus* spp. and *Metridia pacifica* (Questel *et al.*, 2013; Ershova *et al.*, 2015; Eisner *et al.*, 2013; Matsuno *et al.*, 2011). In both years the higher biomass and abundance of copepodite stages rather than adults emphasizes the importance of directly measuring copepodite rates rather than assuming that adult production predominates and provides an adequate proxy for copepodites. *Calanus* spp. and *Metridia pacifica* had similar total biomass, although *M. pacifica* had similar adult and copepodite biomass whereas *Calanus* spp. biomass was primarily as copepodites, likely reflecting differences in how each exploits the spring bloom. Although *Oithona similis* was present in high abundance during both years, their small size limits their contribution to the biomass, and also prevented us from measuring their rates with our experimental design.

For *Calanus* spp., *Pseudocalanus* spp. and *M. pacifica*, within the copepodite stages we found a general decrease in growth rates as the copepodite stages increased, as has been shown previously with these taxa (Liu and Hopcroft, 2007, 2006a, 2008). The prodigious amounts of filamentous algae that prevented clean sorting of *Pseudocalanus* by stage for these experiments likely weakened the observed strength of relationship between growth rate and stage (Table III). Additionally, although the data is more limited for *M. pacifica*, the pattern of lower growth rates at older copepodite stages also emerges for this species, consistent with previously published rates (Table IV).

The apparent correlation between copepod body size and their growth rates, with the large-bodied *Calanus* presenting the highest average growth and *Pseudocalanus* the lowest (Fig.

3), is best explained by differences in life-history strategies. For *Calanus*, despite considerable scatter in growth rates for the younger copepodite stages (CI) growth correlated positively with prosome length (Fig. 5). This within-stage pattern has been observed previously for copepodite growth rate of *Neocalanus* spp., (Liu and Hopcroft, 2006b), another large-bodied sub-arctic copepod. It is probable that size and growth are more dependent on environmental variables during the earlier stages, such that smaller copepodites within a stage are a reflection of poorer conditions for growth, while larger size reflects better growth. Thus, copepods that already had low body condition, then were placed into incubation, likely struggled to grow faster by their next molt. The growth rates determined from the artificial cohort experiments matched relatively well with the rates determined from the stage selected experiments, further indicating that the more time-efficient artificial cohort method is a useful way of determining these rates (Liu *et al.*, 2013).

Within each species, body size appeared to be a main driver for clutch size. Across all taxa there was a trend to have increased eggs per female per day (EPR) with larger body size, yet when egg production was standardized to female weights (SEP), the rates among all the taxa became relatively similar. Although there was no correlation to temperature or chlorophyll for these rates, the former is not surprising given the limited thermal range, whereas preponderance of large filamentous algae during our experiments may have made chlorophyll a poor proxy for the availability of suitable-sized food. It is likely that most copepods were food satiated during these experiments, due to the pronounced spring phytoplankton bloom that occurred concurrent with our sampling.

In general, the growth rates we measured in the Pacific Arctic were lower than those determined for the same taxa in the North Pacific (Gulf of Alaska). It is possible that this is due to colder average temperatures in our study region, although many of the North Pacific rates were Q_{10}-corrected to a similar temperature as occurred in or study, such correction can introduce errors (Liu and Hopcroft, 2007, 2006a, 2008). The *Pseudocalanus* species complex has been the most studied in regards to egg production in this region, likely due to the relative ease of performing the experiments, but such measurements come primarily from summer and fall. Some of the *Pseudocalanus* SEP measured at similar temperatures to ours in this region during early fall (Hopcroft *et al.*, 2010) are only slightly lower than the rates we measured in spring, but others run at colder temperature are substantially lower (Ershova *et al.*, 2017; Lee *et al.*, 2003).

Notably, our EPR is in the lower range measured for these taxa in the North Pacific and southeastern Bering Sea (Napp *et al.*, 2005; Vidal and Smith, 1986). It is therefore likely that a combination of longer-term seasonal variation in food and temperature are driving these rates. While *Calanus* egg production measurements at cold temperatures in our region are limited in number, it has been shown that spring egg production is higher than in summer in the Chukchi and Beaufort Seas (Plourde *et al.*, 2005), likely reflecting the dependence of the *Calanus* lifecycle on the extensive spring bloom in this region. Our rates for *Calanus* egg production were slightly lower than those from the Gulf of Alaska, in part due to colder temperatures, but higher than those measured for the Pacific Arctic (Plourde *et al.*, 2005), likely due to warmer temperatures and presumed food satiation. The growth rates for *Calanus* are surprisingly similar to those measured in the Gulf of Alaska when standardized to similar temperatures (Liu and Hopcroft, 2007). It is however noted that although the Gulf of Alaska rates include measurements throughout spring and summer, they are primarily from the spring bloom period, similar to the rates presented here. For *Metridia pacifica*, our egg production rates are similar to the few rates that have been measured, without apparent differences due to seasonality.

When comparing growth rates to past studies of these taxa, methodology differences become important. The benefits and shortcomings of a variety of methods for estimating growth has been discussed previously (Kimmerer *et al.*, 2007), and it is difficult to determine whether differences in measured rates are due to methodology, location, or environmental conditions. Artificial cohort measurements are rare, and for high latitudes are limited to the Gulf of Alaska, and now the Bering and Chukchi Seas. This complicates any discussion comparing the *in-situ* artificial cohort experiments to laboratory measurements of somatic growth. Overall there are relatively few measurements for the species presented here, but measurements of the same genera are largely available for *Calanus* and *Pseudocalanus* (e.g. Campbell *et al.*, 2001; Vidal, 1980a, 1980b; Smith and Vidal, 1986). When grown at different temperatures, *P. newmani* and *M. pacifica* development time increased with decreasing temperature, indicating potentially different generation times in temperate regions (Lee *et al.*, 2003; Padmavati and Ikeda, 2002). For *C. marshallae*, laboratory growth measurements at 10° C averaged 6.9% body weight per day, which is slighter lower than the estimates presented here (Peterson, 1986). It is likely the lower investment in growth in that study is due to the warmer temperatures, as well that ecosystem's longer productive period.

There were discrepancies between somatic growth rates and the adult egg production rates for all these taxa, and it is clear that the different species are utilizing different life history strategies in terms of where they invest their energy. The large-bodied *Calanus* presented the highest somatic growth rates out of all of the taxa (~15% d^{-1} maximum), but had relatively lower SEP (avg. 9% d^{-1}), although the average growth rate and SEP were not significantly different, likely due to the low growth rates for late-stage copepodites. The small bodied *Pseudocalanus* had considerably lower somatic growth rates (~4 % d^{-1} at the highest), but significantly higher SEP (11-18% d^{-1}). The rates for the omnivorous *M. pacifica* fell between *Calanus* and *Pseudocalanus* for both growth and egg production.

This suggests that *Calanus*, a genus that times its reproductive cycle to take advantage of the seasonal bloom production (e.g. Baier and Napp, 2003), is investing more into somatic growth daily than egg production. Since high-latitude *Calanus* diapause, they must prioritize growth to reach a body size that can contain enough lipids to survive overwintering without feeding. It has been suggested that both *C. glacialis* and *C. marshallae* have a one year lifecycle on the Bering Sea shelf (Baier and Napp, 2003), although in the northern Bering Sea and Arctic they appear to have a two year lifecycle (Smith and Vidal, 1986; Ashjian *et al.*, 2003). In general, high latitude *Calanus* appears to reproduce in late winter and spring, possibly feeding on the ice algae bloom (Durbin and Casas, 2014) while early copepodite development occurs during summer (Ashjian *et al.*, 2003; Peterson and Du, 2015). Thus, *Calanus* diapausing CV's awake, molt to adults and produce eggs during this early productive period, so that younger copepodites can take advantage of the bloom and continue their development throughout summer. Although the bulk of their reproduction appears to be timed to utilize the spring bloom, it has been suggested that late summer or autumn blooms may trigger a second pulse of reproduction (Vidal and Smith, 1986). In the scenario of an autumn bloom it is particularly important for the copepodites to invest heavily into growth in order to reach a lipid storing stage, then load up with lipids to survive the limited food resources during winter.

On the other hand, *Pseudocalanus* invests much less into somatic growth, instead aiming to reach their small adult body size using limited energy, then invest heavily into reproduction whenever there is adequate food. SEP measured in fall in previous studies for *Pseudocalanus* (Ershova *et al.*, 2017; Hopcroft *et al.*, 2010) is only slightly lower than what we measured during spring, indicating sustained investment in reproduction throughout summer and into autumn,

though a slight peak in spring has been indicated for these taxa (Renz *et al.*, 2007). It has been suggested that *Pseudocalanus* have favored slow growth rates to allow for sustainable growth at low chlorophyll levels while maintaining similar development times to other species (Liu and Hopcroft, 2008). This strategy allows them to reliably complete their life cycles under limited food conditions. Therefore, *Pseudocalanus* is prepared to take advantage of any favorable conditions through reproduction, where their apparent energy investment is greatest. Furthermore, their small adult body-size and egg-carrying strategy leads to low predation rates both on the female and their eggs (Hirst and Kiørboe, 2002). It is notable that the different *Pseudocalanus* species directed similar proportionate energy towards egg production, yet they may still occupy slightly different niches and thereby experience different reproductive success under varying oceanographic conditions (Ershova *et al.*, 2017; McLaren *et al.*, 1989).

Metridia pacifica seems to fall somewhere between *Calanus* and *Pseudocalanus*, with average growth rates falling between the two other taxa, and SEP similar to the lower range of *Pseudocalanus*. While *M. pacifica* are larger than the *Pseudocalanus*, and therefore must invest more energy into growth to reach their adult stage, they are a omnivorous species (Campbell *et al.*, 2016; Batchelder, 1985), which may allow them a more extended period where egg production is possible than *Calanus*. It is possible that at these high latitudes *Metridia pacifica* focuses their egg laying to short periods of time optimized to ideal food conditions (Batchelder, 1985), although the Arctic species *Metridia longa* is thought to have the ability to continually reproduce throughout the year (Ashjian *et al.*, 2003). In the North Pacific, *M. pacifica* have been found to have two or three generations per year (Padmavati and Ikeda, 2002; Batchelder, 1985), though at these high latitudes with extreme seasonality they are likely limited to one to two generations. With this limited growing season, they must invest considerable energy into growth to reach their adult stage in time for spawning in fall, or to be at a later, lipid-storing stage in time to overwinter with limited food. It has been noted that the survival of *M. pacifica* eggs during spring is generally low (Halsband-Lenk, 2005; Hopcroft *et al.*, 2005), potentially due to alleochemicals in diatom prey (e.g. Halsband-Lenk, 2005). If we assume this is also the case in the Pacific Arctic, then it is possible that *Metridia* must continue their investment into reproduction throughout a portion of summer to offset low recruitment during the spring bloom. It is uncertain whether the population of *M. pacifica* seen on the Bering and Chukchi shelves are

actually transported to deep waters where they can overwinter, or whether they are advected northward and do not survive, as they are not seen in the higher Arctic .

Despite the notable differences in copepodite growth rates and egg production, and their lack of predictable differences between them, the latter often forms the basis for commonly used global models of copepod production (Hirst and Lampitt, 1998; Hirst and Bunker, 2003). It has already been shown that these models may not match well with direct measurements of somatic growth for the copepodite stages for the species discussed (Liu and Hopcroft, 2007, 2006a, 2008). Rates calculated from these global models, or rates determined at different oceanographic regions, are often used for secondary production estimates but may not result in sufficiently accurate production predictions. Global models are primarily based on egg production (Hirst and Lampitt, 1998), and we show here that egg production and somatic growth rates have substantial differences dependent on the species. For the larger, broadcast spawning species *Calanus* and *Metridia*, egg production rates underestimate production, since juvenile growth rates are higher. For the small sac-spawner *Pseudocalanus,* egg production rates overestimate production, because these species invest more energy into egg production rather than growth.

Additionally, region specific rate measurements are preferable to model estimates, given the impact that environmental variables have on rates (Hirst and Lampitt, 1998). While rates determined at warmer locations can be corrected to cold temperatures using a Q_{10} correction, this introduces an unknown amount of error, given our lack of certainty in the value of Q_{10} that should be applied (Hirst and Bunker, 2003). For comparison to global models (Hirst and Bunker, 2003), using their Q_{10} of 2.7 to standardized to 4°C and our initial weight in each experiment, we predicted model growth rates. For *Calanus*, model estimates for our sampling period for juvenile broadcaster growth rates are 0.09 ± 0.003 day^{-1}, and for adults 0.02 ± 0.002 day^{-1}, that matches with our average juvenile estimates surprisingly well but severely underestimates adult production. This model underestimates *Metridia* juvenile and adult growth, estimating broadcaster rates of 0.08 ± 0.04 day^{-1} for juveniles and 0.04 ± 0.01 day^{-1} for adults. For the sac-spawner *Pseudocalanus*, as expected this model overestimates juvenile production as 0.06 ± 0.01 day^{-1}, but underestimates adult production as 0.08 ± 0.003, which is off by nearly a factor of two.

CONCLUSIONS

We observed that *Calanus* spp., *Pseudocalanus* spp., and *Metridia pacifica* biomass was primarily comprised of copepodites rather than adults during June of 2017 and 2018 within the

northern Bering and southern Chukchi Seas. This is particularly relevant when estimating production because, since we demonstrate that copepodite growth rates can differ substantially from egg production rates for these taxa. The relative differences between adult and juvenile production are not universal and appears to reflect differences in life history strategies employed by different taxa. The large bodied *Calanus* invest considerable energy into growth in order to reach lipid storing CV copepodite stages that are able to diapause by late summer, then emerge to time their reproductive period to the spring bloom. Alternatively, the small-bodied *Pseudocalanus* invest much less into growth, focusing on reaching adulthood where they are primed to invest heavily into reproduction whenever condition allow, regardless of time of year. The life history strategies of *M. pacifica* are less certain, but they too invest a substantial amount into growth, allowing them to reach latter stages that could overwinter. Simultaneously, *M. pacifica* also have higher egg production rates similar to those of *Pseudocalanus* and reproduce when conditions allow, rather than being focused on only the spring bloom. For *Calanus*, global models of rates matched relatively well with our measured juvenile rates, though they underestimated *Metridia* and overestimated *Pseudocalanus* juvenile rates. Global models underestimated adult production for all taxa, highlighting the importance of having directly-measured regional rate measurements.

ACKNOWLEDGMENTS

I gratefully acknowledge the North Pacific Research Board for providing funding for this project. I thank Russ Hopcroft, Seth Danielson and Kenneth Coyle for their feedback on this manuscript. I would also like to thank fellow students plus the captain and crew of the R/V *Sikuliaq* for their assistance with the field portion of this project.

Respiration rates of calanoid copepods during the spring bloom for the Arctic's Bering Strait region

Russell R. Hopcroft & Caitlin A. Smoot

Institute of Marine Sciences, University of Alaska Fairbanks

Introduction

The regions surrounding the Bering Strait are an important transition zone between the Pacific and Arctic Oceans (Grebmeier and Maslowski 2014). Nearly four decades ago, it was estimated that 1.8 million metric tons of Bering Sea mesozooplankton were carried into the Arctic through this region annually (Springer et al., 1989), and that they act as significant consumers of phytoplankton as well as prey for higher trophic levels. The Chukchi has been undergoing pronounced changes in sea ice cover and water temperature for most of this century (Danielson et al. 2020). In its now becoming clear that these changing environmental conditions are propagating to the biological communities with significant implications for the higher trophic levels that of commercial or subsistence importance (Huntington et al 2020). Despite these observations our knowledge of the fundamental rate processes at the organismal level that determine how species will respond to these changes is particularly limited globally and especially so in Arctic waters. The ASGARD program was designed with the goal of significantly increasing of understanding rate process for all trophic components in the Bering Strait region.

Rate processes in zooplankton begin with grazing activity, with calanoid copepods being the dominant components of this grazing community within the Pacific Arctic (Questel et al. 2013, Ershova et al,. 2015). Once food is ingested, a portion of it is assimilated, and the remainder is egested as fecal pellets that sink rapidly to the benthos (O'Daly et al. 2020, LaLande et al. 2020, 2021). Of the matter assimilated, a portion of it is respired, while the remainder goes toward growth, either in the form of body tissue or reproductive products, some may be stored as lipids, and nitrogenous wastes are excreted. Although labor intensive, approaches to estimating growth and egg production in zooplankton are relatively well established, and are reported for this region elsewhere (see Poje chapter). In contrast due to the small size of zooplankton, and in particular of copepods, measurement of respiration has proven particularly difficult to determine routinely. For this reason, in most cases modelers rely on equations determined by global syntheses of respiration rates (Ikeda et al. 2001, Ikeda et al. 2007), that although based on relatively limited data have suggested highly predictive relationships. Nonetheless, if these models prove to be less than universal for all species in all habitats, then significant errors could be introduced in partitioning how much of the food ingested goes into secondary production versus being lost to respiration.

Recent advancement in technologies (e.g., Koster et al. 2008) now allow us to measure respiration for individual copepods in small volumes that was impossible when prior syntheses were undertaken. Most recently this technology has advance to the form of plate readers that allow significant replication. Given these advances we ask the simple question: what are the respiration rates of the dominant zooplankters in the Bering Strait region and how do they compare to the predictions of prior syntheses?

Methods

Experiments were conducted during cruises on the R/V *Sikuliaq* during June of 2017 and June of 2018 in the northern Bering and southern Chukchi seas as part of the Arctic Shelf Growth, Advection, Respiration and Deposition (ASGARD) project (Fig. 1). Zooplankton were collected using a vertically-hauled 60-cm flow-metered twin-ring net fitted with 150-µm mesh. Nets were hauled through the entire water column (depth ranged 30-56 m) at ~0.5 m s^{-1}. Upon retrieval, only the lowest portion of the nets were lightly splashed with seawater before removing the cod-end. Zooplankton were quickly diluted with ambient seawater then placed in incubators set at the typical ambient sub-surface seawater temperature (4°C) until further experimental processing could occur.

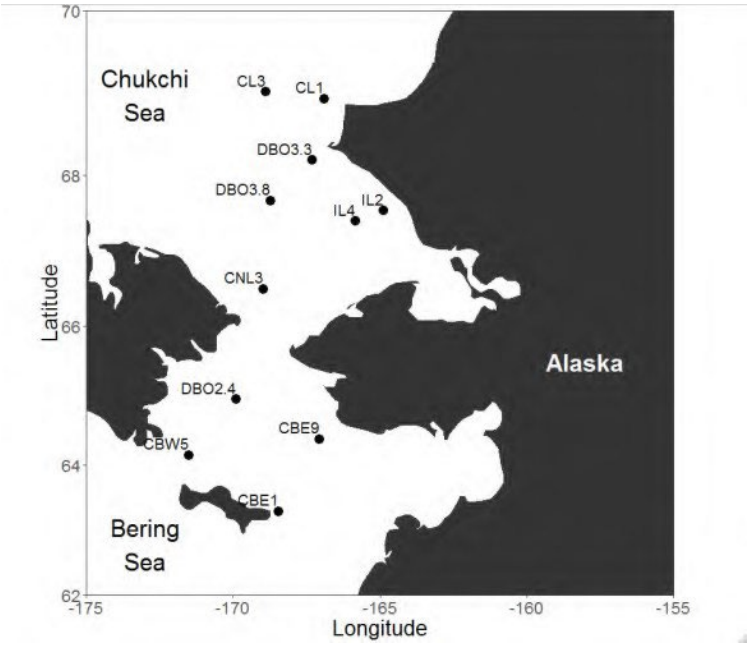

Figure 1: Zooplankton experimental stations for the Arctic Shelf Growth, Advection, Respiration and Deposition project (ASGARD) during 2017 and 2018.

Samples were moved into water-jacketed jars and subsampled for sorting under the microscope to species and stage. Sorted animals were pipetted into water-jacketed trays maintained at 4°C. Most experiments targeted the adult females, although Copepodite-V was targeted for *Neocalanus flemingeri*, and subadults of *Calanus marshallae* were employed on one occasion in 2018. For final sorting, pairs of animals were transferred into each well of a 6-place multiwell plate filled with pre-filtered water. Wells were given several hours to equilibrate oxygen at incubation temperature prior to use. Pre-filtering during 2017 only removed metazoans (~ 20µm) whereas in 2018 we employed 0.2 µm cellulose-acetate filters, and sequentially transferred animals across 3 sets of clean pre-filtered wells immediately prior to being placed in the incubation vial.

Incubations were performed using PreSens oxygen optodes systems (Koster et al. 2008) with SensorVial size scaled to animal size. In 2017 we employed 5-ml vials for *Calanus*, *Neocalanus* and *Metridia*, and 2-ml vials for *Pseudocalanus* and *Metridia* (one occasion only). In 2018 we employed 5-ml vials for *Calanus*, 2-ml for *Metridia*, and custom-made 1-ml vials prototypes for the two dominant species of *Pseudocalanus*. Although animals were sorted in pairs into the 6-well trays, we performed incubations on individual animals. These animals were carefully pipetted with their acclimation water into pre-chilled SensorVial being careful not to introduce or create bubbles any on vial surfaces. From each tray a control vial was filled from an occupied well but leaving both animals behind. Caps were applied then the vial inverted and inspected under the microscope to ensure no bubbles were created during the capping process (a frequent source), or existed on the vial or sensor-dot. Vials were returned to the water baths as quickly as possible. Each experiment consisted of a set of 20 animals and 4 controls filling a 24-place multiwell. Vials were pre-labeled to ensure constant use in the same multiwell position and application of the correct pre-calibrated volume. The multi-well was sealed in a Loligo water bath

that was designed for placement over the SensorDisk plate reader. An alignment guide was 3-D printed to ensure proper placement of the vials and a compressible spacer was employed as needed between the vials and water bath lid. Up to four water baths were connected in series to a Fisher Isotemp circulating chiller that was pre-stabilized thermally and maintained temperature within 0.1°C of the setpoint. At the start of the experiment air was evacuated from each water bath. The entire system was deployed inside a walk-in incubator set at ~4°C and maintained under dim lighting. We learned it was absolutely critical to maintain temperature of all water and vials at the intended setpoint to avoid formation of air bubbles when saturated water warms and because the optodes are highly temperature sensitive.

Figure 2: Water baths each housing 24 sensor vials with a multi-well tray. The water bath has a recessed bottom that aligns directly over an optical plate reader. Hoses connect each to a water bath to maintain thermal stability.

Data was monitored and logged through Presens SDR software (V4) set to read every 15 seconds (2017) or 30 seconds (2018). Experiments were run from 10-24 hours dependent in part on the rate of oxygen change. Despite our best attempts to maintain constant temperature, there was typically a 20-30 minute period at the start of experiment for the vials to stabilize. Presens provides a general calibration for each production-lot of sensors, but our attempts a develop a consistent vial-specific calibration failed, so after removing the pre-stabilization periods, all vials were normalized to the same average oxygen concentration as measured between the first 30-45 minutes of recording. We standardized on using a normalization value of 10.5 mg O_2 L^{-1} which is the saturation value for seawater at 4°C and salinity of 33. Slopes were fit to the 9-point running average the oxygen data for each vial using linear regression. The sensor vials relied on the movement of the animals to maintain a homogenized oxygen concentration, so lines were not always fully linear if a copepod monopolized an end of the vial and/or ceased to generate feeding currents, but in successful experiments linear fits to oxygen concentration were strong (r^2>0.9).

Post-experiment, the identity of experimental animals were confirmed, and their prosome lengths (PL) were measured (Roff and Hopcroft, 1985). Weights were predicted using relationships between prosome length and dry weight (DW) established for the nearby Gulf of Alaska, with the same relationship being applied to all copepodite stages:
Neocalanus DW was calculated using: $\log_{10}$ DW = 3.564*log10[PL] – 10.009 (Liu and Hopcroft, 2006a), *Calanus* DW was calculated using: $\log_{10}$ DW = 4.024*log PL – 11.561 (Liu and Hopcroft, 2007), *Pseudocalanus* DW was calculated using: $\log_{10}$DW = 2.85*$\log_{10}$PL – 7.62 (Liu and Hopcroft, 2008), and *Metridia* DW calculated using $\log_{10}$DW = 3.29*$\log_{10}$PL – 8.75 (Liu and Hopcroft, 2006b).

Where needed, we converted oxygen from mg to ml through multiplication by 0.700 (Molar volume at STP / molar weight of oxygen), and noted that 1 ml O_2 = 44.661 µmol O_2. To further convert to carbon consumption, we assumed the respiration of one carbon atom consumes 1 molecule of oxygen (true at least for glucose), and that carbon was 40% of a copepod's dry-weight (DW).

Results

Failure to adequately prepare controls and remove microbial respiration from sensor vials during 2017 resulted in questionable or low data for most experiments, thus data is not presented. Nonetheless, the 2017 data lead to methodological improvements and highlight the need for both more plate-readers (to consistently encompass the predominant species) and smaller vials to resolve respiration for *Pseudocalanus* species. Even during 2018, experiments at the first 2 process stations failed to produce trustworthy data. By the third process station, CBW5, we were successful in setup up of all 4 predominant calanoid copepod species in our samples: *Calanus marshallae (~3 mm, 500 µg DW)*, *Metridia pacifica (2.1 mm, 150 µg DW)*, *Pseudocalanus minutus* (1.4 mm, 25 µg DW) and *P. acuspes* (1.0 mm, 10 µg DW)(Fig. 3). *Metridia* was not present in adequate number for experimentation at two subsequent stations (CL1 and CL3), while data logging issues at one station compromised both of its *Pseudocalanus* experiments. Due to their short aspect ratio and small sensor-dots, the 1-ml SenorVials proved somewhat more problematic than the larger vials, with jumps in the data possible if the vial shifted position within its plate-holder, or variable data if misaligned to the reader.

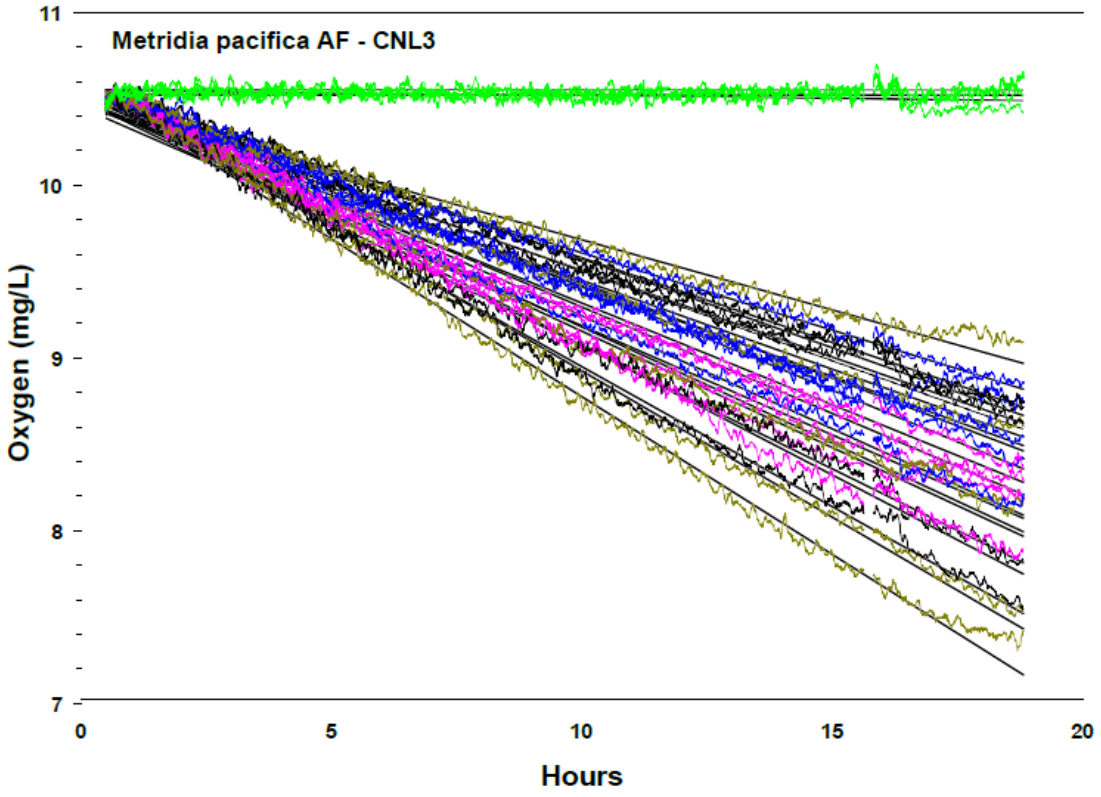

Figure 3. Time-series of oxygen concentration during a respiration experiment for adult female *Metridia pacifica*. The four green lines are controls, with the 20 experimental animals in other colors. Straight lines are linear regressions through data from each vial.

During 2018, the mean respiration for each species was relatively consist across stations (Table 1), with no significant differences between station except for *P. minutus* at station CL1. Gross respiration was greatest the largest species, *Calanus* (~0.9 µg O_2 hr^{-1}), and declined with the body size of species revealing a 20-fold difference to the smallest species, *P. acuspes* (~0.55 µg O_2 hr^{-1}). Variability in respiration rates (as reflected in the standard error) was greatest for the smallest species, *P. acuspes*. This relationship to body size, and particularly body mass is obvious both within and across species when all individual observations are considered (Fig. 4). Standardizing for body mass, specific respiration rate declines with body mass (Fig. 5) from about 5-20% per day in *Pseudocalanus* to 2.5-10% in both *Calanus* and *Metridia*. The data was suggestive of an independent negative relationship to body size within each species.

Abridged Discussion

Zooplankton respiration rates determined during the ASGARD program are the first direct determination for this region. They confirm the overall expectation of increasing growth respiration with body size (Ikeda et al. 2001, Ikeda et al. 2007), as well as the recognized decline in weight-specific respiration within increasing body mass (Ikeda et al., 2000). Although optode technology has resulted in some increased reporting of respiration rates, thus far it has still focused on mostly larger species (e.g., Maas et al. 2021). Making such measurements is even more challenging when operating at colder temperatures where respiratory rates are typically low in comparison to warmer waters.

Direct comparison to the relationships established by Ikeda shows the measured rates to be consistently higher than his relationships (Fig. 6). The regression for the data from this study, log R_{10} = 0.779∗log(DM)+0.24 predicts a value almost 3-fold higher than that predicted by the Ikeda relationship (*i.e.,* 0.73 versus 0.26 for a 100 µg copepod). Furthermore, we were able to directly estimate the weight-specific carbon respired and found it to be 5-20%, scaling inversely with body mass. Both of these observations are of significant in understanding the amount of photosynthesized carbon that will be lost to zooplankton respiration, and they set boundaries on the lowest amount of grazing required by zooplankton to meet their basic metabolic needs (i.e., biomass held in steady-state). Our data suggests that despite the cold water temperatures characteristic of the Arctic's marginal seas, respiratory losses by zooplankton are significant and higher than expected and of similar magnitude to that of growth and egg

production for these species (Poje 2020). Failure to appropriately parameterize models with appropriate field observations can be an important source of error in ecosystem models (e.g., Coyle et al. 2019). By combining these respiratory needs with that of zooplankton growth as reported in elsewhere in this report, we can now place boundaries on the grazing rates of the zooplankton community and its potential to impact the biomass of the phytoplankton communities at the time of these experiments.

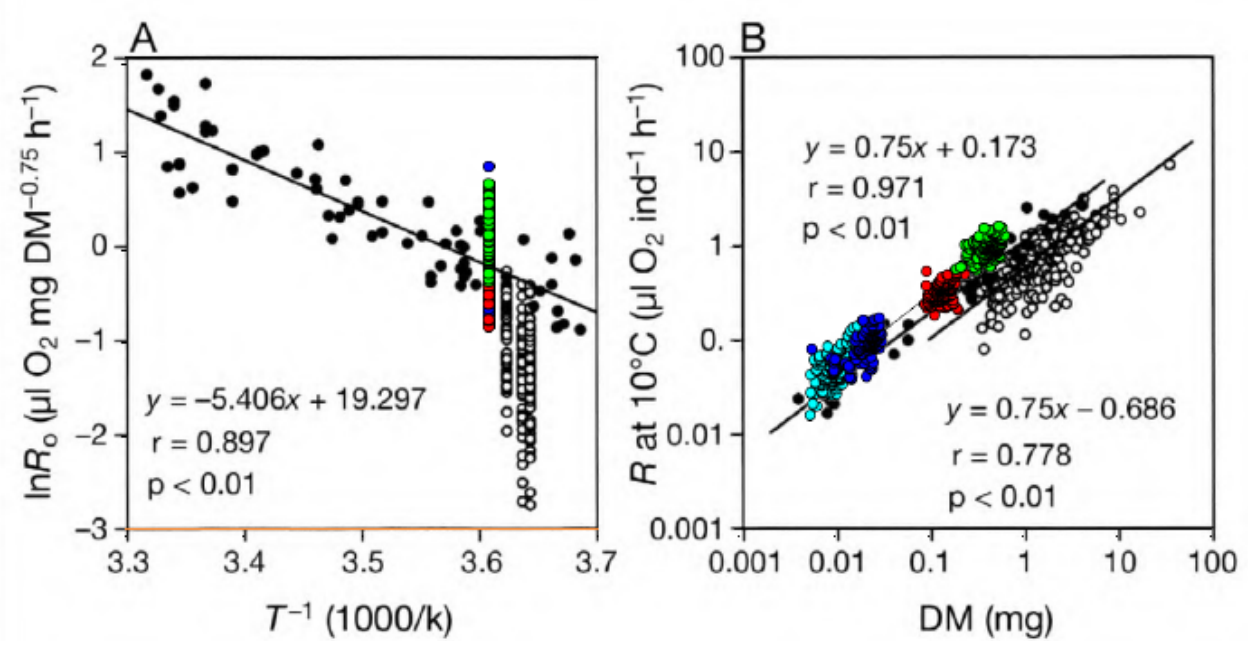

Figure 6. Respiration rates of calanoid copepods in the Bering Strait region compared to the global relationships proposed by Ikeda et al. 2007. The panel at left standardized data to animals of a constant dry mass (1 mg), while the left standardizes data to 10°C. Closed black symbols are epipelagic species, open circles are mesopelagic species. Colors represent species from Bering Strait as in prior figures.

Abstract

Polar cod and saffron cod are dominant components of the fish community in the Chukchi Sea and are ecologically important forage fishes linking plankton to upper-level consumers. In 2017, we conducted a study as part of the Arctic Integrated Ecosystem Research Program to characterize the distribution, abundance, and growth of polar cod and saffron cod early life history stages (ELHS) in late spring and late summer in the Chukchi Sea. Ship-based plankton tows showed that polar cod and saffron cod larvae were centered in Kotzebue Sound in the late spring. By late summer, polar cod juveniles were most abundant in the offshore areas of the northern Chukchi Sea, whereas saffron cod were distributed nearshore in the southern Chukchi Sea around Cape Lisburne. Empirical fish collections were paired with an individual-based biophysical transport model to examine connectivity and relate changes in seasonal distribution to potential environmental variables. Modeled drift trajectories and growth in spring for polar cod and saffron cod matched well with empirical observations, especially along the northern coastline of Kotzebue Sound, offshore of Point Hope/Cape Lisburne. Given the coherence between modeled and observed distributions, Kotzebue Sound is likely a source of gadid ELHS in the nearshore areas of the Chukchi Sea and offshore of Cape Lisburne/Point Hope, although it is not the likely source of polar cod over Hanna Shoal in the late summer. This is the first study to examine seasonal distribution, abundance, and growth of polar cod and saffron cod in the US Arctic and provides data necessary to evaluate the impacts of climate change on forage fishes in the Arctic.

Introduction

The Arctic has experienced accelerated warming at twice the rate of the global average, making Arctic ecosystems particularly sensitive to climate change (Graham et al. 2017; Tokinaga et al. 2017; Overland et al. 2018). The accumulation of heat in the Arctic has increased significantly since the late 1990s, which correlates to a reduction in sea ice thickness (Maslowski 2014), a 60% loss of multiyear ice, a 75% reduction in sea ice volume (Overland et al. 2018), and lower winter ice extent maxima (Graham et al. 2017). Loss of sea ice is expected to influence Arctic ecosystem dynam- ics through bottom-up changes to lower trophic production (Kahru et al. 2011), community structure (Spear et al. 2019), trophic linkages (Hunt et al. 2013), shifts in benthic-pelagic coupling (Grebmeier et al. 2015 and citations therein), and food web interactions (Li et al. 2009). Ecosystem changes also have potential economic ramifications such as range

extensions of commercially important subarctic gadid species, such as walleye pollock (*Gadus chalcogrammus*), Pacific cod (*Gadus macrocephalus*), and salmonid fishes, into regions north of the Bering Strait (Falardeau et al. 2017; Stevenson and Lauth 2019) in the Pacific Arctic.

Although not fished commercially in the US Arctic (NPFMC 2009), polar cod (*Boreogadus saida*), a circumpolar species, and saffron cod (*Eleginus gracilis*) are crucial forage fishes in Arctic marine ecosystems. Both species support bioenergetic pathways that transfer energy from planktonic food webs to upper-level consumers and apex predators (including humans) and are a dominant component of the fish community in the Chukchi Sea, although polar cod is more abundant than saffron cod (Whitehouse et al. 2014; Logerwell et al. 2015). It is estimated that seabirds and marine mammals consume approximately 75% of the polar cod production (Whitehouse et al. 2014). Changes to the Chukchi shelf ecosystem due to climatic warming, loss of sea ice, and perturbations to sea ice phenology (Graham et al. 2017; Overland et al. 2018) may have serious implications for these ecologically important species.

Despite their ecological importance and abundance in Arctic ecosystems, the life history of polar cod and saffron cod are still relatively unknown (Logerwell et al. 2015; Vestfals et al. 2019). Spawning locations of polar cod in the US Arctic are largely unknown, although it is hypothesized that polar cod spawn under sea ice (Rass 1968) and that peak hatching likely occurs in May and June as the ice edge recedes (Bouchard and Fortier 2008; Vestfals et al. 2019). In the Pacific Arctic, development of larvae and early juve- niles occurs along the shelf (Logerwell et al. 2015; Vestfals et al. 2019). Saffron cod are near-shore, demersal, under-ice spawners that deposit demersal eggs in nearshore areas on sandy-pebbly substrates (Vestfals et al. 2019 and citations therein) but exact locations are unknown in the US Arctic. Peak hatching for saffron cod occurs in April and May, earlier than for polar cod, and offspring are often found concentrated closer to shore and at more southerly locations within the Chukchi Sea (Vestfals et al. 2019). The life histories of polar cod and saffron cod are similar in that both are planktonic in shelf waters after hatching through the first summer, after which polar cod move deeper in the water column while saffron cod become demersal as juveniles (Logerwell et al. 2015; Vestfals et al. 2019).

Growth of polar cod and saffron cod is mediated by temperature (Laurel et al. 2016) and an additional consequence of a warming Arctic is that large calanoid copepod species, an important prey resource for Arctic gadids, will be replaced by smaller, less lipid-rich copepods (Aarflot et al. 2018; Møller and Nielsen 2020; Bouchard and Fortier 2020). Larvae and juveniles will be disproportionally affected by these changes relative to adults due to their higher weight-specific growth rates, and polar cod may be more sensitive than saffron cod because they are a stenothermic species (Laurel et al. 2016). Polar cod are adapted to support high growth and lipid allocation at a narrow range of low temperatures (optimal growth rate at 5 °C), while saffron cod experience high growth and lipid allocation over a wider temperature range, particularly, at high temperatures (optimal growth rate > 16 °C) (Copeman et al. 2016; Laurel et al. 2016). As such, saffron cod may be better able to mitigate the effects of ocean warming in the Arctic than polar cod.

In 2017, the Arctic Integrated Ecosystem Research Program (Arctic IERP), funded by the North Pacific Research Board, conducted its first field season in the US Pacific Arctic. Concurrent with the Arctic IERP surveys, the Distributed Biological Observatory (DBO) project and the Arctic Marine Biodiversity Observation Network (AMBON) survey were also sampling the region, providing more coverage to this region that is often under-researched. In this inaugural year of sampling for the Arctic IERP, it was remarkable that the northern Bering Sea and Chukchi Sea were sampled for ichthyoplankton in both late spring and late summer, a first in the region. These sampling efforts provided an opportunity to assess the seasonal abundance, distribution, and growth of fishes during their early life history stages (ELHS). However, the summer of 2017 in the Chukchi Sea was also remarkable in environmental conditions, with an elevated sea surface temperature (+ 4 °C relative to the historic average) and the lowest recorded March sea ice minimum in the 39-year history of the time series (Perovich et al. 2017; Timmermans et al. 2017), providing us with baseline vital rate data for polar cod and saffron cod, albeit during a warm year. Such baseline data, when coupled with further monitoring and modeling, can be used to determine the impact of climate warming on these two ecologically important species. In addition to empirical sampling, we used an individual-based model (IBM) as a tool to simulate larval transport and examine potential linkages and connectivity in polar cod and saffron cod abundance and distribution between the late spring and late summer sampling events. Our goals for this study were to (1) examine spatial patterns of distribution and abundance of polar cod and saffron cod during their larval (June; late spring) and early juvenile (August–September; late summer) stages in 2017; (2) assess the change in mean length to approximate daily growth rates in the summer for polar cod and saffron cod; and (3) evaluate potential sources of larval polar cod and saffron cod using an IBM to compare observed distributions and sizes with model output. This study coupled empirical observations with IBM output to synthesize, for the first time, the seasonal distribution, abundance, and growth of two co-occurring Arctic forage fishes, providing a means to assess the biological impacts of warming on polar cod and saffron cod ELHS.

Methods

Specimen collection

Polar cod and saffron cod ELHS were collected in 2017, using three different sampling gears, as part of several cooperating research projects (Table 1): the Arctic Integrated Ecosystem Survey (AIES; part of Arctic IERP), AMBON survey, the Arctic Shelf Growth, Advection, Respiration, Deposition (ASGARD; part of Arctic IERP) project, and the DBO project. Larval and early juvenile Arctic gadids were targeted with a 60-cm bongo (bongo hereafter) equipped with a flow meter and a 505-µm mesh net fished obliquely from 10 m off the bottom or a maximum depth of 200 m to the surface in the late spring and late summer during the AIES and DBO surveys and to 5 m off the bottom or a maximum depth of 200 m for ASGARD. Demersal juvenile Arctic gadids (age-0, age-1 +) were targeted with a benthic-sampling 3-m plumb-staff beam trawl (Abookire and Rose 2005) equipped with 7-mm mesh and a 4-mm cod end liner during the late summer AMBON and AIES surveys (Table 1). The beam trawl was deployed from the stern of the vessel and towed at 1.5–2.0 knots for four minutes (Logerwell et al. 2015). Juvenile gadids (age- 0, age-1 +) were also collected from the midwater during AMBON using a 1.5 m wide by 1.8 m high Isaacs-Kidd Midwater Trawl Net (IKMT) equipped with 3-mm mesh and a flowmeter (Table 1). The IKMT was towed double obliquely at 3.5–4.0 knots and these data were used to look at length and growth of Arctic gadids in August, prior to the late summer AIES surveys.

All bongo samples were fixed at sea in 5% formalin buffered with seawater and processed at the Plankton Sorting and Identification Center in Szczecin, Poland. ELHS of all fishes were identified to species, enumerated, and up to 50 specimens per taxon at each station were measured to the nearest 0.1 mm. Since specimens were measured after formalin fixation, we applied a + 1.9% correction factor to the measured lengths to account for shrinkage (D. Blood, B. Laurel, NOAA, unpublished data; Vestfals et al. 2019). The identifications of ELHS gadids were verified by scientists at the National Oceanic and Atmospheric Administration's Alaska Fisheries Science Center using Matarese et al. (1989), Dunn and Vinter (1984), and Ichthyoplank- ton Information System IIS (2019). Due to concerns of Walleye Pollock (*Gadus chalcogrammus*) being misidentified as Polar Cod, the Arctic gadids captured during AIES using the beam trawl were verified using genetic methods following Wildes et al. (2016). No specimens of juvenile Arctic cod (*Arctogadus glacialis*) were detected (S. Wildes, Alaska Fisheries Science Center (AFSC), personal communication), suggesting that *A. glacialis* was not present in our study region since the abundance of later stages is reflective of the abundance of the earlier stages (Bouchard et al. 2016).

Catch per unit effort of polar cod and saffron cod was reported as the number of individuals caught under a sea surface area of 10 m^2 (count per 10 m^2). Trawl samples (IKMT and beam trawl) were processed at sea with all individual fishes being identified, enumerated, and measured to the nearest length in millimeters. Standard length (SL) was measured for individuals at flexion size or larger and notochord length (NL) for individuals smaller than flexion. The reported size of flexion is 11.0 mm for polar cod and saffron cod (IIS 2019). Catch for the AIES and AMBON beam trawl was expressed as number of individuals caught per unit area swept (count per 1000 m^2).

Data analysis

All catch and length data were analyzed using R (ver. 3.5.2; R Core Team 2019). For the length data, to account for only a subset of larvae being measured (n = 50 maximum), the estimated proportion of individuals at each length was multiplied by the standardized catch at that station (catch-weighted length). Individuals of polar cod and saffron cod larger than 70 mm SL were presumed to be one year or older based on a cutoff identified in the length–frequency distribution and were excluded from the subsequent length analyses.

Our use of 70 mm SL to delineate between age-0 and age-1 polar cod is smaller than the size of this transition identi- fied in prior work determining length at age using otoliths [84.0 mm fork length (FL) and 81.6 mm total length (TL), respectively] (Craig et al. 1982; Lønne and Gulliksen 1989) because standard length excludes measuring the caudal fin rays that are often damaged during collection. The transition of saffron cod from age-0 to age-1 is not as definitive as that for polar cod due to an overlap in size at these ages occurring between 55 and 110 mm FL in the Chukchi Sea (Wolotira 1985; Copeman et al. 2016; Helser et al. 2017). However, in Arctic samples collected in 2012 all individuals greater than 75 mm FL were age-1 based on otolith analyses, suggesting our size cutoff is reasonable for the region sampled (Copeman et al. 2016). Specimens were then aggregated into 2-mm length bins. For the AMBON samples collected with the IKMT and the beam trawl, subsamples of fish were measured to the nearest millimeter. Many of the smallest individuals (less than 50 mm) were not measured and were instead sorted into approximate 10-mm size bins, enumerated in the field, and then discarded. The binned individuals were combined with the measured individuals by simulating individual lengths of the binned individuals from a uniform random distribution within their assigned size bin. Other distributions (normal, beta) were considered for simulating lengths of the binned individuals but had minimal impact on the resulting length-frequencies.

Daily growth rates were estimated for each species as the change in mean length from June 19th, 2017, the median date of the late spring (June) ASGARD survey, and each late summer survey (AMBON and AIES) under the assumption that these individuals were from the same cohort. The median date of the AMBON survey was August 13th, 2017 and the median date of the AIES survey was September 1st, 2017. Mean length for late spring was based on all individuals collected during the survey using the bongo. Mean length for the late summer individuals was gear-specific and calculated based on all putative age-0 specimens collected during: (1) AMBON survey using a beam trawl, (2) AMBON survey using an IKMT, (3) AIES and DBO surveys using a bongo, and (4) AIES survey using a beam trawl. Data for these growth analyses did not include estimates from midwater-collected gadids sampled during the late sum- mer AIES and DBO surveys, but they were available from the IKMT fished during the 2017 late summer AMBON survey, providing some estimates of growth of midwater-associated fishes. Daily growth rates are presented as a range; the estimate provided from the late summer bongo collections represents a low estimate as larger gadids tend to escape from the bongo net (Shima and Bailey 1994) and likely represents individuals that are smaller-than-average. Late summer beam trawl collections (AIES) represent a high growth estimate as the coarser mesh size of the trawl may select for larger individuals that are larger-than-average and generally resulted in the greatest mean size. For polar cod, length-dependent mortality results in slightly greater length at age estimates (Thanassekos et al. 2012), suggesting our study will be overestimating growth since we are relying on changes in length of survivors (those individuals captured and measured by the various gear types) to estimate growth. A daily growth rate was also calculated using the IKMT data to explore differences in the apparent growth rates between age-0 fishes that are still pelagic and those that have become demersal by the time of sampling. We expected the apparent growth rate to increase as individuals become more demersal. Size distribution from the IKMT and beam trawl are likely to be directly comparable as the IKMT mesh size (4 mm) was identical to that of the beam trawl liner.

Densities (catch per unit area) of polar cod and saffron cod were mapped to explore the seasonal distribution of ELHS of Arctic gadids in the northern Bering and Chukchi seas relative to sea ice concentration on June 19th and September 1st, 2017. Sea ice concentrations were obtained from the National Snow and Ice Data Center at 25 km by 25 km spatial resolution (Cavalieri et al. 1996; NSIDC 2019).

Individual-based biophysical model for polar cod and saffron cod

Late spring and late summer distributions were compared to simulated distributions from biophysical transport mod- els parameterized for polar cod and saffron cod larval and early juvenile stages (Vestfals et al. 2021). Details on the model parameterization and the results of validation testing are described in Vestfals et al. (2021). These models were developed to simulate the growth and dispersal of early life stages in the northern Bering, Chukchi, and Beaufort seas to identify possible spawning locations, which are largely unknown, as well as to examine gadid connectivity between these seas. An implementation of the Regional Ocean Modeling System (ROMS) (Shchepetkin and McWilliams 2005) set up in a Pan-Arctic (PAROMS) configuration (Danielson et al. 2016) was used to realistically simulate the three-dimensional (3-D) circulation field. PAROMS has a horizontal resolution of ~ 5 km south of the Aleutian Islands to 9 km in the North Atlantic and is approximately 5.5–6.0 km in the Chukchi Sea, and is forced by the Japanese 55-year atmospheric reanalysis JRA55-do (version 1.4) (Tsujino et al. 2018), which also provides estimates of freshwater runoff. Boundary conditions come from the Simple Ocean Data Assimilation (SODA) reanalysis (version 3.3.1) (Carton et al. 2018) prior to 2015 and the Hybrid Coordinate Ocean Model (HYCOM) (Chassignet et al. 2009) for more recent years. The Oregon State TOPEX/Poseidon Global Inverse Solution (Egbert and Erofeeva 2002) provides tidal forcing and the sea ice field is based on the single-category

Budgell ice model (Budgell 2005). To simulate advection and growth of larvae, IBMs for polar cod and saffron cod were developed using the particle tracking tool TRACMASS that calculates Lagrangian trajectories from Eulerian velocity fields (Döös 1995).

Stage-specific and size-specific temperature-dependent growth rates were used to model the growth of polar cod and saffron cod (Porter and Bailey 2007; Laurel et al. 2016; Koenker et al. 2018) to 45 mm in length, the size at which these species are thought to transition from pelagic juveniles to more demersal juveniles, with enhanced swimming abilities. In addition, these stages correspond most closely to the stages captured by the water column sampling gear (bongo and IKMT) during the field campaign allowing for comparison between simulated and observed distributions of the two species. Similar to the growth rates calculated for the 2017 empirical data, mean daily growth rates were estimated for the simulated larvae for each species as the change in mean length from late spring (June 19th) to late summer (September 1st) divided by the number of days elapsed.

Hatching locations were identified through a thorough literature review, anecdotal evidence, and known areas of retention in the Pacific Arctic (Vestfals et al 2021 and references therein). However, due to the preponderance of early-stage individuals encountered in the Kotzebue Sound region during spring 2017, we focused this study on this region as a potential source of polar cod and saffron cod in the US Chukchi Sea. For our study, Kotzebue Sound will include the area that extends from the northwestern tip of Seward Peninsula to Point Hope. Simulations were initialized from all PAROMS grid points falling within the eastern-most part of Kotzebue Sound as hatching location (Fig. 1), with 10 particles released per 5 m depth increment to the bottom at each PAROMS grid point. The Chukchi Sea is often shallower than 40 m, which represents the maximum release depth of particles in the model (Vestfals et al. 2021). Based on results from initial particle simulations, dispersal simulations were conducted with larvae hatching on the 1st and 15th day of each month from March 1st to May 15th, for a total of six hatching events. Temperature-mediated growth and dispersal of larvae were simulated until September 1st, the midpoint of the late summer Arctic field surveys in 2017, so that the simulated distribution and size composition during summer could be compared to the observed distributions and size compositions of individuals captured during the surveys.

IBM parameterization-polar cod

Several vertical behaviors were developed for polar cod based on available literature (Borkin et al. 1986; Bouchard et al. 2016) and from laboratory observations (B. Laurel, AFSC, *unpublished data*). Of the five different vertical behavior routines tested, simulations with surface-oriented individuals, where all stages were found at 5 m matched best with prior field observations from acoustic-trawl surveys conducted in 2012 and 2013 (DeRobertis et al. 2017; Vestfals et al. 2021). Polar cod growth was based on growth equations described in Koenker et al. (2018) and Laurel et al. (2016). Simulated larval sizes and distributions on June 19th (midpoint of the ASGARD survey) and September 1st (midpoint of AIES) from simulations originating in Kotzebue Sound were compared to field observations.

IBM parameterization-saffron cod

Similar vertical behaviors were used for the saffron cod simulations as for polar cod since no information on the vertical distribution of saffron cod larvae is available at present. Preflexion larval growth from hatch to 10 mm in length was based on temperature-dependent growth experiments (B. Laurel, unpublished data; Vestfals et al. 2021). At present, temperature-dependent growth models for saffron cod ELHS > 10 mm in length are not available. As growth of saffron cod at these small sizes is linear and resembles that of walleye pollock (B. Laurel, AFSC, unpublished data), the growth model described in Porter and Bailey (2007) was used to model saffron cod growth from 10 to 45 mm.

Results

Field data

Sea ice

As of June 1st, just prior to the survey, sea ice was present in the Kotzebue Sound region (S. Danielson, University of Alaska Fairbanks (UAF), unpublished data). By June 19th, the mid-point of the late spring survey, sea ice was receding and the entire survey area was ice-free.

Abundance, distribution, and size of polar cod

In June, the highest densities of polar cod (> 640 individuals per 10 m^2) were found at nearshore stations of Kotzebue Sound and Point Hope transects and along the entire Cape Lisburne transect (Fig. 2a). Polar cod density was lower south of the Bering Strait with most individuals being encountered along the northernmost transects sampled in the Chukchi Sea. By late summer (August and September), sea ice remained absent in the survey region south of 75°N, except in the nearshore area of Kotzebue Sound. The overall density of polar cod decreased from an average catch of 1183 individuals per 10 m^2 in the late spring to 7 individuals per 10 m^2 in the late summer in the

Bongo –Late spring black squares and late summer (August/September) gray squares; beam trawl–AMBON survey (August) blue inverted triangles and AIES (August/September) dark gray triangle; and Isaacs-Kidd Midwater Trawl (IKMT) –AMBON survey (August) white circles. Simulated release locations from the individual-based model in the eastern-most area of Kotzebue Sound (KS), which is shaded in purple. Kotzebue Sound also refers to the broader region from the northwestern tip of Seward Peninsula and Point Hope to the north. Depth contours extend from 50 to 250 m in 50 m increments

water column. The highest densities of polar cod in the water column (> 10 individuals per 10 m^2) were observed in the northern portion of the survey area in the late sum- mer, particularly around Barrow Canyon and Hanna Shoal (Fig. 2b). The distribution of polar cod in the water col- umn was similar to the distribution of demersal individu- als. Demersal catches of juvenile polar cod (< 70 mm SL) were highest offshore in the northern Chukchi Sea in the late summer in areas where bottom water temperatures were below approximately 5 °C (Fig. 3a and b).

In June, the mean length of polar cod larvae in the water column was 9.8 mm NL (n = 850), with most larvae being less than 12.0 mm in length (Fig. 4a; Table 2). By the end of the summer, the length distribution of polar cod had expanded and the mean length increased to 30.1 mm SL ± 0.9 (n = 140) and 30.7 mm SL ± 0.4 (n = 433) for specimens collected in the water column with the bongo and IKMT gears, respectively (Fig. 4c, e; Table 2). In late summer (August–September) the mean length of demersal polar cod was 39.7 mm SL ± 0.4 (n = 718) in the AMBON

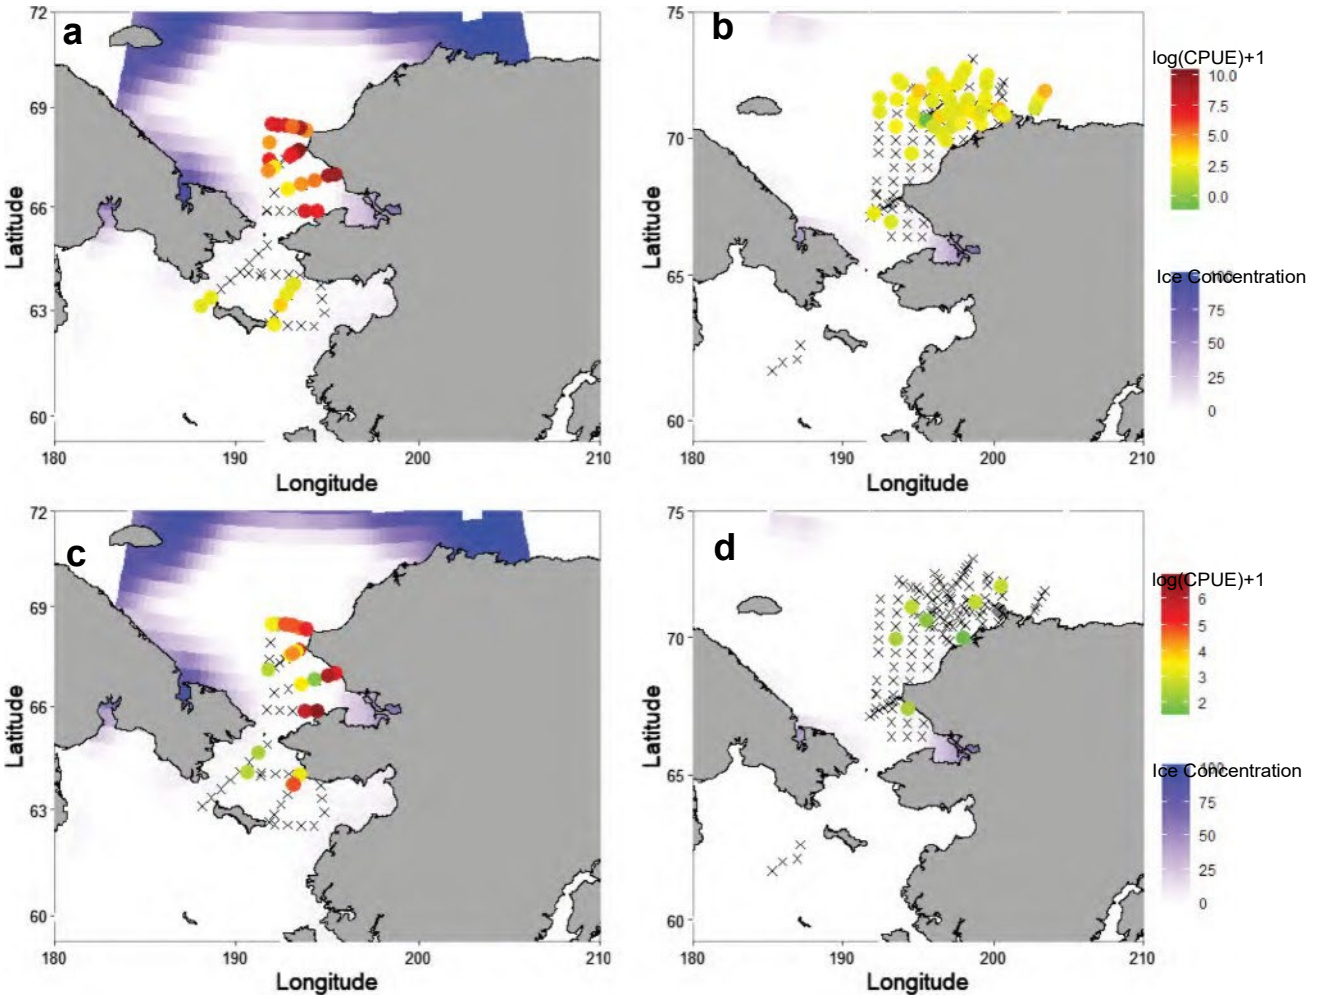

Fig. 2 Distribution of polar cod (*Boreogadus saida*) (**a**, **b**) and saffron cod (*Eleginus gracilis*) (**c**, **d**) in late spring (left column) and late summer (right column) 2017 collected in the water column with the 60-cm bongo net. Catch data are reported as catch-per-unit-effort (CPUE) and log(CPUE)+1 to highlight variability at lower abundances. Ice concentration (% cover) is plotted in the background. Black X's denote sampled stations where polar cod and saffron cod were not caught. Note the different scales for CPUE between the species

beam trawl samples and 47.8 mm SL ± 1.6 (n = 690) in the AIES beam trawl samples (Fig. 4g, i; Table 2). Based on changes in length and an assumption that larvae collected in the late summer surveys were from the same cohort as fish collected in the late spring, the estimated daily growth rate for polar cod during 2017 ranged from 0.27 mm day^{-1} based on individuals in the water column to 0.53 mm day^{-1} based on individuals that had become demersal (Table 3), with an overall mean of 0.39 ± 0.06 mm day^{-1} (n = 4) based on all measured individuals.

Abundance, distribution, and size of saffron cod

The density of pelagic larval saffron cod in June was high- est at the nearshore stations in Kotzebue Sound and Cape Lisburne, which were both ice covered on June 1st, prior to the mid-point of the survey, with densities ranging from 68 to 444 individuals per 10 m^2. The highest observed density of saffron cod was at the innermost station along the southern margin of Kotzebue Sound (Fig. 2c). Catches south of Kotzebue Sound were low (less than 30 individu- als per 10 m^2). Densities of saffron cod were much lower later in the summer (August and September), with most of the stations yielding no saffron cod (Fig. 2d). Unlike saffron cod in the water column, demersal larval and early juvenile saffron cod in later summer were rarely encountered offshore, with most individuals concentrated near Cape Lisburne (Fig. 3c and d). Demersal saffron cod were observed in areas with higher bottom temperatures than demersal polar cod. In early August, saffron cod were con- centrated in areas with bottom water temperatures greater

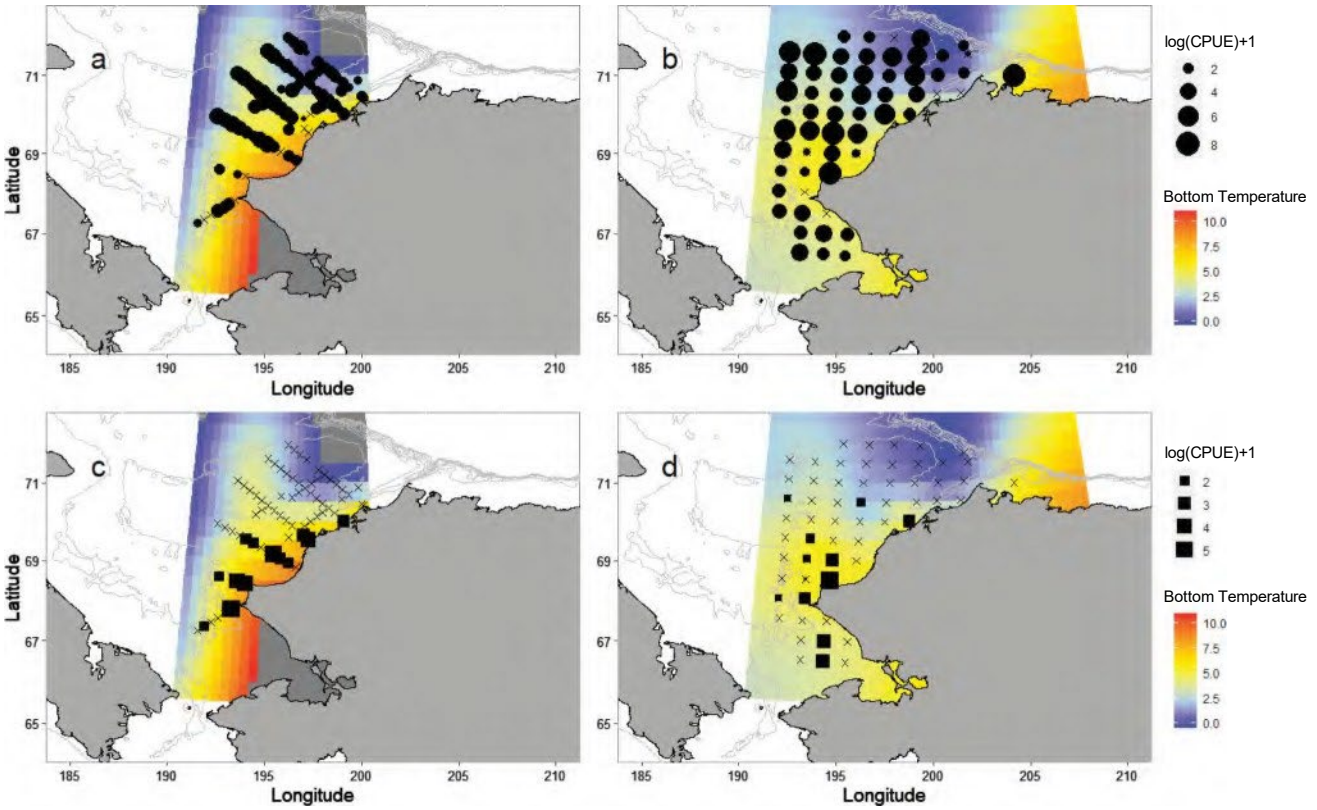

Fig. 3 Late summer distributions of demersal juvenile polar cod (*Boreogadus saida*) from AMBON (**a**) and AIES (**b**) beam trawl collections and of demersal juvenile saffron cod (*Eleginus gracilis*) from the AMBON (**c**) and AIES (**d**) beam trawl collections. The background color denotes bottom temperature in °C. Catch data are reported as catch-per-unit-effort (CPUE) and log(CPUE) + 1 to highlight variability at lower abundances. Note the different scales for CPUE between the species

than 7.5 °C and by September occupied areas with bottom water temperatures greater than 5.4 °C.

Saffron cod had a mean length of 9.3 mm NL ± 0.4 (n = 299) in June, with most individuals measuring less than 14.0 mm in length (Fig. 4b; Table 2). By late summer, the mean length of saffron cod ranged from 18.5 mm SL ± 1.4 (n = 7) in the bongo to 40.3 mm SL ± 1.7 (n = 41) in the IKMT (Fig. 4d, f). The mean length of demer- sal saffron cod was 51.6 mm SL ± 0.4 (n = 318) in the AMBON beam trawl and 55.1 mm SL ± 1.7 (n = 54) in the AIES beam trawl by late summer (Fig. 4h, j; Table 2). The daily growth rate for saffron cod was estimated as 0.12 mm day^{-1} to 0.76 mm day^{-1} (Table 3), with a mean of 0.37 ± 0.16 mm day^{-1} (n = 4).

Comparison of distribution and size of polar cod and saffron cod

Catches of saffron cod were lower relative to polar cod regardless of season. In June, the core distribution of saffron and polar cod overlapped in Kotzebue Sound, with polar cod found farther offshore than saffron cod (Fig. 2). Later in the summer, saffron cod were encountered in bongo samples of the water column at only 7 of the 136 stations sampled. Demersal juveniles of polar cod were observed farther offshore and to the north relative to saffron cod in the late summer. They were also most abundant offshore of the region between Cape Lisburne and Wainwright at stations with bottom water temperatures cooler than 5.0 °C. In contrast, demersal juveniles of saffron cod were most abundant nearshore off Cape Lisburne and in northern Kotzebue Sound where bottom water temperatures were warmer than 7.5 °C (Fig. 3b, d).

Polar cod and saffron cod were similar in mean size in June when their distributions also overlapped. Later in the season, far fewer saffron cod (n = 420) were captured and measured compared to polar cod (n = 1981). Demer- sal saffron cod were larger than those found in the water column in the late summer. The range of daily growth rates was wider for saffron cod than polar cod, but the mean daily growth rate was similar between saffron cod and polar cod at 0.37 ± 0.16 and 0.39 ± 0.06 mm day^{-1}, respectively (n = 4).

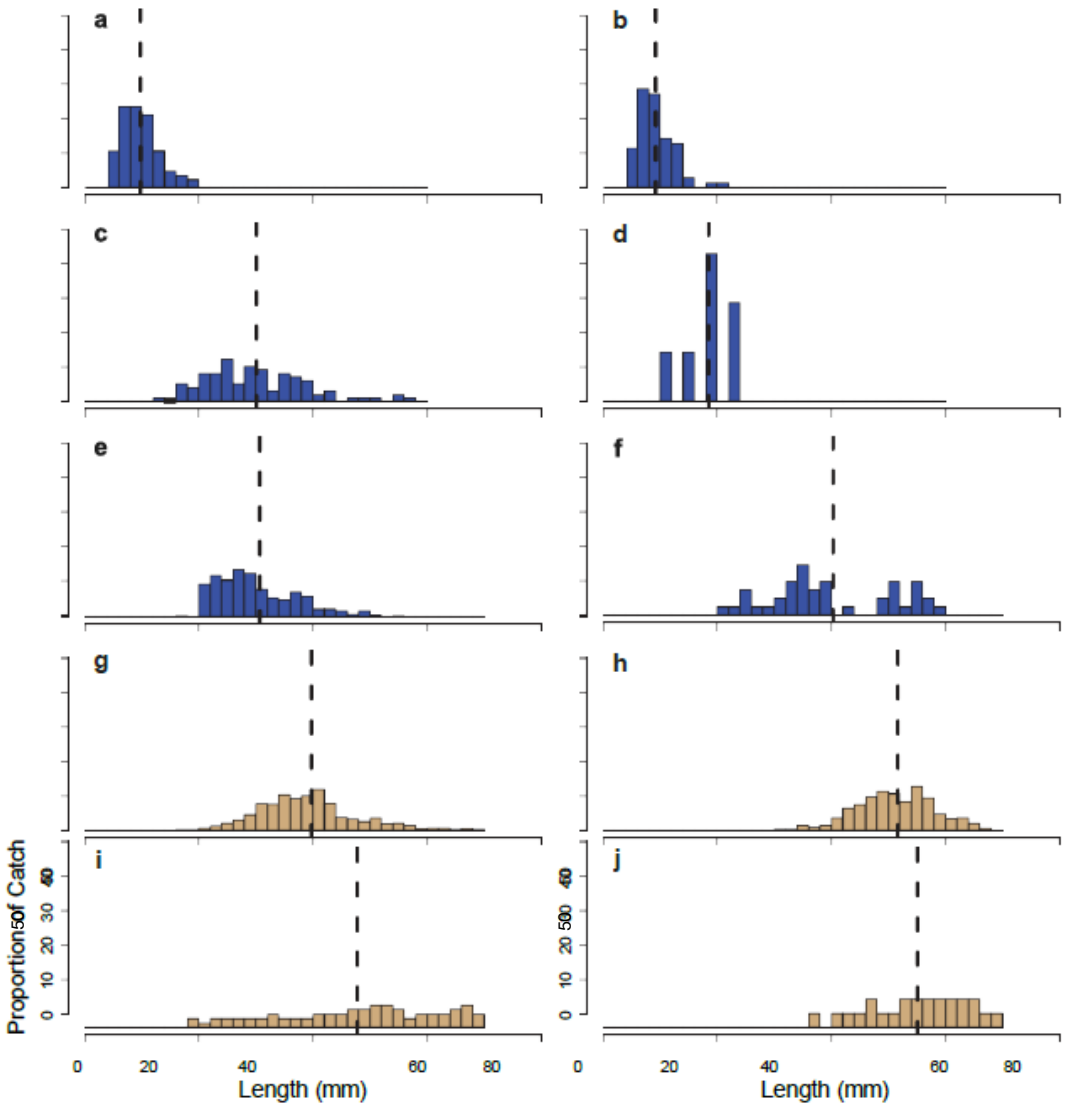

Fig. 4 Length distributions of polar cod (*Boreogadus saida*) (left) and saffron cod (*Eleginus gracilis*) (right) during the late spring (**a**, **b**) and late summer collections with 60-cm bongo (**c**, **d**), Isaacs-Kidd Midwater Trawl (IKMT) (**e**, **f**), AMBON beam trawl (**g**, **h**), and AIES beam trawl (**i**, **j**). Dotted black lines denote the mean length for each histogram. Blue bars represent individuals collected from the water column and brown bars represent those collected along the seafloor. Specimens are binned into 2-mm length intervals and standardized by CPUE when all captured individuals were not measured (i.e., bongo)

IBM simulated data

Simulated distribution and size of polar cod

On June 19th, simulated polar cod hatching in Kotzebue Sound between March 15th and May 15th had similar dispersal trajectories and were mostly found to be retained in and around Kotzebue Sound and in the nearshore region northward to Cape Lisburne (Fig. 5). At Cape Lisburne, some larvae were transported offshore to the north and to the west, and were concentrated in two different trajectories, except for simulated individuals hatched on May 15th. Other individuals were transported northward along the coastline. Based on the 2017 simulations, no individuals were transported to the south in the late spring, though polar cod were observed in the late spring survey around St. Lawrence Island (Fig. 2a; Fig. 5). By September 1st, simulated polar cod were found in the nearshore region from Kotzebue Sound north to Wainwright (Fig. 6). Simulated polar cod were advected offshore, almost due west, at Cape Lisburne/

Point Hope. Hatch date did not greatly impact the end points of the simulated polar cod on September 1st (Fig. 6). In the late summer, simulated polar cod were abundant offshore of Cape Lisburne/Point Lay and Wainwright but uncommon nearshore along the coastline from Kotzebue Sound to Wainwright (Fig. 6), which was consistent with the empirical data (Fig. 2b; Fig. 3).

The mean size of simulated polar cod individuals hatched between March 1st and April 1st was larger than individuals captured in the field (Fig. 4, Fig. 7). Simulated individuals hatched on May 1st and May 15th were on average smaller than the field samples. For larvae that hatched on April 15th, the average size of simulated polar cod matched the average size of the captured individuals, although the range was broader for the individuals caught in the field compared to the simulated individuals (Table 2, Table 4). In the late summer, the average size of the simulated polar cod was smaller than the wild-caught specimens regardless of hatch date (Fig. 7). The simulated sizes were most similar to polar cod captured using the bongo in the late summer (Table 2, Table 4).

Simulated distribution and size of saffron cod

The simulated distribution of saffron cod in the late spring and late summer was similar to that of polar cod (Fig. 8). Similar to polar cod in the late spring, no simulated saffron cod larvae were found along the southern coastline of Kotzebue Sound, whereas saffron cod larvae were captured along the southern coastline of Kotzebue Sound and northern coastline of Norton Sound (Figs. 2–3). In the late summer, simulated saffron cod were densely concentrated along the coastline extending from Kotzebue Sound to just north of Wainwright with two offshore advection areas at Point Lay/Cape Lisburne and south of Wainwright (Fig. 9). Catches of saffron cod were low in the late summer but the areas with the highest catches corresponded to high den- sity areas identified by the model, particularly offshore of Wainwright and Point Lay/Cape Lisburne (Figs. 2–3; 9).

Regardless of season or hatch date, simulated saffron cod were smaller on average than field captured individu- als (Table 2, Table 4). In addition, the length range of simulated individuals was narrower than the captured individuals in the late spring and late summer (Fig. 10). Unlike simulated polar cod, there was little overlap in the late spring and late summer sizes of simulated saffron cod (Fig. 10). In the late spring, simulated saffron cod did not grow larger than 8.5 mm NL and had a mean size of 5.7 mm NL ± 0.0025–0.0037 for all simulated hatch dates (Fig. 10, Table 4). In the late summer, the average size of simulated saffron cod ranged from 14.6 mm SL ± 0.024 to 14.9 mm SL ± 0.023 (Fig. 10, Table 4).

Hatch dates are: **a** March 1st, **b** March 15th, **c** April 1st, **d** April 15th, **e** May 1st, and **f** May 15th. Density is calculated in a 0.5 × 0.5 degree grid

Discussion

Spawning areas and drift

Sea ice was present in Kotzebue Sound at the approximate time of hatch for both polar cod and saffron cod until early June (S. Danielson, UAF, unpublished data; Cavalieri et al. 1996), suggesting that sea ice may be important for the newly hatched larvae of both species. Kotzebue Sound may indeed be a hatching area for polar cod and a source of juveniles to the north later in the summer. One of the main northward currents in the eastern Chukchi Sea is the Alaska

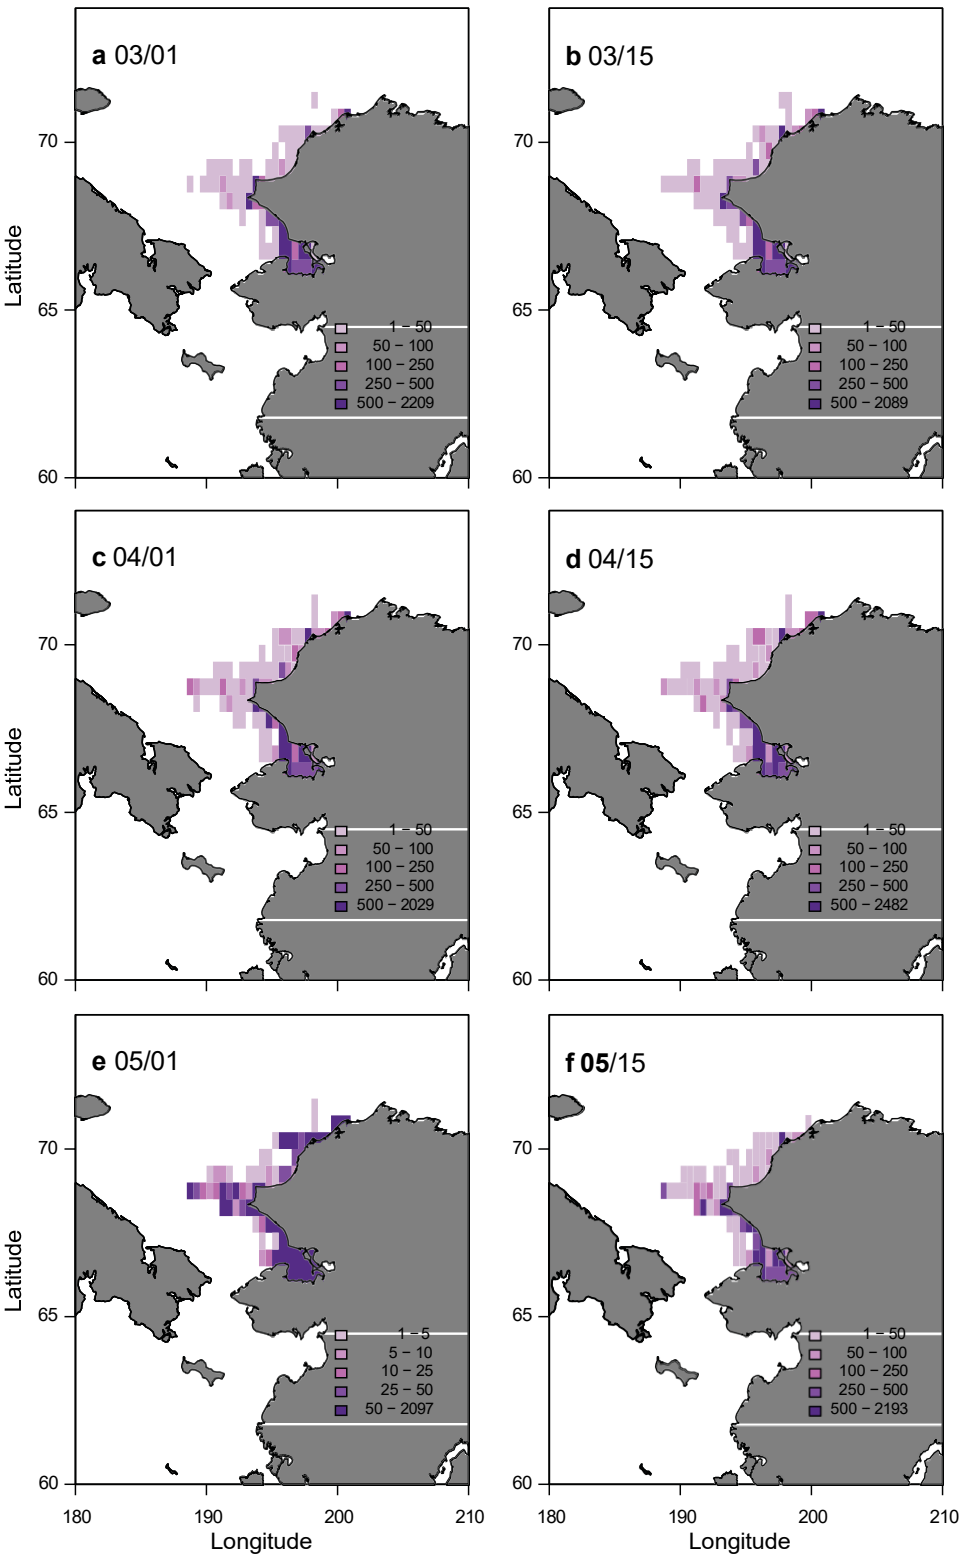

Fig. 6 Density of simulated endpoints from individual-based models in the late summer (September 1st, 2017) for polar cod (*Boreogadus saida*) hatching in Kotzebue Sound. Hatch dates are: **a** March 1st, **b** March 15th, **c** April 1st, **d** April 15th, **e** May 1st, and **f** May 15th. Density is calculated in a 0.5 × 0.5 degree grid

Coastal Current (ACC), which flows through Bering Strait and past the mouth of Kotzebue Sound and it is likely to entrain larvae originating in the Sound. Transport through Bering Strait has been increasing in recent years, which, in turn, has increased heat transport into the Chukchi Sea and the rate of sea ice retreat in the spring (Woodgate et al. 2012; Woodgate 2018), as well as current velocity that may increase the dispersal potential for ELHS entrained in the

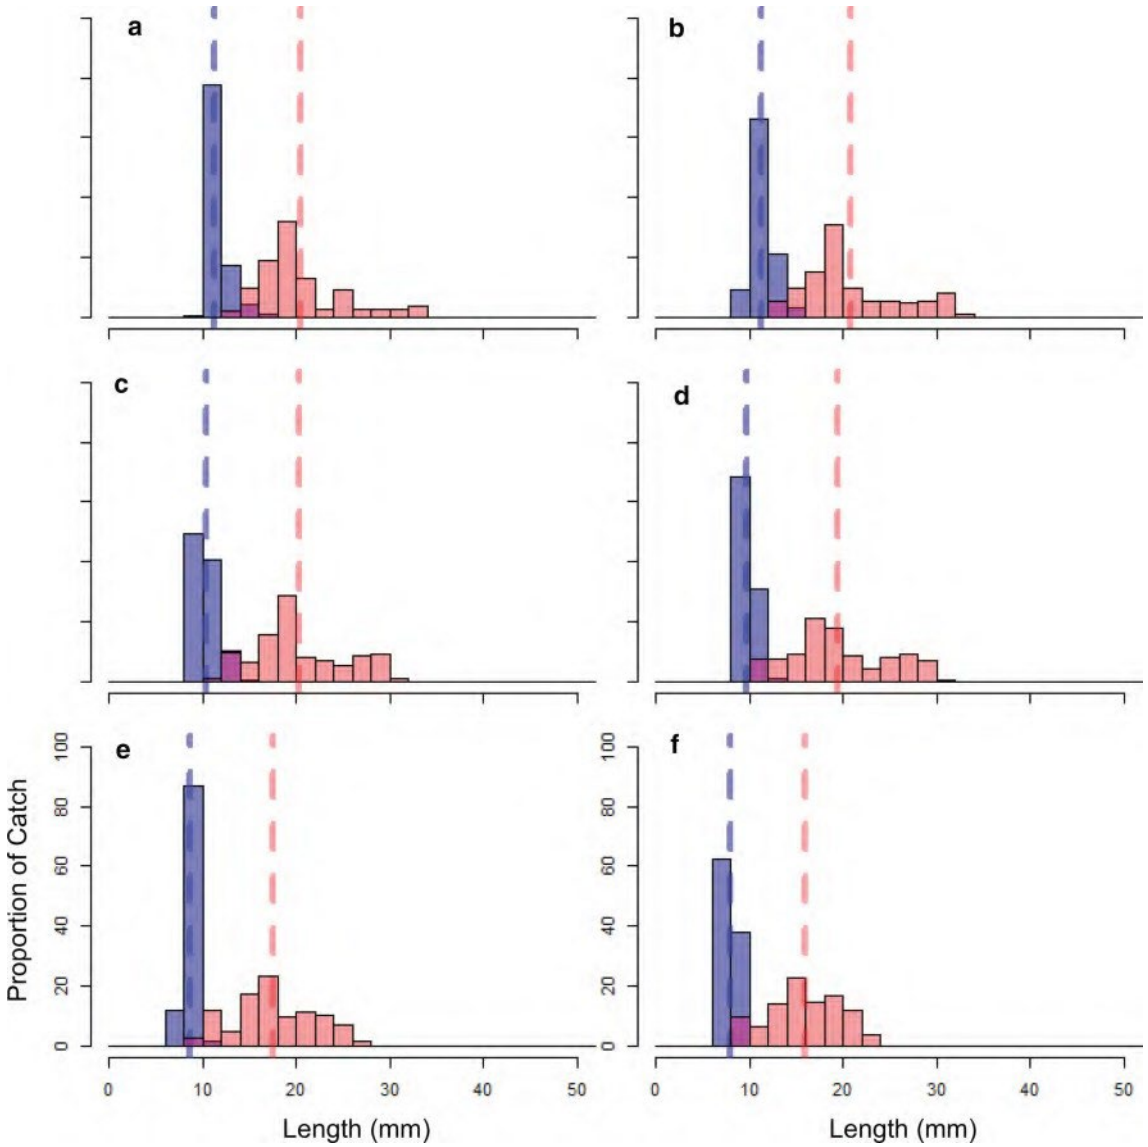

Fig. 7 Length histograms of simulated polar cod (*Boreogadus saida*) larvae by hatch date from the individual-based model in 2017. Hatch dates are: **a** March 1st, **b** March 15th, **c** April 1st, **d** April 15th, **e** May 1st, and **f** May 15th. Blue bars represent late spring (June 19th) lengths and red bars represent late summer (September 1st) lengths. The dashed blue line denotes the mean size of the simulated polar cod in the late spring, whereas the red dashed line denotes the mean size of the simulated polar cod in the late summer. Specimens are binned into 2-mm length intervals

ACC. However, high polar cod abundance in the summer of 2014 corresponded to reduced transport through the Bering Strait (Randall et al. 2019), leading to decreased advection and higher local retention of ELHS. Simulations suggest that polar cod collected along the seafloor and in the water column along the coast and in some offshores areas were likely hatched in Kotzebue Sound and were transported north by the ACC to the northern Chukchi Sea. We believe the likelihood of contamination of polar cod by Arctic cod (*A. glacialis*) is low and not of concern for our analyses. The identity of polar cod collected in the late summer AIES beam trawl was confirmed genetically (S. Wildes, Alaska Fisheries Science Center (AFSC), personal communication). Since the primary currents entering the US Chukchi Sea shelf flow from the south to the north (Danielson et al. 2017), it is unlikely that there is a source of Arctic cod, a high Arctic species, in the southern Chukchi Sea or Bering Strait that would substantially contribute to the larval gadid community of the region (Aschan et al. 2009), especially considering the low sea ice and high water temperatures observed in 2017 (Timmermans et al. 2017; Perovich et al. 2017).

Saffron cod are caught in lower densities than polar cod in the late summer, likely due to their ELHS preferring nearshore habitats not sampled by our surveys (Logerwell

Mean size in mm and standard error are reported within the parentheses for each hatching date and sample size (*n*) is reported

et al. 2015; Vestfals et al. 2019). Similar to polar cod, Kotzebue Sound may be a hatching or early nursery area for saffron cod in the late spring. Demersal saffron cod were concentrated in the nearshore, warm waters in northern Kotzebue Sound and around Cape Lisburne, which was similar to the model-predicted distribution, suggesting that saffron cod hatched in Kotzebue Sound were the major source of demersal individuals in the late summer of 2017. Albeit speculative, the few larval saffron cod caught in the water column offshore of Wainwright and Barrow Canyon may be a result of a bet-hedging spawning strategy for saffron cod spawned in Kotzebue Sound and Bering Strait, such as has been documented in other sub-arctic gadids (Laurel et al. 2008; Hutchings and Rangeley 2011). Prolonged hatching periods will result in later hatched saffron cod larvae developing in warmer water where growth rates may be enhanced if mortality related to prey and predators is reduced (Laurel et al. 2008).

Growth and development

The daily growth rates calculated for polar cod and saffron cod were based on individuals collected in the water column and along the bottom using gears that collectively target larvae and juveniles and are used as a coarse estimate of growth in the US Chukchi Sea in the absence of otolith-derived growth rates. Assuming no size-selectivity over the range of sizes that were present, we were able to estimate a range of daily growth rates based on changes in mean length between specimens collected in the late spring and late summer of 2017. Our estimates assume that measured individuals were randomly selected from the same cohort sampled in the late spring and again in the late summer. However, it is probable that individuals from other hatching locations and cohorts were present in the northern Chukchi Sea in the late summer, violating this assumption (e.g., larvae originating from the other side of the U.S. –Russian Federation maritime boundary). In our region in 2017, hatching was observed from January through May, with a peak in April (Z. Chapman, UAF, personal communication), based on the individuals captured during the late spring bongo samples. However, we are likely missing newly hatched larvae in the late spring bongo samples due to the extrusion of these individuals through the 505 μm bongo net mesh (Thanassekos et al. 2012), biasing our samples to individuals that hatched earlier or possessing higher growth rates. The daily growth rate results should be interpreted with caution without a more robust measure of growth using otolith-derived estimates, which is impos- sible for our study due to our specimens being preserved in formalin at sea. Otolith-derived ages would provide refinement of the length-based daily growth rates estimated in this study by determining individual growth rates and allowing for subsequent exploration of differences in growth trajectories by gear type, sampling season, and region. However, we did account for differences in growth rate by gear type and sampling time by estimating daily growth rates as a range, providing a conservative and a maximal estimate each late summer survey and gear type. Our length-based daily growth estimates also assume a constant growth rate over the sampling season, which is likely violated as individuals attain later stages and larger sizes (Thanassekos and Fortier 2012). Daily growth estimated in this study for polar cod ranged from 0.27 mm day^{-1} to 0.53 mm day^{-1} with a mean of 0.39 ± 0.06 mm day^{-1} (n = 4). Our most conservative

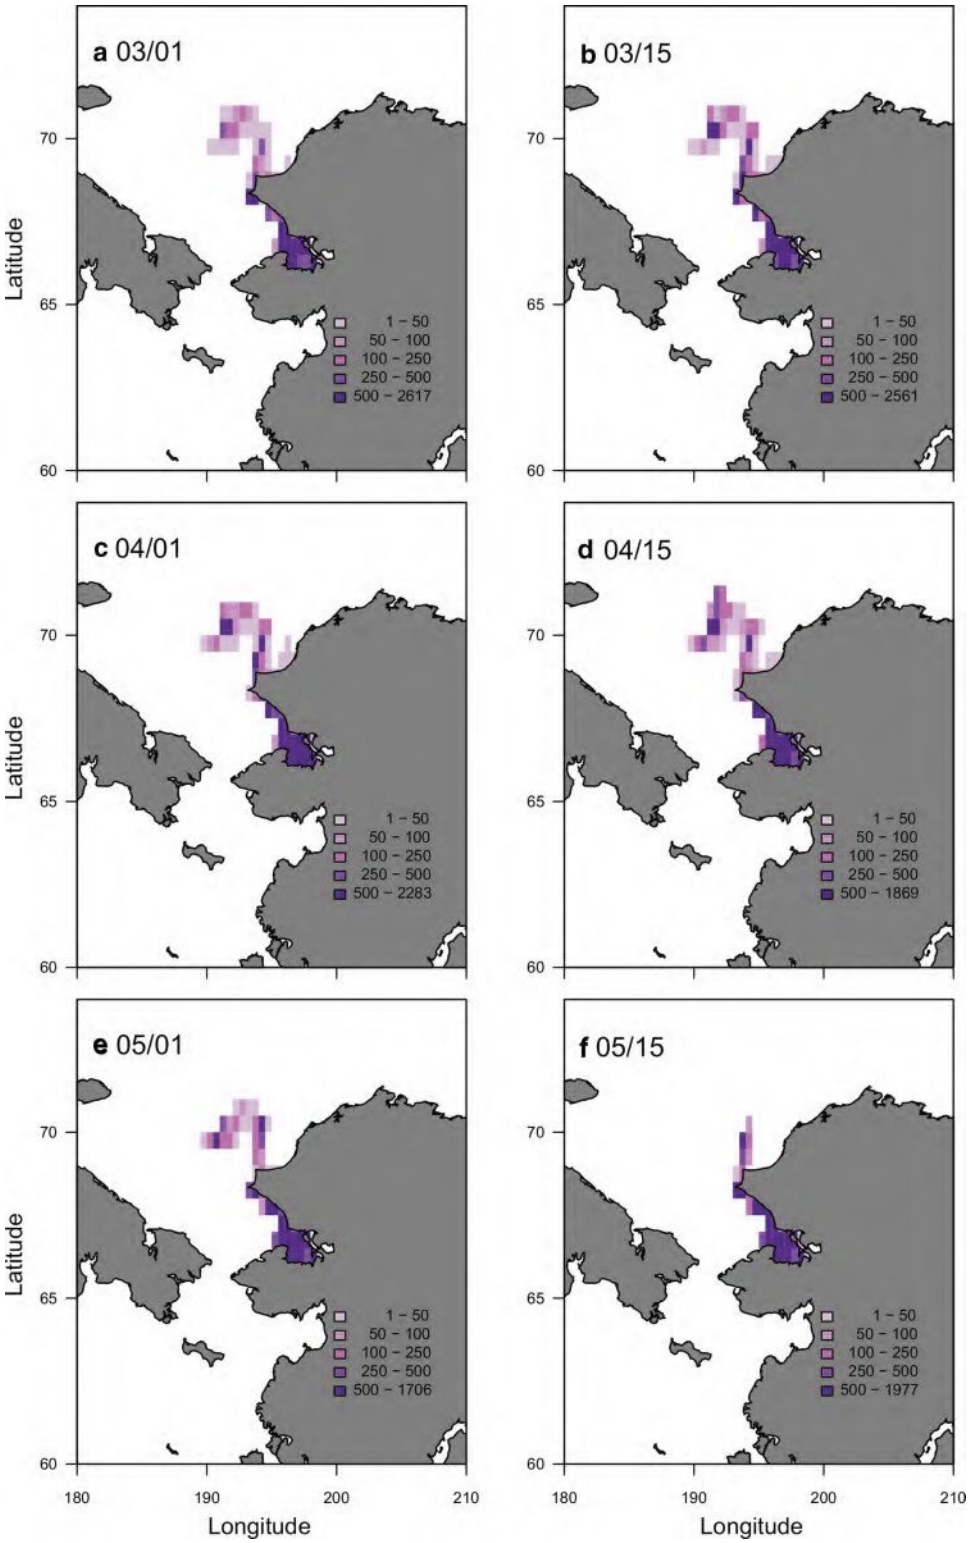

Fig. 8 Density of simulated endpoints from individual-based models in the late spring (June 19th, 2017) for saffron cod (*Eleginus gracilis*) hatching in Kotzebue Sound. Hatch dates are: **a** March 1st, **b** March 15th, **c** April 1st, **d** April 15th, **e** May 1st, and **f** May 15th. Density is calculated in a 0.5 × 0.5 degree grid

growth estimate for polar cod (0.27 mm day^{-1}) agrees well with previous field studies (Bouchard and Fortier 2011; Thanassekos et al. 2012; Vestfals et al. 2019). Daily growth for polar cod in this study may also be higher than is typical due to the elevated water temperatures experienced in 2017. Even though polar cod are adapted to maximize growth at colder temperatures than saffron cod, warmer spring sea surface temperature and earlier ice retreat may be advantageous to larval polar cod due to the availability of zooplankton production supported by earlier

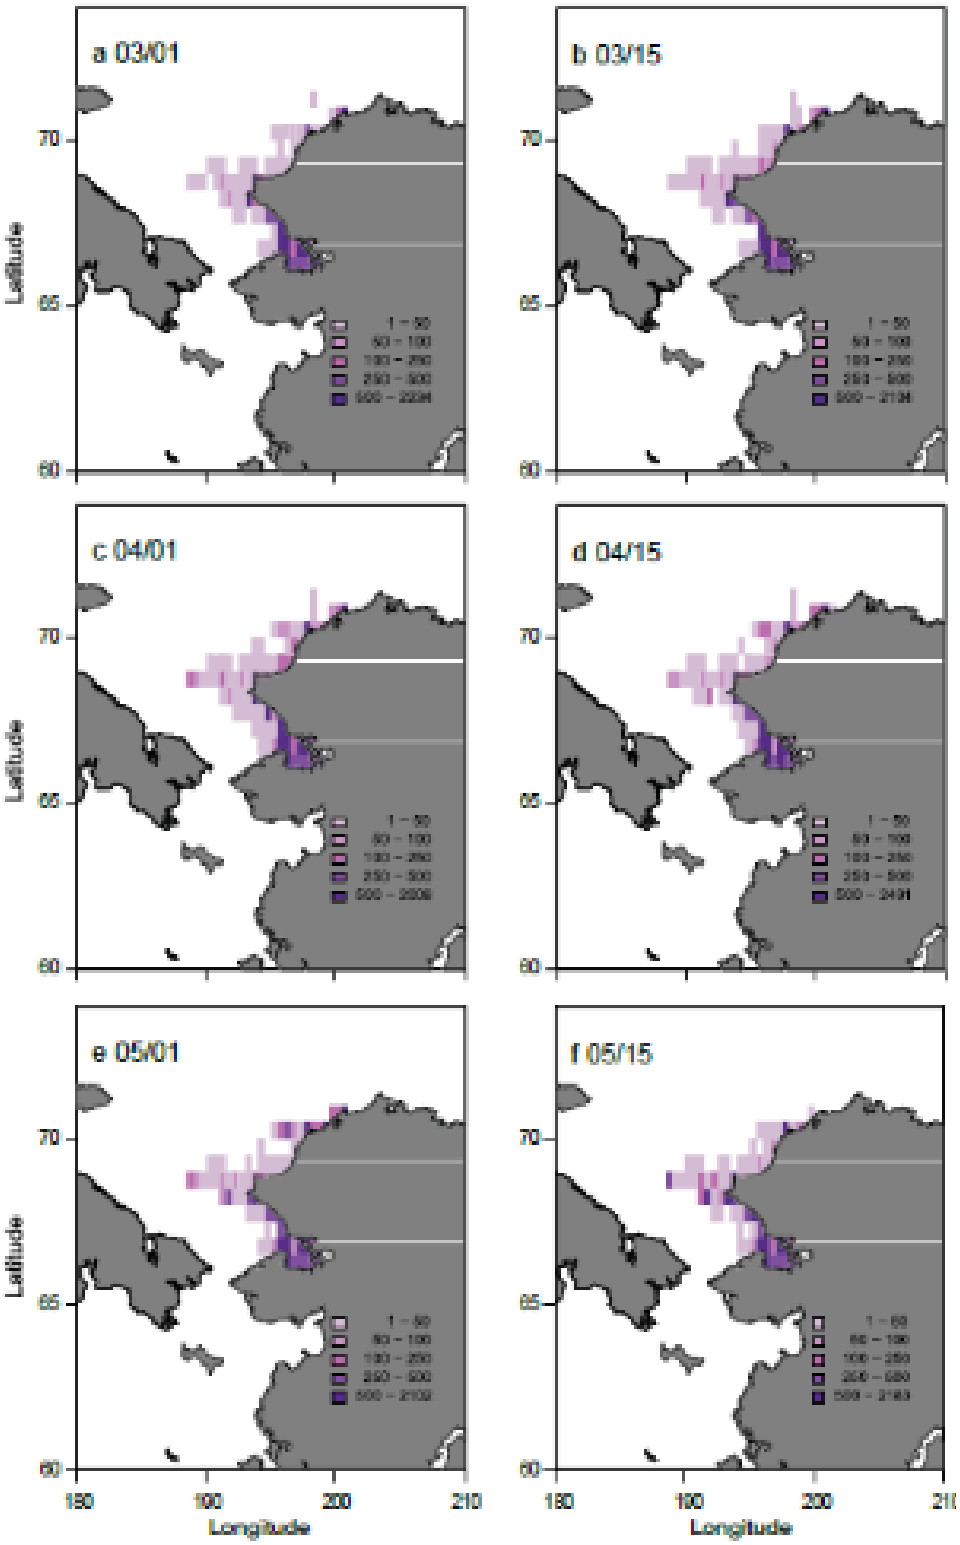

Fig. 9 Density of simulated endpoints from individual-based models in the late summer (September 1st, 2017) for saffron cod (*Eleginus gracilis*) hatched in Kotzebue Sound. Hatch dates are: **a** March 1st, **b** March 15th, **c** April 1st, **d** April 15th, **e** May 1st, and **f** May 15th. Density is calculated in a 0.5 × 0.5 degree grid

ice algae and phytoplankton blooms. This would improve the temporal match of early hatching polar cod with their zooplankton prey (Bouchard et al. 2017). Under scenarios of continued warming in the Arctic, polar cod may lose this growth advantage leading to reduced survival when thermal tolerances of their ELHS are exceeded.

This study is one of the first to estimate daily mean growth for ELHS of saffron cod (0.12–0.76 mm day^{-1};

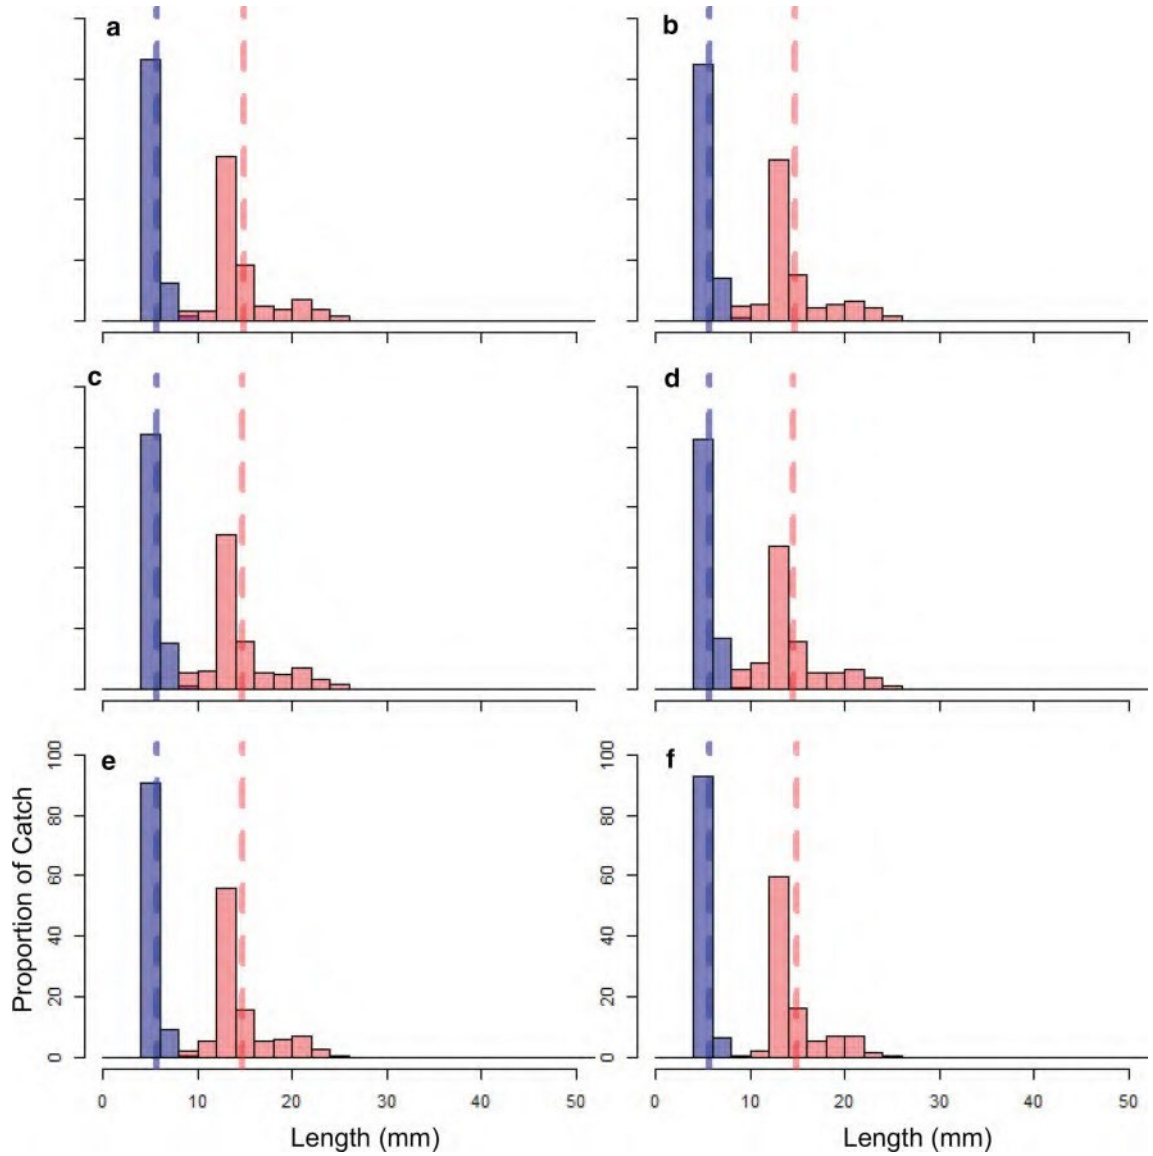

Fig. 10 Length histograms of simulated saffron cod (*Eleginus gracilis*) larvae by hatch date from the individual-based model in 2017. Hatch dates are: **a** March 1st, **b** March 15th, **c** April 1st, **d** April 15th, **e** May 1st, and **f** May 15th. Blue bars represent late spring (June 19th) lengths and red bars represent late summer (September 1st) lengths. The dashed blue line denotes the mean size of the simulated saffron cod in the late spring, whereas the red dashed line denotes the mean size of the simulated saffron cod in the late summer. Specimens are binned into 2-mm length intervals

0.37 ± 0.16 mm day^{-1}; n = 4) collected within the Chukchi Sea. The conservative estimate for daily growth for saffron cod was based on bongo collections in the late summer. The lack of larger saffron cod in the bongo gear compared to the mid-water trawl suggests that larger saffron cod were present in the water column, but avoided the bongo net, which targets smaller individuals (De Robertis et al. 2017; Vestfals et al. 2019). A more realistic lower estimate for daily growth was derived from the mid-water IKMT at 0.56 mm day^{-1}. Saffron cod experience faster growth and better condition at higher temperatures than polar cod (Laurel et al. 2016; Vestfals et al. 2019), consistent with larger sizes and higher apparent growth rates in this study, therefore, a warming Arctic may favor saffron cod over polar cod. The growth advantage for saffron cod at higher temperatures may come at the expense of increased metabolic demands and a shift in the zooplankton community to smaller, less lipid-rich copepod species (Copeman et al. 2017; Aarflot et al. 2018; Møller and Nielsen 2020; Bouchard and Fortier 2020).

Model-data comparison

Kotzebue Sound was selected as the source of simulated polar cod and saffron cod ELHS in this study due to the preponderance of small larvae observed in this area in the late spring, highlighting the region's potential role as a key hatching and/or nursery habitat for the ELHS of these species. The observed distribution of Arctic gadids along the northern coastline of Kotzebue Sound in the late spring matched well with simulated larval distributions from the model. At Point Hope and Cape Lisburne, a portion of the ACC is often deflected offshore (Danielson et al. 2017), which is reflected in both the late spring model simulations and survey catch data. The IBM predicts that larval polar cod and saffron cod will be advected offshore and northward at Cape Lisburne. Consistent with the model simulations, we observed high catches of polar cod and saffron cod offshore of Cape Lisburne during the spring survey. High abundances of polar cod and saffron cod may also be present north of Cape Lisburne in the spring as predicted by the IBM, but we lack the empirical data to test this as sampling did not extend north of Cape Lisburne. Additionally, the simulated distributions for saffron cod and polar cod from the IBM were similar to each other. This is due to the use of a single release location (Kotzebue Sound) for both species and identical behavior routines so that differences in distribution in our study were associated with the species-specific temperature-dependent growth rates used to parametrize the IBMs (Vestfals et al. 2021).

There was no evidence from the model that larvae are advected south from Kotzebue Sound. Any spawning in Kotzebue Sound is likely not the origin of individuals that were caught around St. Lawrence Island or nearshore along the northern Seward Peninsula during spring. Recent modeling work suggests that polar cod hatching south of Bering Strait could be the source of larvae and early juveniles encountered in surveys in the northeastern Chukchi Sea in 2012 while Bering Strait and Kotzebue Sound were likely source regions for saffron cod in 2012 and 2013 (Vestfals et al. 2021).

In the late summer, the IBMs for polar cod and saffron cod indicated high concentrations of larvae and early juveniles nearshore from northern Kotzebue Sound to Wainwright, offshore of Point Hope/Cape Lisburne, and offshore of Wainwright. The modeled distributions agree with the observed late summer distribution of saffron cod where higher abundances were generally nearshore, especially around Point Hope and Cape Lisburne, with abundance decreasing offshore. This suggests that Kotzebue Sound is a center of abundance and potentially serves as an important spawning and hatching area for saffron cod in the Chukchi Sea, a possibility that has been suggested anecdotally (A. Whiting, Village of Kotzebue, personal communication; Vestfals et al. 2021). Larval polar cod were ubiquitous offshore in the Hanna Shoal region during the late summer surveys in 2017, which is consistent with polar cod distributions in other years (Logerwell et al. 2020), but was not captured well by the model, indicating that other hatching locations are major contributors to the observed age-0 aggregations in this area (Vestfals et al. 2021). The simulated distribution overlapped with the distribution of late summer polar cod ELHS individuals offshore of Point Hope and Cape Lisburne, as well as nearshore extending from Cape Lisburne to Wainwright, suggesting Kotzebue Sound may be a potential source of polar cod to these areas in the late summer.

Simulated lengths for both polar cod and saffron cod were smaller than observed specimens collected in the late spring and late summer from the water column or the bottom, with a much larger discrepancy for saffron cod than polar cod. This suggests that the model is underestimating growth, small larvae in the field experience higher mortalities than large larvae, temperatures in the model are underestimates, hatching occurs earlier than assumed, or a combination of these and potentially other factors. The growth equations for polar cod and saffron cod within the IBM are temperature-mediated (Vestfals et al. 2021), making simulated lengths and estimates of daily growth sensitive to thermal conditions in the model, which may differ from those experienced in the field. No growth model exists for ELHS of saffron cod larger than 10 mm in length and the growth model was parameterized using data for walleye pollock due to their similar, linear growth trajectories prior to 10 mm (B. Laurel, AFSC, personal communication; Porter and Bailey 2007; Petrik et al. 2015). However, saffron cod may deviate from linear growth trajectories at later stages or temperatures (Vestfals et al. 2021). Additionally, field estimates of apparent growth tend to be higher than those observed in the lab because of ecological interactions, such as size-selective predation (Houde 2009). The field-based growth calculations were relatively coarse, encompassing all the collected individu- als aggregated from a large spatial area, over a two-month sampling period, and likely originating from multiple spawn locations, whereas the model is based on a single release location.

In the late spring, simulated polar cod hatched before April 15th were larger on average than the individuals captured from the water column, suggesting the model is realistically reflecting the enhanced growth rates of polar cod in the late spring due to earlier ice retreat and warmer water temperatures in 2017 relative to average conditions. The narrow size range of individuals in the model compared to the field collections can indicate several potential scenarios. Firstly, Kotzebue Sound was selected as the source of polar cod and saffron cod larvae, but it is not the only source of larvae in the Chukchi Sea. For example, recent modeling work suggests that Bering Strait and Chukotka

Peninsula were important hatching areas for polar cod in the Chukchi Sea in 2012 and 2013 (Vestfals et al. 2021). Secondly, the presence of smaller polar cod in the catch in the late spring may also suggest a simulated hatch date of April 15th or later, although the model does not capture the full range of observed sizes, particularly at the upper end. We selected to model hatch dates between March 1st and May 15th, which corresponded to the duration of peak hatching for polar cod in 2017, although hatching has been reported as early as January 1st for polar cod in the Arctic (Bouchard and Fortier 2011; Z. Chapman, UAF, personal communication). In polar cod, hatch date explains more variability in length than temperature conditions (Bouchard et al. 2017), therefore, some of the inconsistencies between the sizes, and subsequent calculated growth rates, of field collected and simulated individuals may be due to the hatch date variability. Thirdly, field estimates also differ from those observed under controlled laboratory conditions due to ecological factors that are difficult to account for (Bailey and Houde 1989; Houde 2009; Vestfals et al. 2019) such as patchy prey distribution and small-scale environmental variability (temperature, salinity, etc.). Polar cod are likely able to take advantage of a "big risk, big reward" strategy to forage for limited periods of time in warm, productive waters along thermal-salinity fronts to maximize growth relative to conspecifics (Laurel et al. 2016; Bouchard et al. 2017), which may contribute to the wider size range observed for the field-collected individuals compared to simulated individuals in the late spring.

Differences between simulated and empirical data may also be related to the onset of demersal behavior in polar cod and saffron cod, which is an adaptation to avoid predation, enhance foraging, and find areas of physiological preferred temperature ranges. Given the dominance of gadids by number and biomass in demersal catches in the Arctic (Logerwell et al. 2015), fish predators of ELHS of polar cod and saffron cod are likely conspecifics. Cannibalism has been documented in other subarctic gadids and is mitigated by vertical partitioning between juveniles and adults (Bailey 1975, 1989). Adult walleye pollock in the Bering Sea are semipelagic and cannibalism was highest when juveniles moved deeper in the water column, overlapping with the adults (Bailey 1989). Cannibalism is considered rare for polar cod due to their planktivorous foraging strategy, although fishes do become an important prey category as polar cod grow, and instances of cannibalism have been documented (Bain and Sekerak 1978; Benoit et al. 2010; Christiansen et al. 2012; Whitehouse et al 2017). Polar cod forage primarily on copepod nauplii (e.g., *Pseudocalanus* spp.) when smaller than 25 mm SL and shift to foraging on the copepodite stages of copepods, specifically *Calanus* spp. and *Metridia* spp., and fishes when larger than 25 mm SL (Benoit et al. 2010; Christiansen et al. 2012; Bouchard et al. 2016; Bouchard and Fortier 2020). Saffron cod likely become more piscivorous with increasing size (Laurel et al. 2009), suggesting cannibalism may be more likely in this species than polar cod. Diet data are limited for saffron cod in the Chukchi Sea (Copeman et al. 2016). Increased water temperatures and constriction of available habitat for Arctic taxa may lead to increased cannibalism for polar cod and saffron cod as well as increased competition and predation if subarctic species move into the Chukchi Sea (Bouchard et al. 2017). A number of adult fish species from the Ber- ing Sea, such as walleye pollock and Pacific cod, expanded northward in response to a reduced Cold Pool (bottom water temperatures < 2 °C) over the Bering Sea shelf (Stevenson and Lauth 2019) and are possible competitors as well as predators of Arctic gadids in the Chukchi Sea if climatic warming persists (Marsh and Mueter 2019). Near bottom waters may also act as a thermal refuge for smaller Arctic gadids, particularly small polar cod that are not as tolerant to higher water temperatures as saffron cod (Laurel et al. 2016).

Summary

The late spring distributions of polar cod and saffron cod centered in Kotzebue Sound suggest that sea ice may be an important environmental factor influencing hatching, and it may provide a nursery habitat for newly hatched individuals of both species. Kotzebue Sound was likely a source of ELHS of polar cod and saffron cod offshore of Point Hope/Cape Lisburne and nearshore from Kotzebue Sound to Wainwright during 2017. Without otolith-derived individual growth estimates, it is difficult to know if polar cod and saffron cod experienced greater growth during 2017 compared to other years or regions due to elevated temperatures, although our daily growth estimates were higher than reported in past research (Bouchard and Fortier 2011). Saffron cod should benefit in a warmer Arctic if their ELHS are resilient to the loss of sea ice, and if energetic trade-offs can offset prey-mediated factors that may depress growth (i.e., reduced nutritional value, zooplankton community shift) (Llopiz et al. 2014; Spear et al. 2019) and an increase in competition and predation from sub-Arctic demersal fishes shifting to the north (Stevenson and Lauth 2019). With the forecasted warming in the Arctic and projected changes in sea ice dynamics, studies such as this one synthesizing the seasonal distribution, abundance, and growth of Arctic forage fishes are critical to assess changes in phenology, distributions, and abundance for these species and the impacts of warming on habitat availability for Arctic fishes.

Acknowledgements The authors thank all of the boat and field crews of the USCGC *Healy*, M/V *Ocean Starr*, and R/V *Sikuliaq* who collected these data and without their tireless efforts, this project would not have been possible. We thank the Plankton Sorting and Identification Center in Szczecin, Poland and the ichthyoplankton team at

the Alaska Fisheries Science Center for their taxonomic expertise that makes studies of the ecology of Arctic fishes possible. We also thank Jens Nielsen and Adam Spear for their assistance gathering and plotting the sea ice data as well as intellectual discussions on the interpretation of the data. Finally, we thank Katherine Hedstrom at the University of Alaska Fairbanks for providing the PAROMS model output and Caitlin Smoot and Cheryl Hopcroft, also at the University of Alaska Fairbanks, for facilitating data collection and curation of ASGARD samples. Funding for this project was provided by the North Pacific Research Board through the Arctic Integrated Ecosystem Research Program. AMBON collections were made possible through a National Ocean Partnership Program (NOPP Grant NA14NOS0120158) by the National Oceanic and Atmospheric Administration, the Bureau of Ocean Management and Shell Exploration & Production. The findings and conclusions in the paper are those of the author(s) and do not necessarily represent the views of the National Marine Fisheries Service. Mention of trade names does not imply endorsement by NOAA or any of its subagencies. This is contribution number EcoFOCI-1015 of Ecosystems and Fisheries-Oceanography Coordinated Investigations.

Author contributions ALD, EAL, EDG, and JTD conceived and framed the key questions of the study. CDV conducted all IBM analyses, contributed code to generate figures related to the IBM, and provided text in the *Methods* sections. FJM, SLD, EAL, and RRH provided data that made the analyses possible. ALD wrote the manuscript and generated the figures. All authors read and approved the manuscript.

Declarations

Conflict of interest The authors have no conflict of interest to report.

Ethical approval All field sampling was done in accordance with NOAA NMFS policies, as outlined under the Animal Welfare Act and US Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training. Collections were made under the following permits approved by the Alaska Regional Office, National Marine Fisheries Service (CF-17-023), a US Fish and Wildlife Service Seabird Salvage Permit (MB035470), and a State of Alaska Resource Permit (CF-16-010).

Abstract

Polar cod (*Boreogadus saida*) is a key forage fish in the Arctic marine ecosystem and provides an energetic link between lower and upper trophic levels. Despite its ecological importance, spatially explicit studies synthesizing polar cod distributions across research efforts have not previously been conducted in its Pacific range. We used spatial generalized additive models to map the distribution of polar cod by size class and relative to environmental variables. We compiled demersal trawl data from 21 cruises conducted during 2004–2017 in the Chukchi and Beaufort seas, and investigated size-specific patterns in distribution to infer movement ecology of polar cod as it develops from juvenile to adult life stages. High abundances of juvenile polar cod (≤ 70 mm) in the northeastern Chukchi Sea and western Beaufort Sea were separated from another region of high abundance in the eastern Beaufort Sea, near the US and Canadian border, suggesting possible population structure in the Pacific Arctic. Relating environmental correlates to polar cod abundance demonstrated that temperature and salinity were related to juvenile distribution patterns, while depth was the primary correlate of adult distribution. A comparison of seasonal 2017 abundances of polar cod in the southern Chukchi Sea found low demersal abundance in the spring when compared to the summer. Seasonal differences in polar cod abundance suggest that polar cod migration may follow a classical 'migration triangle' route between nursery grounds as juveniles, feeding grounds as subadults, and spawning grounds as adults, in relation to ice cover and seasonal production in the Chukchi Sea.

Introduction

Currently, understanding of the basic life history of many marine organisms in the Arctic, including polar cod (*Boreogadus saida*), is based on intermittent "snapshots" of species' presence, abundance, and distribution. While the distribution and movement of polar cod has been investigated in Atlantic Arctic regions such as the East Greenland shelf (Astthorsson 2015), and the Barents, Laptev, and East Siberian seas (Ponomarenko 1968; Lønne and Gulliksen 1989), a comprehensive study synthesizing multiple research efforts to describe the distribution of polar cod is yet to be completed for its range in the Chukchi and Beaufort seas (Mueter et al. 2016).

Polar cod is an abundant, circumpolar forage fish species and is a critical trophic link in the Arctic marine ecosystem (Lowry and Frost 1981; Mecklenburg et al. 2011; Hop and Gjosaeter 2013). This small-bodied species spawns under sea ice in the late fall and early winter and has buoyant eggs

that float to the ice–water interface (Graham and Hop 1995; Bouchard and Fortier 2011). Its diet is composed primarily of zooplankton such as copepods, hyperiid amphipods, and euphausiids in the summer, open water season (Rand et al. 2013; Gray et al. 2016), and ice amphipods and Calanus copepods in the winter, ice-covered season (Kohlbach et al. 2017). In the Pacific Arctic, polar cod is found in high salinity and intermediate water temperatures of the Chukchi Sea shelf (Norcross et al. 2010; Logerwell et al. 2017; De Robertis et al. 2017b). In the Beaufort Sea, polar cod is ubiquitous, present at all depths both on the shelf and the extending seaward down the slope (Benoit et al. 2008; Geoffroy et al. 2011; Norcross et al. 2017).

Body size and ontogeny influence the ability of fishes to exploit available resources and may affect their distribution with respect to these resources. As fish size increases, individuals become stronger swimmers and can exploit larger and more energetically valuable prey (Werner and Hall 1974; Christensen 1996; Clark et al. 2005), while increasing gape size widens the size range of exploitable resources (Scharf et al. 2000; Gray et al. 2017). In the Chukchi and Beaufort seas, body size influences the composition of prey in polar cod diets (Walkusz et al. 2013; Gray et al. 2016). Smaller polar cod are restricted to consuming small-bodied prey (i.e., calanoid and cyclopoid copepods), while larger individuals can also consume large-bodied zooplankton (i.e., hyperiid amphipods and euphausiids) (Gray et al. 2016; Norcross et al. 2017). Therefore, as ontogenetic increases in body size also improve prey resource accessibility, polar cod distribution is likely impacted by size-specific resource distribution.

Differential distribution in fish size with respect to resources can influence species-level life history strategies, including both ontogenetic and seasonal migration patterns. In classic 'migration triangle' theory, species migrate from nursery grounds to feeding grounds and finally to spawning grounds throughout the course of a life cycle (Harden Jones 1968; Secor 2002). Many species in the North Pacific exhibit this life history strategy, including close relatives of polar cod, Pacific cod (*Gadus macrocephalus*), and walleye pollock (*Gadus chalcogrammus*) (Shimada and Kimura 1994; Kotwicki et al. 2005). Seasonal migrations are also common for fish species in the highly seasonal North Pacific ecosystem. Pacific herring (*Clupea pallasii*) and yellowfin sole (*Limanda aspera*), for example, exploit abundant food resources as they migrate between summer feeding grounds and offshore overwintering grounds (Nichol 1998; Tojo et al. 2007). Both the ontogenetic and seasonal migration patterns of polar cod in the Pacific Arctic are not well established and could be improved with additional sampling beyond the August and September open water sampling season.

Global attention has recently shifted to the Arctic, creating a unique opportunity for national and international fisheries management organizations to incorporate precautionary management strategies from the outset. In 2009 the North Pacific Fisheries Management Council (NPFMC) closed US Arctic waters to commercial fishing until sufficient information becomes available to sustainably manage a fishery (NPFMC 2009). Polar cod is listed as one of only two finfish species with commercial potential within the NPFMC Arctic Fisheries Management Plan, and any fishery development would require a review of the life history of the potential target species, as well as an evaluation of the impacts to essential fish habitat. While a number of recent pelagic and demersal trawl surveys conducted by both the National Marine Fisheries Service and academic researchers (Rand and Logerwell 2011; Norcross et al. 2013; De Robertis et al. 2017b) have described broad patterns in polar cod distribution and overall abundance (Logerwell et al. 2015), a study specifically investigating polar cod distribution patterns across multiple years and many cruises is yet to be completed. Accordingly, we generated a comprehensive understanding of polar cod distribution in the Chukchi and Beaufort seas, investigating patterns with respect to size class, environmental covariates, and seasonal data in the southern Chukchi Sea to inform a hypothesis about a polar cod migration triangle.

Methods

Study region

Within US waters, polar cod is abundant in the Chukchi and Beaufort seas, two waterbodies with differing physical and biological conditions. The Chukchi Sea has a wide and shallow shelf with average depths ranging from 40 to 60 m. This sea benefits from an inflow from three primary water masses, nutrient poor Alaska Coastal Water (ACW), nutrient-rich Bering Shelf Water (BSW), and nutrient-rich Anadyr Water (AW) (Fig. 1; Weingartner 1997; Weingartner et al. 2013; Danielson et al. 2017b). There is considerable mixing between the BSW and AW, creating a water mass that has been termed Bering Chukchi Summer Water (BCSW) (Danielson et al. 2017b). The ACW, BSW, and AW originate in the Bering Sea and travel northward through Bering Strait, transporting nutrients and creating areas of high primary production and rich benthic habitats in portions of the Chukchi Sea (Dunton et al. 2005; Grebmeier et al. 2006). The high levels of Chukchi Sea shelf productivity are influenced to a greater extent by nutrient input from BCSW, than by ACW (Grebmeier et al. 1988). In contrast to the Chukchi Sea, the Beaufort Sea has a much narrower shelf with a slope that drops off steeply to the Arctic Basin. In addition to nutrient-rich waters flowing eastward from the Chukchi Sea, oceanographic processes in the Beaufort

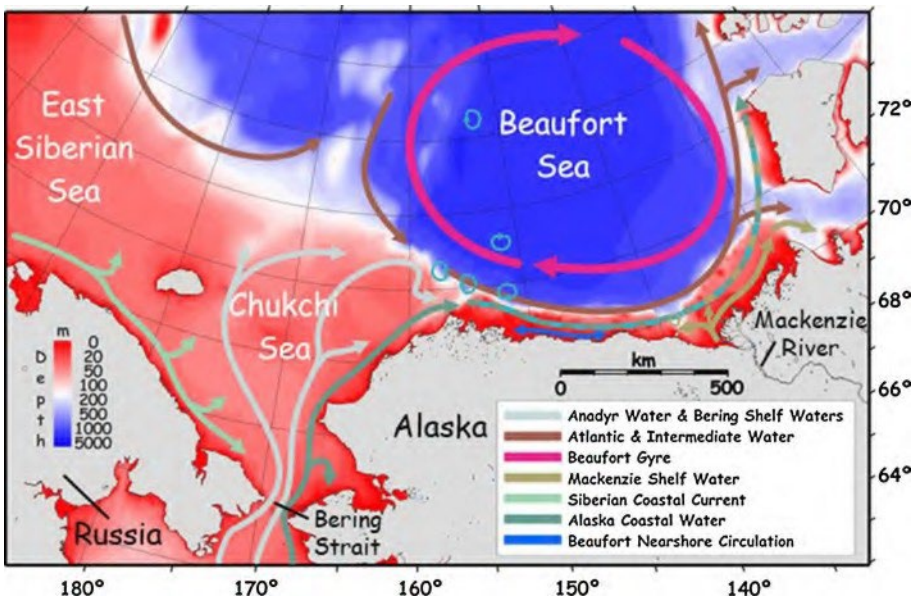

Fig. 1 Schematic of oceanic current flow in the Chukchi and Beaufort seas. After S. Danielson, personal communication

Sea are influenced by water from the Atlantic Ocean, the Beaufort Gyre, and freshwater input from the Mackenzie River (Carmack and Macdonald 2002). Water masses in the Beaufort Sea include a continuation of the eastward flowing ACW from the Chukchi Sea, Summer Shelf Water (SSW) influenced by both sub-Arctic and Arctic currents, and deep Atlantic Water (AtlW) transported west from the Atlantic Ocean (Carmack et al. 1989; Lansard et al. 2012; Norcross et al. 2018). Without nutrient subsidies from richer sub-Arctic waters, production in the Beaufort Sea is much lower than in the Chukchi Sea (Dunton et al. 2005). Regional differences in production create an unequal availability of resources between the Chukchi and Beaufort seas, which may drive both broad-scale patterns of polar cod distribution between the two seas, as well as more fine-scale patterns of polar cod distribution by size class in each respective sea.

Data collection

Data were compiled from 21 research surveys that were conducted during the open water season in the Chukchi and Beaufort seas beginning in 2004 and extending through 2017. Data were available from 16 cruises in the Chukchi Sea and five cruises in the Beaufort Sea (Table 1). In the Chukchi Sea, station locations ranged from approximately 170° W to Point Barrow, 156° W, and from the Bering Strait, 66.4° N, to approximately 73° N. Because the Chukchi Sea is relatively shallow, sampled depths were commonly between 40 and 60 m, with a maximum depth of 90 m. Station locations in the Beaufort Sea extended along the Alaskan coast from Point Barrow and into Canadian waters past the Mackenzie River to 137° W, and offshore to approximately 72° N (Fig. 2). Sampled depths reached nearly 1000 m in the Beaufort Sea. Cruises were divided into two seasons, spring and summer, based on temporal proximity of sampling to sea ice retreat and spring bloom conditions, which has a median date of approximately 20–21 June, based on data collected from 1997–2009 (Kahru et al. 2011). A cruise conducted from 9 to 29 June 2017 in the Chukchi Sea (ASGARD, Table 1), produced some of the earliest seasonal sampling events to ever take place in this region and was categorized as a spring season cruise because sampling occurred at the same time as the spring bloom (Danielson et al. 2017a). The remaining 20 cruises, conducted from 7 July to 10 October, occurred after the initial pulse of spring production from the spring bloom, and were thus categorized as summer season cruises. Because sampling in the spring occurred much earlier than during other cruises, data from this season were excluded from a spatial analysis of the summer distribution of polar cod. Further description of sensitivity analyses regarding seasonal divisions are discussed below.

All polar cod were captured in one of two configurations of a 3-m plumb staff beam trawl (PSBT), either standard (Gunderson and Ellis 1986) or modified with rollers (Abookire and Rose 2005), which were deployed for 1–10 min and towed at a speed over ground of 1.5–2.0 knots. A rigid 3.05 m beam held the net open for an effective swath of 2.26 m; net mesh size was 7 mm in the body with a 4 mm codend liner. In a gear comparison study, neither catch per unit effort (CPUE) of all fishes nor size classes of polar cod were significantly different between these two gear types (Norcross et al. 2018), therefore, abundance data from both gear types were pooled for analysis. Fishing effort for each haul was defined as the total seafloor area swept by the net. Catches were standardized to an area of 1000 m^2 (catch per unit effort or CPUE in no. of fish per 1000 m^2).

					Total no. of hauls	697

Due to difference in sampling seasons, ASGARD_2017 cruise excluded from spatial analysis

In addition, at each haul location a Seabird conductivity-temperature-depth (CTD) recorder was deployed from the vessel separately and used to measure depth (m), bottom water temperature (°C), and bottom water salinity (PSU), hereafter referred to as depth, temperature, and salinity. Fish specimens were measured for total length.

Data analysis

Patterns in polar cod abundance and total length were plotted and inspected prior to statistical analysis. Length frequencies of 6519 and 2752 fish in the Chukchi and Beaufort seas, respectively, were plotted by 10 mm increments (1–10 mm, 11–20 mm, etc.) and examined to inform selection of size classes for analysis (Fig. 3). Visual inspection suggested the presence of three modes, therefore size classes were identified using an expectation–maximization (EM) algorithm to fit a mixture of three Gaussian distributions to the length-frequency data (Benaglia et al. 2009). Based on the results, abundances of polar cod were separated by total length into small (≤ 70 mm), medium (71–130 mm), and large (> 130 mm) size classes. Size classes approximately correspond with age 0, 1, and 2 + polar cod, respectively, based on previously published work (Helser et al. 2017). However, given considerable overlap in length-at-age distributions, the medium size class likely contains a mixture of age-1 and age-2 individuals.

Generalized additive modeling (GAM) was used to relate CPUE of polar cod to spatial and environmental predictor variables. A GAM is a regression technique that uses non-parametric smoothers to allow non-linear relationships between dependent and independent variables (Hastie and Tibshirani 1986; Wood 2006). The GAM approach was chosen to accommodate non-linear relationships between abundance and both spatial (latitude, longitude) and environmental (depth, temperature, salinity) predictors. All models were fit using the 'mgcv' package version 1.8–17 (Wood 2006) in R version 3.4.1 (R Core Team 2017). Analysis may be found in Online Resource 1.

To determine the most appropriate model framework for both the spatial and environmental GAM analyses, preliminary analyses and model diagnostics were conducted prior to selection of final models. Abundance of polar cod was non-normal, including a high proportion of zero-catch hauls, as well as a few hauls with very high abundance values. Exploratory analyses compared models using a Gaussian distribution with log-transformed polar cod CPUE and the identity link function, with negative binomial and tweedie

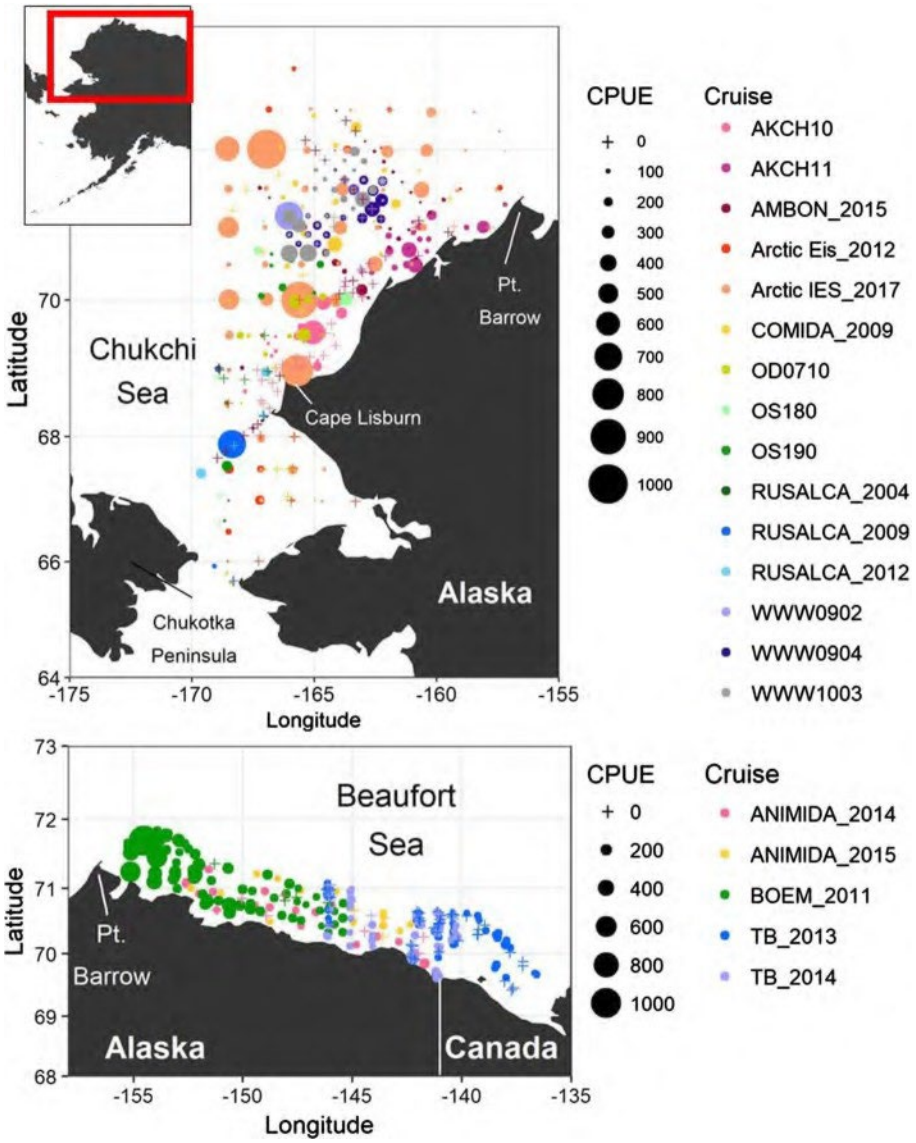

Fig. 2 Catch per unit effort (CPUE, no. of fish per 1000 m²) of polar cod by haul in the Chukchi Sea (top panel) and Beaufort Sea (bottom panel). The + symbol denotes hauls where zero polar cod were caught. Colors correspond to separate cruises. Symbol size is proportional to CPUE. For details about each cruise, see Table 1

distributions using counts of polar cod and the log link function. The negative binomial distribution with a log link was selected as the top performing model based on residual diagnostics, deviance explained, and generalized cross validation scores. This model framework was thereafter used for all GAM analyses. The negative binomial distribution utilizes count data, and is commonly used for analyzing ecological data, as it can accommodate overdispersed observations, or observations with a high proportion of zeros (Zuur et al. 2007). Therefore, we used the count data with a log link and accounted for fishing effort by including the logarithm of area swept (m²) as an offset in the model.

GAM analyses were conducted on cruises conducted in the summer season, defined as open water and more than 30 days after the start of the spring bloom. Two cruises, T/S Oshoro-Maru IV 2008 (Table 1) and WWW0904 2009 were conducted early and late in the summer season (July and October). To verify that it was appropriate to include these cruises in an analysis of polar cod summer distribution patterns, a sensitivity analysis both including and excluding these cruises was conducted. The results of all analyses were virtually identical; therefore, T/S Oshoro-Maru IV 2008 and WWW0904 2009 were included in summer season analyses. Due to considerable differences in oceanographic and bathymetric conditions and due to their spatial separation, analyses were conducted separately for the Chukchi and Beaufort seas.

To describe polar cod distribution patterns and the impact of environmental drivers on those patterns, two separate analyses were undertaken using GAM. The first analysis described the spatial distribution of polar cod abundance using latitude and longitude as covariates. Environmental conditions were strongly confounded with spatial location; for example, in the Beaufort Sea, depth increased with

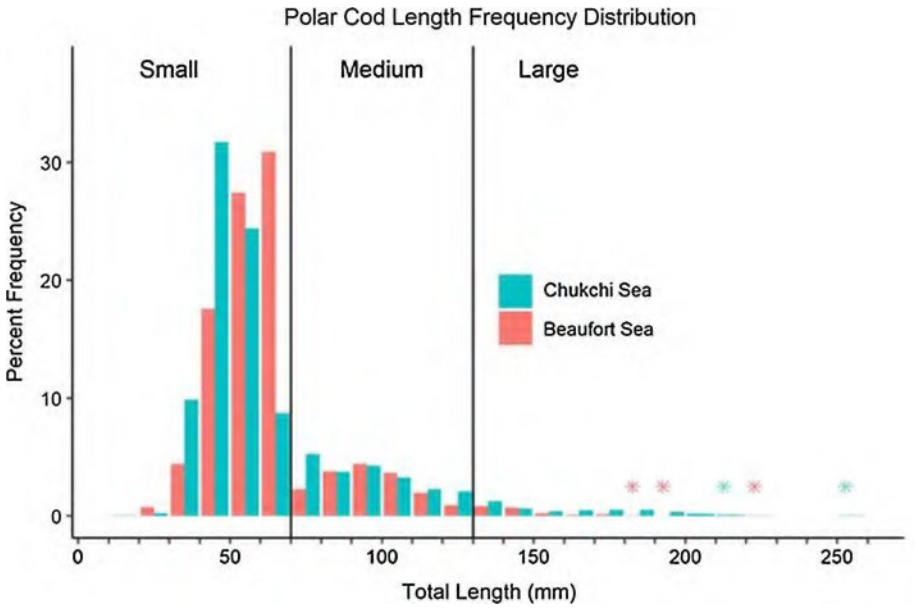

Fig. 3 Length-frequency distribution of polar cod captured in Chukchi Sea (blue) and Beaufort Sea (pink), weighted by station-specific catch per unit effort (CPUE, no. of fish per 1000 m²). Percent frequency is percent of total CPUE for that sea, and bars represent size class in between tick marks. Asterisks above a length bin indicate percentage < 0.1%, color corresponds to sea

latitude as sampling moved both northerly and offshore. Thus, we modeled spatial patterns separately from assessing the effects of environmental covariates. We compared the predicted values of the spatial and environmental models at each station to examine to what extent environmental covariates were able to account for estimated spatial patterns in polar cod distribution. Results of this analysis may be found in Online Resource 2. Spatial and environmental analyses were conducted for each of the three length classes of polar cod in the Chukchi and Beaufort seas. The spatial model was fit as follows:

$$\log(\text{count of polar cod}) \sim s(\text{latitude}, \text{longitude}) + \log(\text{area swept}), \quad (1)$$

where log denotes the natural logarithm and s denotes a smooth function of latitude and longitude estimated using a thin-plate regression spline. The second analysis investigated the impact of environmental correlates by modeling polar cod abundance as a function of selected environmental covariates:

$$\log(\text{count of polar cod}) \sim s(\text{depth}) + s(\text{temperature}) + s(\text{salinity}) + \log(\text{area swept}), \quad (2)$$

where the s_i are smooth functions of the respective covariates estimated using thin-plate regression splines. For the environmental analysis, a model selection approach was used to select a best-fitting model. To evaluate the effect of each environmental covariate on polar cod abundance, a suite of seven models was developed for each size class and in each sea, where every combination of environmental variables was considered. Within a size class and a sea, models were compared and the model with the lowest Akaike Information Criterion (AIC) was selected as the best performing model. Results from the best-fitting model for each size class were visually examined to describe the estimated relationships between polar cod abundance and the environmental predictors. When the best performing environmental model included both temperature and salinity, the temperature and salinity values were used to identify water masses and relate them to polar cod abundance. Literature values characterizing typical water mass temperature and salinity ranges in the Chukchi Sea (Danielson et al. 2017b) or Beaufort Sea (Norcross et al. 2018) were overlaid on relationships of polar cod abundance relative to those variables to determine patterns of polar cod abundance with respect to water mass.

Environmental model residuals suggested some degree of spatial autocorrelation among sites, where sites closer to each other were more similar than sites that were located farther apart. Both spatial and environmental models were tested for residual spatial autocorrelation by plotting the semivariance of model residuals as a function of distance between sampling points by year. Data for all length classes were combined to determine the spatial relationship between stations in each sea within a year. Comparison of AIC between the full model with spatial autocorrelation and the full model without spatial autocorrelation indicated slightly lower values in each sea (Chukchi Sea: ΔAIC = 2; Beaufort Sea: ΔAIC = 10) and thus a modest preference for the models that include a spatially autocorrelated error structure. Each environmental model, therefore, included an exponential decline in residual correlation with distance, as well as a nugget effect, conditioned on sampling year. Spatial correlation scale parameters (range and nugget) were estimated independently for each sea using the full model and were

included in all subsequent models. Due to statistical programming constraints caused by the inclusion of a spatially autocorrelated error structure, the dispersion parameter of the negative binomial distribution was estimated independently using the full model and fixed for each sea. After the incorporation of a spatially correlated error structure in the environmental model, both the spatial models and environmental models met assumptions of independence.

The completion of the spring cruise in the Chukchi Sea in June 2017 provided a seasonal comparison of offshore polar cod abundances. As these data were collected in spring rather than summer, they were not included in the previously described spatial analysis. However, the spring abundance data were directly compared to abundance from a cruise conducted during August and September 2017 in the southern Chukchi Sea. The two research efforts used the same gear and sampled from the Bering Strait (66.4° N) to Cape Lisburne (69.1° N). Due to the small number of sample stations within the area of overlap (spring $n = 9$, summer $n = 14$), we were not able to develop a geostatistical model and instead compared abundance of polar cod between spring and summer using a non-parametric (rank-based) Wilcoxon two-sample test. The test assumes that sampling in each season resulted in independent random samples that were representative of the area of overlap. Several August hauls caught large numbers of fish ≤ 70 mm, a size that was not observed in June. These small fish presumably consist of young-of-the-year fish that were too small to be retained by the beam trawl in June. Therefore, instead of statistically comparing overall seasonal abundances for all sizes of polar cod, we only applied to Wilcoxon two-sample test to compare seasonal abundances for fish > 70 mm, i.e., those fish that were available to be caught by the gear in both spring and summer. Mean values of depth, temperature, and salinity for each season are reported; however, environmental data were not available for two stations sampled in August 2017.

Results

A total of 697 hauls from 21 cruises over 13 years were available for analysis (Table 1). The number of hauls conducted annually ranged from 5 to 88 in the Chukchi Sea and 18 to 97 in the Beaufort Sea. Sampling was conducted from 9 June to 10 October in the Chukchi Sea and from 29 July to 4 September in the Beaufort Sea. Bottom water in the Chukchi Sea ranged from − 1.8 to 10.9 °C, with salinities from 27.2 to 34.5 PSU. In comparison, conditions in the Beaufort Sea lacked the warmest and very coldest temperatures, with a range from − 1.6 to 4.8 °C, and had salinities from 29.2 to 34.9 PSU.

When pooling data across all years, polar cod showed latitudinal patterns in abundance in the Chukchi Sea and a strong longitudinal gradient in the Beaufort Sea. Generally, abundance of polar cod in the Chukchi Sea showed a south to north gradient, with the highest abundance values north of Cape Lisburne (Fig. 2). In the Beaufort Sea, polar cod abundance showed a predominantly west to east gradient, with the highest abundance west of 150° W (Fig. 2). Length frequencies of the catches were similar across both study regions; polar cod ranged from 11 to 260 mm in the Chukchi Sea and from 21 to 230 mm in the Beaufort Sea (Fig. 3).

Spatial analysis

In the Chukchi Sea, GAM analysis of trawl catches revealed distinct patterns of polar cod distribution by size class. The small size class of polar cod was most abundant in the northern Chukchi Sea, north of approximately 68° N (Fig. 4), where the Bering Chukchi Summer Water mass is commonly present, while fewer small polar cod were found south of 68° N. The distribution of the medium size class was different when compared to the distribution of the small size class and did not show the same region of abundance in the NE Chukchi Sea. Medium-sized polar cod were present across the entire Chukchi Sea shelf and showed pockets of high abundance in both nearshore and offshore regions. However, the regions of high abundance for the medium size class were not the same as the regions of high abundance for the small size class offshore at 169° W and north of 70° N (Fig. 4). Finally, the large size class of polar cod was less abundant in the nearshore region and more abundant beginning ~ 80 km offshore and extending seaward, with an area of higher abundance south of Cape Lisburne (Fig. 4). Deviance explained for the small, medium, and large size class models was 24.4%, 20.2%, and 57.5%, respectively (Table 2).

Similar to the Chukchi Sea, the GAM spatial analysis in the Beaufort Sea also found distinct, size-based patterns of polar cod distribution. The small size class was distrib- uted primarily along a west to east gradient, with an area of high abundance west of 150° W, and another smaller area of abundance nearshore and east of 144° W (Fig. 5). There was also a nearshore to offshore gradient, where small polar cod were distributed close to shore; however, the western aggregation was dispersed across the width of the entire Beaufort Sea shelf (to ~ 80 km), more than the eastern aggregation that was generally distributed closer to shore (within ~ 50 km). Abundance of the medium size class showed a less extreme longitudinal gradient than the small size class, and while abundance was highest west of 150° W, medium polar cod were diffuse across the entire Alaskan Beaufort Sea shelf. Unlike the small size class, medium-sized polar cod did not show a separate area of high abundance east of 144° W. The large size class of

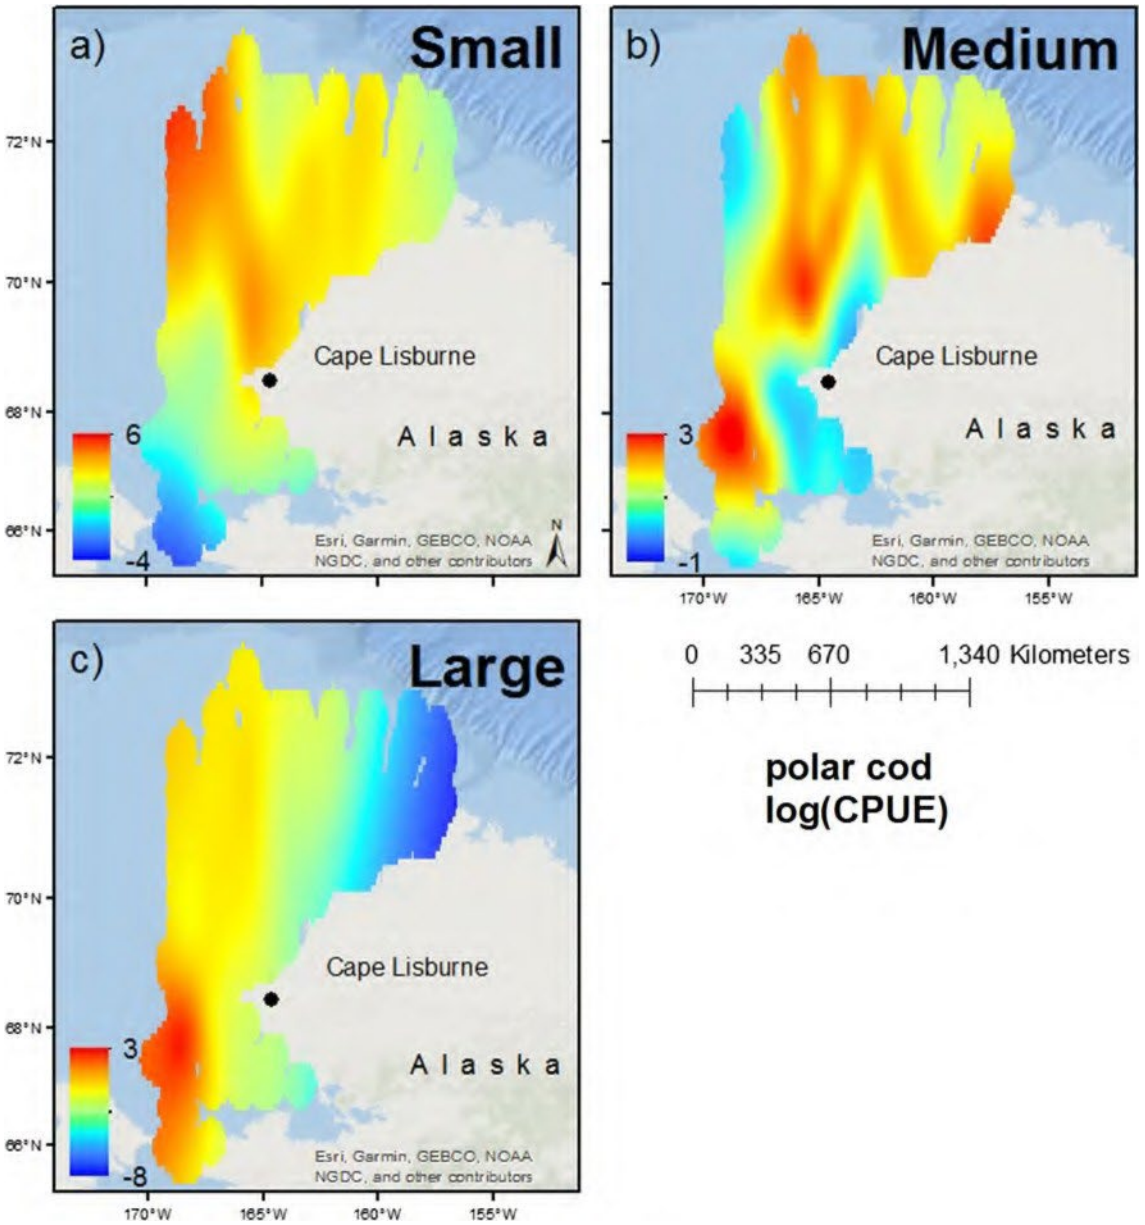

Fig. 4 Spatial distribution of polar cod catch per unit effort (CPUE, no. of fish per 1000 m²) in the Chukchi Sea for **a** small (≤ 70 mm), **b** medium (71–130 mm), and **c** large (> 130 mm) size classes. Abundances as predicted by generalized additive model (GAM) using a smooth function of latitude and longitude, shown on the log scale

polar cod was distributed offshore, beyond ~ 60 km. The deviance explained for the small, medium, and large size class analysis was 62.7%, 22.9%, and 21.7%, respectively (Table 2).

Environmental analysis

In the Chukchi Sea, the influence of the environmental variables on polar cod abundance depended on size class. For the small size class of polar cod, the top performing model included both temperature and salinity (Table 3). A dome-shaped curve described the relationship between polar cod abundance and temperature with a peak at 4–5 °C, while abundances increased linearly with salinity to a maximum of 34.5 PSU (Fig. 6). For polar cod in the medium size class, the top performing model only included depth and abundance increased linearly with depth (Table 3, Fig. 6). The best-fitting model for the large size class of polar cod in the Chukchi Sea also only included depth as a covariate; there was a positive relationship between depth and abundance of large polar cod in the Chukchi Sea (Table 3, Fig. 6).

Table 2 Results of generalized additive models (GAMs) for spatial distribution of polar cod, with latitude and longitude as explanatory variables (see Eq. 1)

Region	Size class	Θ	edf	χ^2	p value	AIC	Deviance explained (%)
Chukchi	Small	0.19	19.5	99.3	< 0.0001	1928.0	24.4
Chukchi	Medium	0.40	26.6	67.0	< 0.0001	1642.0	20.2
Chukchi	Large	0.18	13.7	58.1	< 0.0001	426.9	57.5
Beaufort	Small	0.38	13.4	300.2	< 0.0001	1073.2	62.7
Beaufort	Medium	0.53	7.6	61.4	< 0.0001	1051.0	22.9
Beaufort	Large	0.19	3.0	23.1	< 0.0001	353.9	21.7

Separate models developed in each sea and for each size class. θ parameter used for negative binomial parameterization, estimated degrees of freedom (edf), chi-square statistic, p-value denoting significance of latitude and longitude covariates, Akaike Information Criterion (AIC), and deviance explained

As in the Chukchi Sea, the relationships between environmental variables and abundance of polar cod in the Beaufort Sea were specific to size classes. The best-fitting model for the small size class in the Beaufort Sea included both temperature and salinity (Table 4). Abundance of small polar cod in the Beaufort Sea increased linearly to a maximum temperature of 4.8 °C, which was similar to the Chukchi Sea, and was highest at intermediate salinities; small polar cod were less abundant at the lowest (< 31 PSU) and highest (> 34 PSU) salinity values (Fig. 7). The top performing model for the medium size class in the Beaufort Sea included both depth and temperature (Table 4), unlike the analogous model in the Chukchi Sea, which only included depth. In the Beaufort Sea, abundance of medium polar cod increased with depth to approximately 300 m and then began to decline; medium polar cod abundance increased linearly with temperature (Fig. 7). As in the Chukchi Sea, the top performing model for the large size class included only depth as a covariate (Table 4). Notably, large polar cod abundance increased with depth in the Beaufort Sea to about 400 m, but as depth surpassed 400 m, abundance of polar cod decreased (Fig. 7). The shape of the relationship between depth and abundance was similar for both medium and large polar cod, but the medium size class was more abundant at shallow depths than the large size class of polar cod.

Seasonal analysis

Comparison of polar cod catches between spring and summer in the southern Chukchi Sea revealed striking differences in fish abundance. Overall mean abundance of polar cod was much lower in June 2017 compared to August 2017 (Table 5). During the spring, polar cod was scarce in our nets; only four individuals were captured at three sampling locations (Fig. 8). In contrast, polar cod abundance was higher at locations sampled in August 2017 (Table 5). There were summer hauls that captured high abundances of small-sized polar cod, including one station with an abundance of 832 fish per 1000 m², with individuals ranging from 31 to 70 mm in length. Catch length-frequency composition in the summer contrasts with the polar cod caught in the spring, where only one fish < 70 mm was captured (Fig. 8). Polar cod 31 to 70 mm captured in August were likely young-of-the-year; these small fish were not available to the beam trawl in June due to both their pelagic distribution and small size before the summer growing season. Therefore, to verify that the observed seasonal differences in abundance were truly changes in abundance, and not the result of small fish growing in size and descending to the seafloor to become increasingly represented in the catch as the summer progressed, only spring and summer abundance of individuals > 70 mm were statistically compared. Seasonal differences in abundance were significant, using a Wilcoxon two-sample test, after the exclusion of small, highly abundant polar cod in August (Table 5, $p = 0.02$).

Discussion

By visualizing the distribution patterns of small, medium, and large polar cod, understanding of ontogenetic shifts in distribution as well as possible migration patterns of this species in the Pacific Arctic has been improved. Furthermore, by relating patterns in distribution to environmental variables, we provide insight into potential mechanisms driving polar cod distribution. The importance of environmental covariates varies among the three size classes and suggests that the relative influence of external drivers on polar cod distribution influences life stages differently. A comparison of abundance between spring and summer in the southern Chukchi Sea revealed seasonal differences in polar

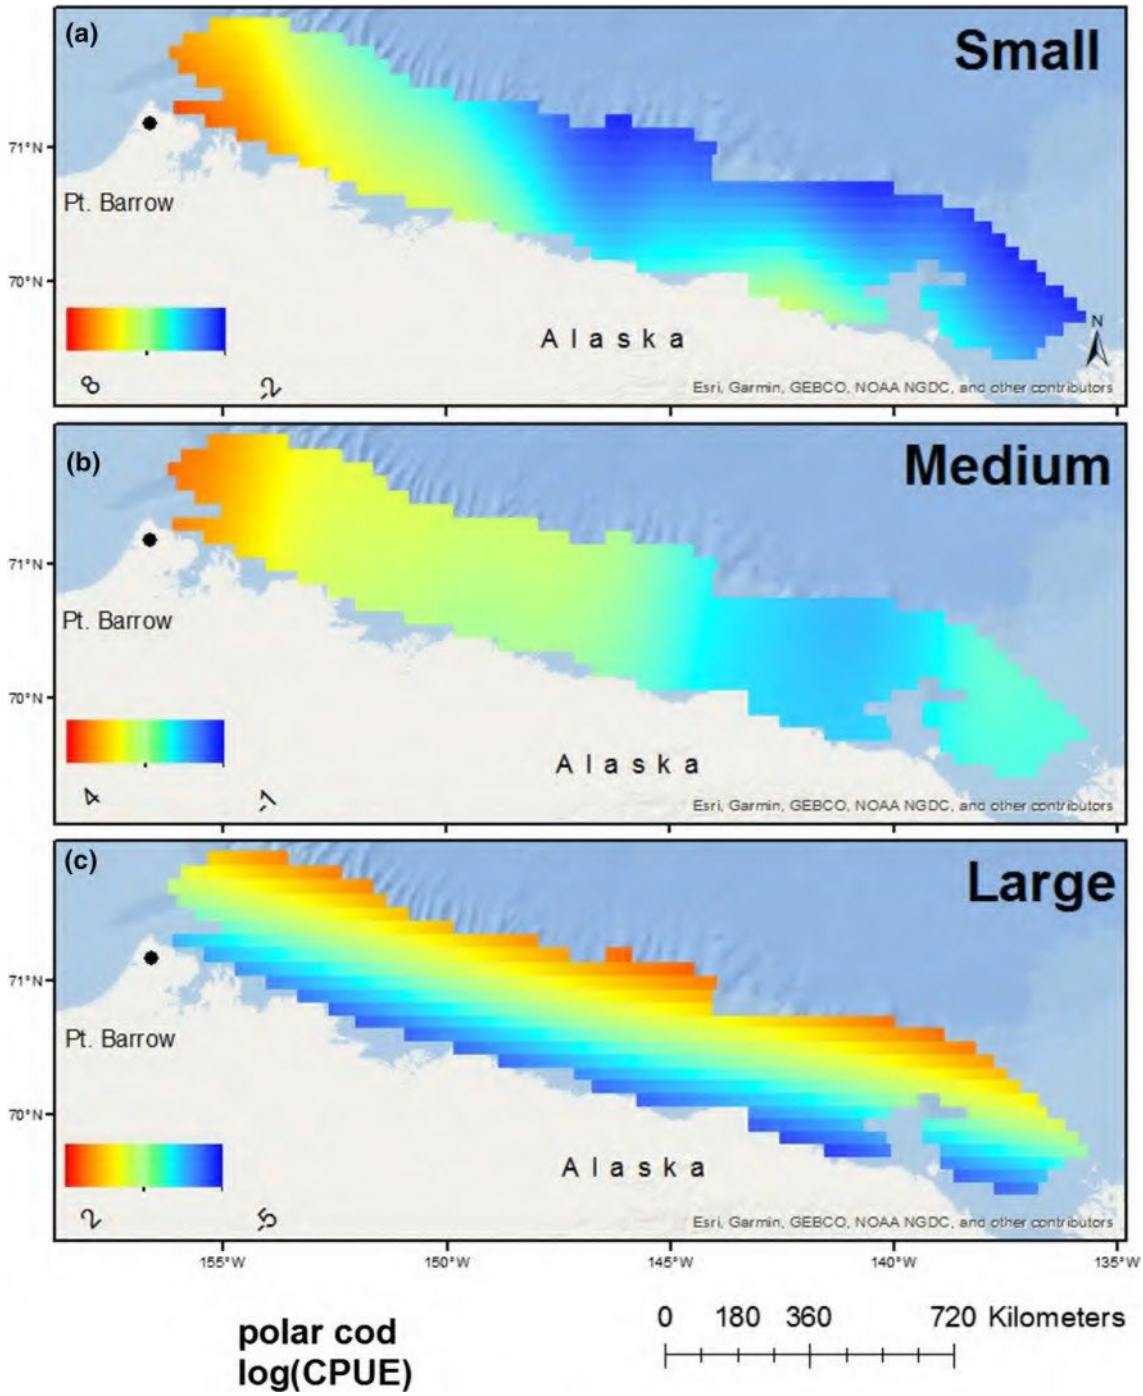

Fig. 5 Spatial distribution of polar cod catch per unit effort (CPUE, no. of fish per 1000 m²) in the Beaufort Sea for **a** small (≤ 70 mm), **b** medium (71–130 mm), and **c** large (> 130 mm) size classes. Abundances as predicted by generalized additive model (GAM) using a smooth function of latitude and longitude, shown on log scale

cod abundance. Finally, we hypothesize that both ontogenetic and seasonal movements of polar cod described in this study are evidence of a migration scenario that may be used to explain polar cod movement patterns in the Pacific Arctic.

There are several assumptions implicit in this analysis that could impact the interpretation of polar cod distribution patterns and potential environmental drivers of those patterns. First, we assume that our sampling gear is reasonably

effective at capturing all size classes of available polar cod. The 4 mm mesh codend liner ensures that this is an accurate assumption for individuals < 150 mm; however, a gear selectivity study indicates that the PSBT may not be the most effective sampling gear for polar cod > 150 mm (Kotwicki et al. 2017). Despite this selectivity, the results presented here nevertheless capture the bulk of the polar cod length distribution, as similar studies deploying a net with higher selectivity for large fish found that the majority of polar cod catch was < 150 mm in both the Chukchi Sea (Goddard et al. 2016) and the Beaufort Sea (Rand and Logerwell 2011). Second, we assume that the negative binomial distribution is effective at accommodating both the non-normal distribution of abundance and the high proportion of zero catches in the data. Sensitivity analysis comparing the performance of other distribution families (i.e., normal distribution with log-transformed response and tweedie distribution) showed that the top performing model used a negative binomial distribution. Nevertheless, interpretation of analyses for the large size class should be undertaken cautiously, as there is a high proportion of zero-catch hauls for large fish. Patterns in abundance by size class (Online Resource 3) may be compared to GAM analysis output. Finally, by pooling data across years, we assume that the spatial patterns in average fish abundance are not biased by interannual variability in catches. In addition, the environmental analysis is limited in scope to local variables that were measured contemporaneously with at-sea sampling. Additional variables that may be correlated to polar cod distribution, such as mean sea ice coverage or mean distance to sea ice edge in the winter, were ultimately excluded, as we considered it inappropriate to relate the summer distribution of polar cod from multiple cruises conducted at different points in space and time to long-term means of winter sea ice conditions. However, it is important to consider that variable ice conditions dur- ing winter and spring likely also play a role in explaining

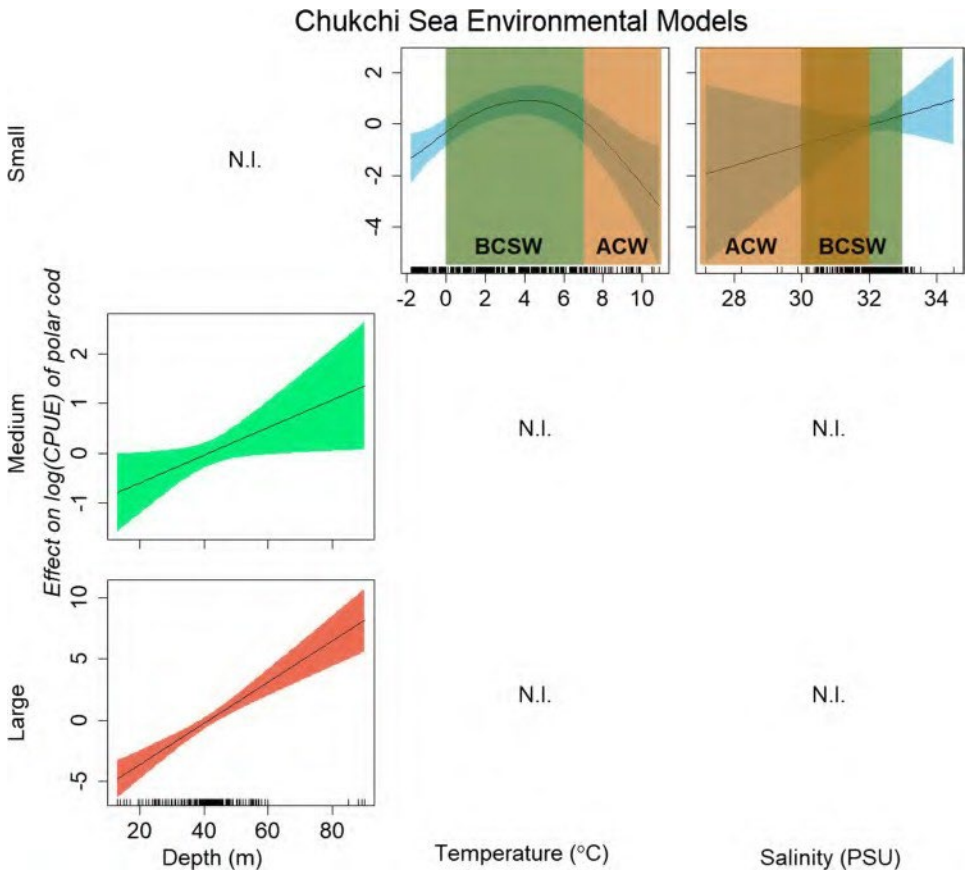

Fig. 6 Estimated effects of three environmental variables on log(CPUE) of three size classes of polar cod in the Chukchi Sea based on generalized additive model (GAM) analysis; *y*-axis is magnitude of effect, rug along *x*-axis marks data values, colored envelopes are 95% confidence intervals. the distribution patterns of polar cod during the following summer.

Spatial analysis

In the Chukchi Sea, visualizing the distribution of the small size class of polar cod suggests oceanic transport of the juvenile life stage of this species. Due to small body size and weak swimming ability, the distribution of small individuals, such as the ≤ 70 mm polar cod considered here, is largely influenced by the direction and speed of the prevailing oceanic currents and sea ice drift (Graham and Hop 1995; David et al. 2016). Because age-0 polar cod descend in the water column throughout their first summer (Geoffroy et al. 2016), the small polar cod captured in the demersal trawl had likely descended to the seafloor recently, after being subjected to movement by pelagic ocean currents. Pelagic acoustic surveys in the Chukchi Sea have also detected large numbers of small, 30–40 mm, age-0 polar cod in the water column in the northern Chukchi Sea (De Robertis et al. 2017a, b), which supports the idea that young-of-the-year polar cod hatch in the spring and are advected from hatch locations via ocean currents.

The primarily northward flow of water through the Bering Strait and across the Chukchi Sea (Weingartner et al. 2013) suggests that the abundance of age-0 polar cod found in the northeast Chukchi Sea in the late summer could have been transported from spawning locations in the southern Chukchi and northern Bering seas in Bering Shelf Water (BSW) and Anadyr Water (AW). Generally, polar cod hatch from buoyant eggs, occupy the water column as larvae, and descend to a demersal environment as they grow (Graham and Hop 1995; Ponomarenko 2000). Though still an area of active research, potential spawning grounds for polar cod in the Pacific Arctic have been proposed near St. Lawrence Island and east of the Chukotka peninsula, Russia (Ponomarenko 1968; Christiansen and Fevolden 2000; Vestfals et al. 2018), and could be the source of age-0 polar cod transported northward and captured in the northeast Chukchi Sea in late summer. However, the detection of larvae throughout the Canadian Arctic (Bouchard and Fortier 2011) indicates that spawning grounds in the Bering and Chukchi seas may be only a few of several spawning regions throughout the Pacific range of polar cod.

As a result of the orientation of the Alaskan coastline, the distribution patterns in the Beaufort Sea of small polar cod display a primarily west to east gradient, coupled secondarily with an inshore to offshore gradient. As in the Chukchi Sea, however, the distribution of small individuals in the Beaufort Sea is likely largely influenced by oceanic currents.

A component of the Alaska Coastal Current (ACC), which may play a role in transporting polar cod northward in the Chukchi Sea, continues to flow along the Alaskan Coast, around Point Barrow, and into the Beaufort Sea (Okkonen et al. 2009). Barrow Canyon in the northern Chukchi Sea facilitates the movement of the ACC towards the Beaufort Sea (Pickart et al. 2005) and could effectively transport larval polar cod into the western Beaufort Sea as it does for zooplankton and other small particles (Ashjian et al. 2005; Berline et al. 2008). Further, small polar cod were also detected in the ACC in a plume extending 300 km eastward of Barrow Canyon (Crawford et al. 2012), demonstrating that small fish may be transported into the Beaufort Sea via eastward flowing currents.

Eastern and western aggregations of small polar cod in the Beaufort Sea, separated by a gap from 150° W to 144° W, suggests two separate groupings and perhaps distinct populations. Despite the prevailing eastward flow of water, the spatial separation indicates that polar cod in the eastern Beaufort Sea did not originate in the Chukchi Sea. Larval, juvenile, and adult polar cod are commonly captured in the Canadian Beaufort Sea (Bouchard and Fortier 2011; Geoffroy et al. 2011; Walkusz et al. 2013) and could be a source of small polar cod in the eastern US Beaufort Sea. In 2011, pelagic, larval polar cod were most abundant in the eastern US Beaufort Sea when compared to the western US Beaufort Sea (Gallaway et al. 2017), suggesting that some polar cod in the US Beaufort Sea originate from Canadian sources. The distribution patterns are corroborated by a population genetic study which found that while polar cod comprises a single population, a significant difference in microsatellite alleles between polar cod from the southern Chukchi Sea and the central Beaufort Sea implies some degree of spatial genetic differentiation consistent with an isolation-by-distance pattern (Wilson et al. 2017, 2019). The low abundance of small polar cod between 150° W and 144° W is not an artifact of sparse sampling effort in the middle section, as the station sampling density is similar across the entire Beaufort Sea shelf; nor is it the result of a single year of low polar cod abundance, as this region was sampled over multiple years. Together, spatial and genetic information indicate that small polar cod across the Beaufort Sea shelf belong

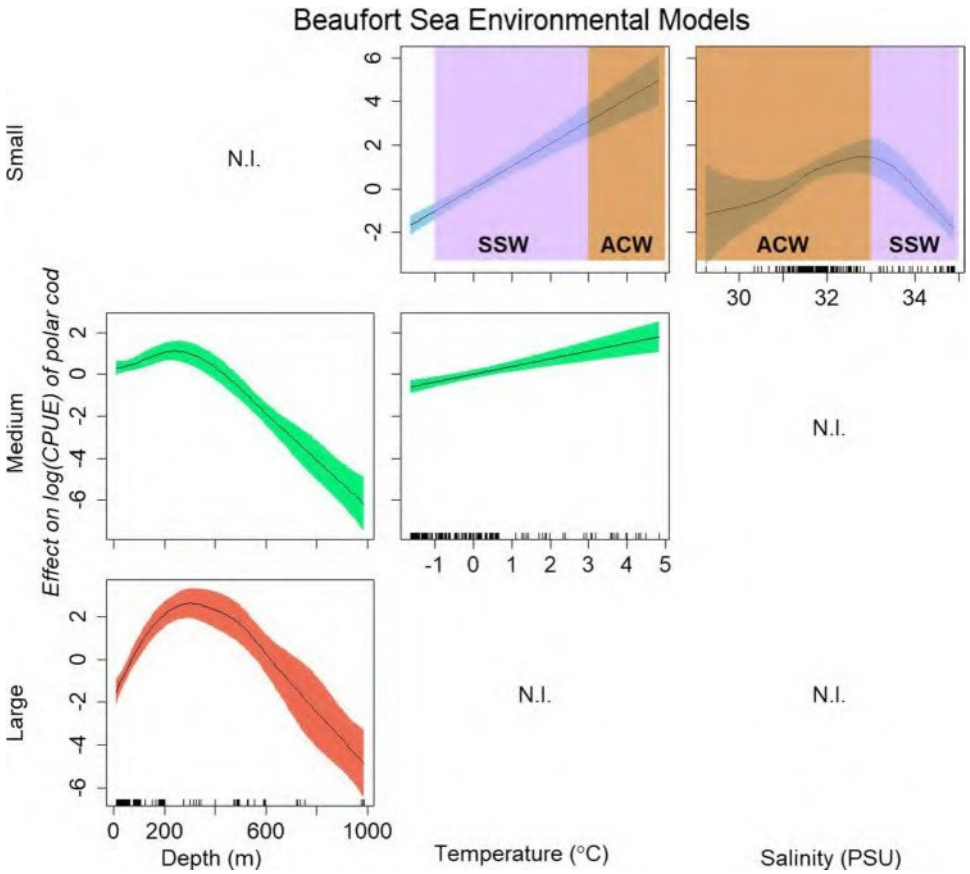

Fig. 7 Estimated effects of three environmental variables on log(CPUE) of three size classes of polar cod in the Beaufort Sea based on generalized additive model (GAM) analysis; *y*-axis is magnitude of effect, rug along *x*-axis mark location of data values, and colored envelopes are 95% confidence intervals. Table 5. Polar c od mean CPUE in spring and summer 2017 in the southern Chukchi Sea.

Season	Station (*n*)	Depth	Temperature	Salinity	Size class	CPUE
Spring	9	43.1 (9.69)	1.69 (1.22)	32.42 (0.39)	All	0.71 (1.11)
					> 70mm	0.50 (1.04)
Summer	14	39.1 (13)	4.18 (0.95)	32.26 (0.56)	All	70.31 (219.92)

Mean and (standard deviation) environmental conditions reported for depth (m), temperature (°C), salinity (PSU). Mean and (standard deviation) CPUE reported for all polar cod as well as only polar cod > 70 mm. CPUE significantly different ($p < 0.05$) between spring and summer for polar cod > 70 mm

to two spatially segregated groups from different spawning locations.

In both the Chukchi and Beaufort seas, distribution patterns of medium and large polar cod suggest that larger fish actively disperse from areas occupied by the smallest fish. The small size class had a region of high abundance in the northeast Chukchi Sea that was not seen in the medium or large size classes. As fish develop, swimming ability improves (Webb 1994) and juveniles may disperse from nursery grounds to adult habitats (Gillanders et al. 2003). Improved dispersal capabilities gained with increasing body size could explain the spread of the medium size class beyond the confines of the areas occupied by small polar cod in the Chukchi and Beaufort seas. The large size class showed further evidence of offshore ontogenetic movement in both the Chukchi and Beaufort seas, where large polar cod were most abundant beginning around 80 km in the Chukchi Sea and 60 km in the Beaufort Sea and extending seaward. Animals are often distributed with respect to resource availability to maximize fitness and reduce competition (Fretwell and Lucas 1969). The northeast Chukchi Sea and western Beaufort Sea, where there were regions of high abundance of the medium size class, are areas of high summer produc- tion (Walsh et al. 2005; Sigler et al. 2011). Therefore, mid- sized individuals may be maximizing growth by dispersing to productive feeding grounds. Offshore movement of large polar cod may be a component of adult spawning migrations. In the Chukchi Sea, several spawning grounds have been

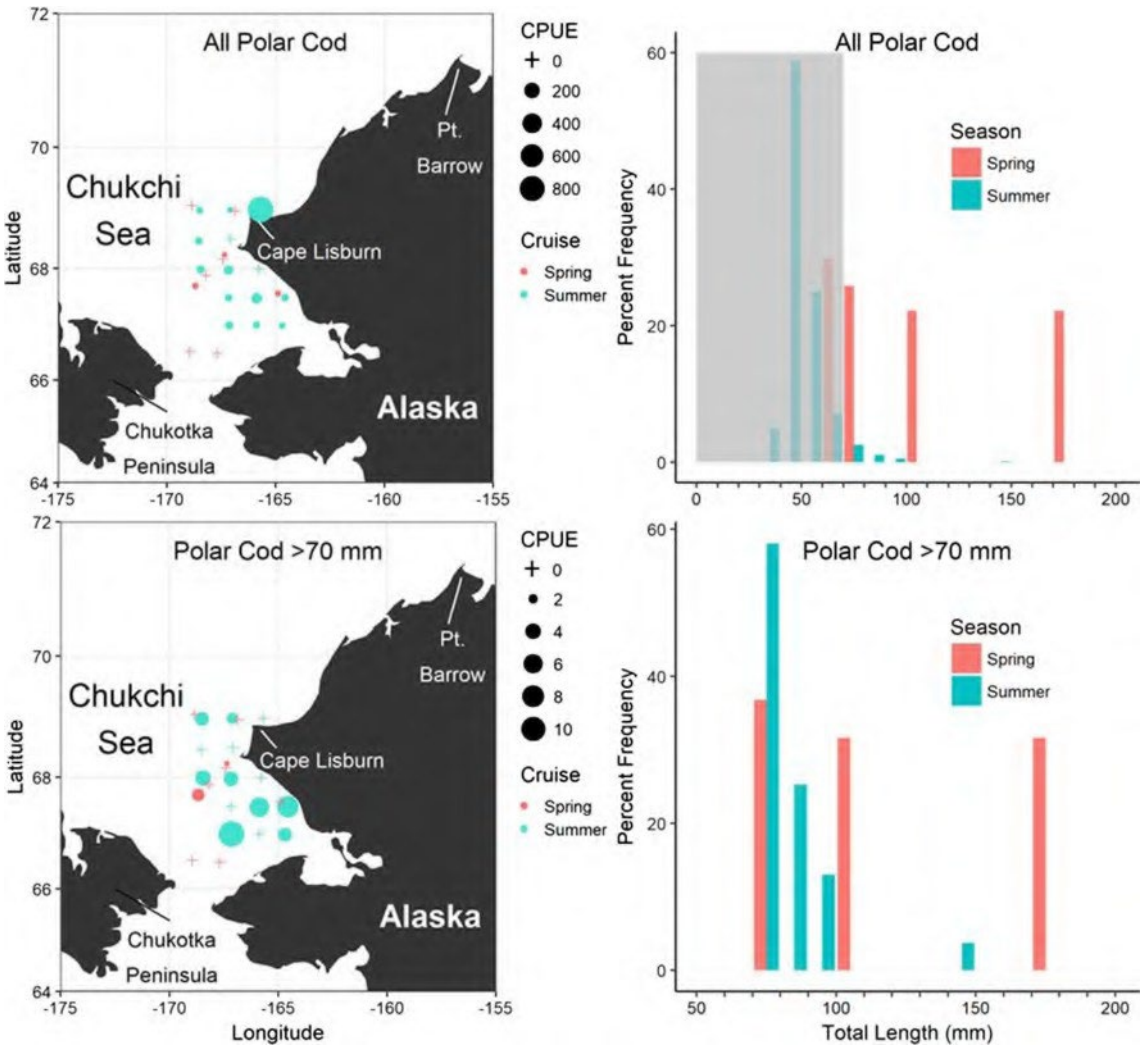

Fig. 8 Distribution and length-frequency of polar cod in the Chukchi Sea in spring and summer 2017. Length-frequency scaled by CPUE. Top two panels are all captured sizes of polar cod, total CPUE (fish per 1000 m^2) spring = 6.43, summer = 984.40. Bottom two panels are only polar cod > 70 mm, total CPUE spring = 4.51, summer = 42.29; gray box in top right shows small fish excluded from lower two plots. Note difference in scale between top left and bottom left plot

proposed in the northern Bering Sea and near the Chukotka peninsula (Ponomarenko 1968; Christiansen and Fevolden 2000; Vestfals et al. 2018). The abundance of the large size class of polar cod, both offshore and south of Cape Lisburne in the late summer, could reflect a movement towards these southern winter spawning locations.

Environmental analysis

Generally, both availability of food resources and temperature influence habitat selection of ectothermic species (Crowder and Magnuson 1983). Food resources are distributed unevenly among water masses (Eisner et al. 2013; Pinchuk and Eisner 2017; Smoot and Hopcroft 2017; Danielson et al. 2017b), which are identified by characteristic temperature and salinity ranges in the Chukchi and Beaufort seas. Temperature also has a direct physiological effect on growth rates of juvenile polar cod (Laurel et al. 2017) and likely influences their distribution. Depth commonly influences distribution patterns and is associated with offshore migrations of other species such as Pacific cod and Pacific halibut (*Hippoglossus stenolepis*), in the neighboring Bering Sea (Shimada and Kimura 1994; Webster et al. 2013). In Alaskan waters, the addition of environmental information to species distribution maps has been identified as a recent research objective in the Alaska Essential Fish Habitat Research Plan, which is mandated by the Magnuson-Stevens Fishery Conservation and Management Act (Sigler et al. 2017). Characterizing the role of environmental conditions for polar cod at different life stages moves towards this

goal and identifies underlying processes influencing spatial patterns in distribution.

In the Chukchi Sea, small polar cod were associated with the intermediate temperature and salinity of the highly productive Bering Chukchi Summer Water (BCSW) mass. BCSW is a commonly detected water mass throughout the northeast Chukchi Sea during the open water season, with temperatures ranging from 0 to 7 °C and salinity from 30 to 33.5 PSU (Danielson et al. 2017b), which were the temperature and salinity ranges most commonly occupied by small polar cod (Fig. 6). Other water masses in the Chukchi Sea include the cooler Bering Chukchi Winter Water (BCWW) with temperatures from − 2 to 0 °C and salinity from 30 to 33 PSU, and the warmer Alaska Coastal Water (ACW) with temperatures from 7 to 12 °C and salinity from 27 to 32 PSU (Danielson et al. 2017b); however, small polar cod were less abundant in these water masses. BCSW is a nutrient-rich water mass with a characteristic zooplankton community of calanoid copepods and euphausiids (Eisner et al. 2013), which are prey for polar cod (Rand et al. 2013; Gray et al. 2016). In contrast, the BCWW and ACW are less nutrient rich, and have smaller-bodied zooplankton communities, including species such as *Oithona similis*, *Calanus abdominalis*, and *Pseudocalanus* spp. (Eisner et al. 2013), which are marginal resources when compared to lipid-rich Calanus copepods (Falk-Petersen et al. 2009). Maximizing energy intake as a result of consuming high-quality prey resources is beneficial to polar cod and results in increased growth rates and improved body condition (Hop et al. 1997). Therefore, distribution patterns of small polar cod in the Chukchi Sea are likely influenced by the abundance and composition of prey resources in different water masses.

In the Beaufort Sea, small polar cod were primarily associated with relatively warm and moderately fresh water found near the Alaskan coast. Environmental conditions in the Beaufort Sea are markedly different from those found in the Chukchi Sea; the warmest sampled Beaufort Sea temperature of 5 °C is comparable to the intermediate temperatures found in the Chukchi Sea. Yet in both the Chukchi and Beaufort seas (Figs. 6, 7), small polar cod were most abundant in water temperatures 4–5 °C. However, the relationship between small polar cod abundance and salinity differed between the Chukchi and Beaufort seas. Unlike in the Chukchi Sea where abundance increased linearly with salinity to a maximum of 34.5 PSU, small polar cod in the Beaufort Sea were less abundant at salinities > 34 PSU. Cold and saline water is associated with Summer Shelf Water (SSW), and our results suggest that the differing effect of salinity between seas is likely due to this association of small polar cod with distinct water masses, characterized by a signature combination of temperature and salinity (Danielson et al. 2017b).

The warm and fresh water occupied by small polar cod in the Beaufort Sea is associated with nearshore coastal habitats and the eastward flowing ACW (Okkonen et al. 2009; Carmack et al. 2015), and could impact growth of individuals in the small size class. This warm coastal water is not nutrient rich (Dunton et al. 2005), but does provide a thermal habitat that is advantageous for polar cod. Though polar cod is a cold-adapted species and capable of surviving in sub-zero temperatures (Osuga and Feeney 1978), it is more commonly found at temperatures above 0 °C (Crawford et al. 2012). Small polar cod in the Beaufort Sea appear to be occupying the warmest available water to maximize growth. Higher growth rates are advantageous for the small, age-0, individuals (Helser et al. 2017). In harsh Arctic winters, survivorship increases dramatically when pre-winter size and body condition are good (Fortier et al. 2006; Heintz and Vollenweider 2010), while large gape size and increased swimming speeds enable better resource exploitation (Scharf et al. 2000). In the Beaufort Sea, the thermal advantages of warm, coastal water appear to be correlated with patterns of distribution of small polar cod. Though warm coastal water may be advantageous for growth in certain scenarios, the cost of occupying low nutrient and low production waters could result in a tradeoff with negative energetic consequences, including a scenario where accelerated growth outstrips resource availability, impacting polar cod growth and survival in the Beaufort Sea.

The positive relationship between depth and abundance (Figs. 6, 7) indicates that depth is a key environmental component correlated with the offshore shift in distribution of the medium and large size classes of polar cod in the Chukchi and Beaufort seas. In the Chukchi Sea, where sampled depths were 13–90 m, the increasing linear relationship with depth suggests that polar cod moves to offshore, somewhat deeper locations as they grow larger. In the Beaufort Sea, where sampled depths reached nearly 1000 m, medium and large polar cod were most abundant at 300 and 400 m, respectively, demonstrating that as individuals increase in size, they move offshore to a specific bottom depth range. A nearly identical pattern was identified in the Canadian Beaufort, where medium and large fish (~ 90+ mm) were encountered at deep, offshore stations and the highest abundances of those fish were found at depths between 350 and 500 m (Geoffroy et al. 2011; Benoit et al. 2014; Majewski et al. 2016). The distribution pattern of polar cod was attributed to distinctly layered water masses in the Canadian Beaufort Sea (Pickart 2004), with polar cod occupying a layer of Atlantic Water, which was warmer than 0 °C and detected from 350 to 500 m depth. In the present study area, Atlantic Water was observed in the US Beaufort Sea at depths > 250 m (Norcross et al. 2017; Smoot and Hopcroft 2017), and this was where large polar cod were most abundant (Fig. 7).

Therefore, polar cod occupies the Atlantic Water mass in both the US and Canadian Beaufort Sea.

Seasonal analysis

Springtime demersal abundance of polar cod in the southern Chukchi Sea was strikingly low compared to late summer abundance. Low springtime abundance of demersal polar cod during 2017, when only four fish were captured, was corroborated the following year when a June 2018 research cruise captured only two polar cod at the same sampling locations (Danielson et al. 2018). While adult polar cod were not present in the demersal environment in the southern Chukchi Sea in the spring, small polar cod (< 20 mm) were captured in Bongo nets (R. Hopcroft, personal communication) concurrently sampled with the bottom trawl in June 2017 and 2018. The bottom trawl gear used in June 2017 and 2018 was identical to the gear used in the late summer collections that successfully captured demersal polar cod in the same region. Though there were approximately half the number of stations sampled in June when compared to August, the stations were distributed across the study area to maximize spatial sampling extent (Fig. 8). It is likely that growth of age-0 polar cod between June and August/September resulted in a higher catch of age-0 polar cod in the late summer. However, the complete lack of larger (> 70 mm), older (age 1 +) individuals, which would be equally susceptible to the net in June and August/September suggests that the collections in June likely truly represent a lower abundance of subadult and adult polar cod near the sea floor in the southern Chukchi Sea in the spring.

Strong linkages between sea ice and polar cod life history suggest that the distribution of polar cod in the southern Chukchi Sea could be influenced by the distribution of sea ice. While polar cod occupies environments that are seasonally ice free, it is often characterized as a sympagic species for a portion of its life cycle (Craig et al. 1982; Lønne and Gulliksen 1989). Polar cod is thought to spawn under sea ice, and buoyant eggs float to the ice–water interface before hatching in early spring (Graham and Hop 1995; Bouchard and Fortier 2011). Sea ice also provides a platform for the growth of sea ice algae, which is not only an important source of primary productivity in the Arctic, but also has a distinct isotopic signature that can be traced throughout Arctic food webs (Iken et al. 2005; Gradinger 2009). Isotopic and fatty acid analyses have linked polar cod to sea-ice-derived carbon, demonstrating the significant influence that sea ice can have on the diet of polar cod (Kohlbach et al. 2017; Dissen et al. 2018). Finally, the seasonal melting of sea ice is a driver of springtime patterns of productivity in the Arctic, with ice-edge blooms typically following the retreat of sea ice, resulting in peak productivity ~ 20 days after ice retreat (Perrette et al. 2011). The spring bloom stimulates and supports secondary productivity, ultimately resulting in planktonic food resources for polar cod (Sigler et al. 2011; Wassmann and Reigstad 2011).

Given the link between sea ice and polar cod life history, sea ice extent and retreat may influence the spring distribution of polar cod in the southern Chukchi Sea. It is possible that polar cod tracks the springtime ice retreat and the wave of productivity that follows. However, in the springs of both 2017 and 2018, when sampling occurred, the sea ice edge had already retreated far north of the sampling region (NASA 2018). If polar cod followed the ice edge in these years, then its distribution would be beyond the northernmost station sampled during the June cruises, explaining the extremely low abundances of subadult and adult polar cod observed in the southern Chukchi Sea. It is unlikely that the low abundances of subadult and adult polar cod in the southern Chukchi Sea can be explained by polar cod moving south into the northern Bering Sea. Though polar cod is found episodically in the northern Bering Sea in association with cold conditions and large ice extent (Wyllie-Echeverria and Wooster 1998; Cui et al. 2009), these conditions did not occur in 2017 or 2018. Furthermore, sampling in the northern Bering Sea from St. Lawrence Island to the Bering Strait caught few polar cod in 2017 and 2018 (Danielson et al. 2018), suggesting that polar cod did not move into the northern Bering Sea.

Movement inferred from size-based and seasonal patterns in distribution describes a plausible migration scenario. In classical fisheries science, the life history of a species that undertakes a migration triangle travels from nursery grounds as juveniles, to feeding grounds as subadults, to spawning grounds upon maturation. The trian- gle is complete when eggs and larvae are passively transported from the spawning grounds to the nursery grounds via oceanic currents and the cycle begins again (Harden Jones 1968; Secor 2002). Small, young polar cod are most abundant in the northeast Chukchi Sea, perhaps indicat- ing that region functions as nursery grounds for juveniles. The northeast Chukchi Sea was also proposed as a nursery area by researchers analyzing the pelagic distribution of age-0 polar cod, though the suggestion remains untested (De Robertis et al. 2017b). The next step in a migration triangle is the movement of subadults to feeding grounds; in the current study, the distribution pattern of the medium size class was different from the small size class, indicating that medium polar cod move away from areas occupied by small fish and disperse across the productive northeast Chukchi Sea shelf (Grebmeier 2012) to take advantage of feeding opportunities. The final component of a classic migration triangle is movement to spawning grounds; the current study cannot address this directly as polar cod spawns in the late fall and early winter under sea ice (Ponomarenko 2000). Several locations in the northern Bering

Sea and near the Chukotka peninsula have been recognized for their potential as polar cod spawning grounds (Ponomarenko 1968; Christiansen and Fevolden 2000; Vestfals et al. 2018); and are geographically close to the late summer distribution of the large size class in this study, which contains the majority of the mature spawners (Nahrgang et al. 2016). Potential spawners in the southern Chukchi Sea in late summer would not have far to travel to proposed spawning grounds during the fall and winter seasons.

Completion of the proposed migration scenario could be achieved via advection of eggs and larvae by the northbound currents traveling through Bering Strait and across the Chukchi Sea (Weingartner et al. 2005). Pelagic (De Robertis et al. 2017b) and demersal distributions are consistent with northward advection of eggs and larvae from southern spawning grounds. The spring absence of polar cod from the southern Chukchi Sea may be explained within the framework of the proposed migration triangle. In the spring, adult polar cod following the seasonal northward retreat of sea ice may be spawners seeking resources to replenish their depleted energy reserves. Spawning is energetically costly and these individuals would likely need to take advantage of the earliest available food resources (Hop et al. 1995). This possible movement scenario synthesizes both size-based and seasonal distribution patterns of polar cod and represents a new effort to characterize polar cod migration patterns in the Chukchi Sea. The migration of a small-bodied, high-latitude fish species is not unprecedented, but there remains much uncertainty surrounding the migration patterns of polar cod in the Chukchi Sea. Other marine fish species, such as Pacific herring and walleye pollock in the Bering Sea, exhibit seasonal migrations between feeding grounds and spawning grounds (Kotwicki et al. 2005; Tojo et al. 2007). Additionally, telemetry studies in the Atlantic Arctic found that polar cod is physically capable of traveling over 100 km in response to rapidly evolving ice conditions (Kessel et al. 2015). The migration triangle proposed here is currently constrained by data collected during open water sampling efforts. Moored acoustics offer an opportunity to confirm and refine understanding of polar cod movement during the Arctic winter and are currently being deployed in the Chukchi and Beaufort seas (Kitamura et al. 2017; Hauri et al. 2018). Patterns in backscatter collected at moorings during the ice-covered season provide information on fish presence and abundance when net sampling is not possible (Kaartvedt et al. 2009). In addition to increased field sampling efforts, modeling studies using tools like ROMS will corroborate the direction and timing of transport of polar cod eggs and larvae in ocean currents, improving understanding of polar cod movement throughout their life cycle in the Chukchi Sea. The scale of detail of the migration triangle proposed here is coarse and based on a small sample size, but nevertheless provides an initial framework against which new information may be tested to advance understanding of polar cod movement patterns in the Chukchi Sea.

Conclusions

Advancing fisheries science in the remote and difficult to access Arctic ecosystem is a significant research challenge. The work presented here compiles a large number of disparate individual sampling efforts to develop a holistic picture describing polar cod summer distribution in the Chukchi and Beaufort seas. The size-based analysis demonstrates ontogenetic shifts in distribution, while consideration of environmental covariates provides insight into potential mechanisms driving these patterns. Though much work remains to be done in understanding polar cod distribution and migration, the comparison between spring and summer abundances shows that polar cod distribution in the Pacific Arctic varies by season and suggests that this species may undertake some form of seasonal migration. The mapping of polar cod distribution in the Chukchi and Beaufort seas improves understanding of one of the most abundant and critical trophic links in the Arctic ecosystem. As the Arctic experiences increased anthropogenic and climatological pressures, thorough knowledge of key components of this system, including species like polar cod, will inform responsible decision making in this dynamic and rapidly changing ecosystem.

Acknowledgements We thank reviewers Kevin Hedges, Wojciech Walkusz, and Hauke Flores for their insightful and constructive review of this manuscript. We thank the scientists, research vessels' captains and crew who collected the data compiled in this study. We also thank past and present members of the UAF Fisheries Oceanography lab for their laboratory work processing specimens. Funds were provided by the North Slope Borough and the Arctic Integrated Research Program sponsored by the North Pacific Research Board (NPRB). In addition, this study was funded in part by material sampled under Award Numbers M10AC0004, M12AC00011, and M13PC00019 of the U.S. Department of the Interior, Bureau of Ocean Energy Management (BOEM), Alaska Outer Continental Shelf Region. In-kind support was contributed by the National Oceanic and Atmospheric Administration (Alaska Fisheries Science Center) and the University of Alaska Fairbanks. This paper represents NPRB publication ArcticIERP-15.

Conflict of interest The authors declare that they have no conflicts of interest.

Ethical approval All applicable national and international guidelines for the care and use of animals were followed. Sample collections in US waters were approved by the Institutional Animal Care and Use Committee (IACUC) of the University of Alaska Fairbanks.

Extraordinary Carbon Fluxes on the Shallow Pacific Arctic Shelf During a Remarkably Warm and Low Sea Ice Period

The shallow Pacific Arctic shelf has historically acted as an effective carbon sink, characterized by tight benthic pelagic coupling. However, the strength of the biological carbon pump in the Arctic has been predicted to weaken with climate change due to increased duration of the open-water period for primary production, enhanced nutrient limitation, and increased pelagic heterotrophy. In order to gain insights into how the biological carbon pump is functioning under the recent conditions of extreme warming and sea ice loss on the Pacific Arctic shelf, we measured sinking particulate organic carbon (POC) fluxes with drifting and moored sediment traps, as well as rates of primary production and particle-associated microbial respiration during June 2018. In Bering Shelf/Anadyr Water masses, sinking POC fluxes ranged from 0.8 to 2.3 g C m^{-2} day^{-1}, making them among the highest fluxes ever documented in the global oceans. Furthermore, high export ratios averaging 82% and low rates of particle-associated microbial respiration also indicated negligible recycling of sinking POC in the water column. These results highlight the extraordinary strength of the biological carbon pump on the Pacific Arctic shelf during an unusually warm and low-sea ice year. While additional measurements and time are needed to confirm the ultimate trajectory of these fluxes in response to ongoing climate change, these results do not support the prevailing hypothesis that the strength of the biological carbon pump in the Pacific Arctic will weaken under these conditions.

INTRODUCTION

Arctic marine systems are currently undergoing rapid and profound changes due to the effects of climate change, including reduced sea ice extent, earlier sea ice retreat, protracted ice-free seasons, warming air and ocean temperatures, and shifts in currents and water column stratification (Vaughan et al., 2013; Richter-Menge et al., 2019). These environmental changes have recently

Abbreviations: ACW, Alaska Coastal Waters; ASGARD, Arctic Shelf Growth, Advection, Respiration, and Deposition rate experiments project; BSAW, Bering Shelf/Anadyr Waters; PN, particulate nitrogen; POC, particulate organic carbon.

accelerated on the Pacific Arctic's Bering and Chukchi Sea shelves (Stabeno and Bell, 2019; Huntington et al., 2020; Thoman et al., 2020). During 2017 and 2018, bottom water temperatures in the Bering Sea were 3°C higher than the 2005–2016 baseline (Stabeno and Bell, 2019), and the four lowest maximum sea ice extents since 1979 in the Bering and Chukchi Seas have occurred after 2015 (Fetterer et al., 2017). Cascading impacts on the regional ecosystems, biogeochemical cycles, climate, and human communities on and around the Pacific Arctic shelf are expected, although the nature and magnitude of these impacts remain largely speculative (Carroll and Carroll, 2003; Grebmeier, 2012; Moore and Stabeno, 2015; Stabeno and Bell, 2019).

The shallow Pacific Arctic shelf, averaging 50 m depth, has historically acted as a strong sink of carbon (Bates, 2006; Chen and Borges, 2009). Water movement on these shelves is generally northward carrying different water masses of Pacific origin into the Arctic (Pickart et al., 2016; Danielson et al., 2017), with a significant seasonal modulation (Woodgate et al., 2015) (see **Supplementary Figure 1** for visualization of currents). This region is also characterized by a strong biological carbon pump having pelagic primary productivity (Walsh et al., 1989; Springer and McRoy, 1993), sedimentation (Naidu et al., 2004), and benthic productivity (Grebmeier and McRoy, 1988; Grebmeier and McRoy, 1989) rates that are all amongst the highest measured in any marine system. When light is sufficient, pelagic primary productivity may reach up to 16 g C m^{-2} day^{-1} and 470–840 g C m^{-2} $year^{-1}$ (Walsh et al., 1989; Springer and McRoy, 1993) due to elevated nutrient concentrations (5–20 μM) (Danielson et al., 2017) advected into the region with the Anadyr current from deep Pacific upwelling (Walsh et al., 1989; Springer and McRoy, 1993). The spring phytoplankton bloom is typically dominated by large, rapidly sinking sympagic or pelagic diatoms (Springer and McRoy, 1993; Gradinger, 1999, 2009) that contributed to an annual particulate organic carbon (POC) flux of up to 145 g C m^{-2} $year^{-1}$ near Hanna Shoal (Lalande et al., 2020) and likely facilitate substantial carbon burial in sediments. Similar to other Arctic shelves (Grebmeier and Barry, 1991), total organic carbon on the Pacific Arctic shelf averages 1% and reaches up to 2% in surface layers (Grebmeier and McRoy, 1989; Grebmeier and Barry, 1991; Bluhm and Gradinger, 2008). This active biological carbon pump supports large populations of benthic-feeding pelagic seabirds and marine mammals (Bluhm and Gradinger, 2008; Moore and Kuletz, 2019), many of which are important to Indigenous communities that rely on subsistence hunting (Hovelsrud et al., 2008).

The strength of the biological carbon pump in the Arctic is predicted to weaken with climate change due to increased duration of the open-water period for primary production and enhanced nutrient limitation (Piepenburg, 2005; Wassmann and Reigstad, 2011; Grebmeier, 2012). Warmer waters could increase metabolic rates of pelagic grazers and heterotrophic bacteria and potentially favor smaller phytoplankton and faster-growing grazers that more rapidly recycle organic matter within the water column (Wassmann and Reigstad, 2011; Neeley et al., 2018). Additionally, increased frequency of storms could increase mixing and efflux of carbon dioxide (Hauri et al., 2013; Slats et al., 2019). If these predictions prove accurate, such mechanisms could accelerate feedback processes on the services supported by the biological carbon pump. While the effects of changing ice conditions and warming water on production on the Pacific Arctic shelf have been investigated for many years (Lee et al., 2012; Arrigo et al., 2014; Hill et al., 2018), few studies have directly measured pathways within the biological carbon pump (Fukuchi et al.,1993; Lalande et al., 2020). As part of the Arctic Shelf Growth, Advection, Respiration, and Deposition rate experiments (ASGARD) project, we measured the strength and efficiency of the biological carbon pump by directly quantifying and comparing rates of primary productivity, sinking POC flux, and microbial respiration associated with trap-collected sinking particulate matter during June of 2018 on the Pacific Arctic Shelf. This study occurred after the winter with the lowest maximum sea ice extent on record and in a prolonged time of abnormally warm water (Stabeno and Bell, 2019; Danielson et al., 2020; Huntington et al., 2020). These unique environmental conditions, described in detail in Huntington et al. (2020), provided an opportunity to test the prevailing hypothesis that the biological carbon pump will decrease in strength with climate change (Piepenburg, 2005; Wassmann and Reigstad, 2011; Grebmeier, 2012).

MATERIALS AND METHODS

Hydrography Sampling

All cruise operations were performed on the R/V *Sikuliaq*. The CTD unit consisted of a Seabird SBE16plus unit coupled with WetLabs fluorometer and transmissometer. A Satlantic SUNA V2 instrument was also mounted to the rosette to measure nitrate. To characterize the water mass at each station, surface salinity and temperature data were retrieved from the CTD profiles at each station, then plotted on a temperature–salinity (T/S) diagram.

Drifting Sediment Trap Sampling

A standard Lagrangian-type surface-tethered drifting sediment trap (KC Denmark model number 28.200) was used to collect sinking particles (Moran et al., 2012) at seven locations (**Figure 1**). Two of the four tubes contained a removable clear-bottomed cup filled with 250 mL of viscous polyacrylamide gel. The cups were fitted with a thin sloping ramp to funnel all sinking particles into the gel within the cup and prevent particles from settling between the inside of the tube and the outside of the cup. All four tubes were filled with chilled (0°C) filtered seawater (0.3 μm) collected in Niskin bottles from the same depth and station at which the drifting sediment trap was deployed. The remaining two tubes collected sinking particles in bulk, maintaining *in situ* chemistry as much as possible. The trap array was deployed at 30 m below the surface at each station, estimated to correspond to the bottom of the euphotic zone, for 3–12 h depending on the timing of other cruise operations (**Table 1**). We used the same depth for consistency and to reduce issues of resuspension by sampling too close to the seafloor. The drifting sediment trap was fitted with an ARGOS beacon and a go-Tele GPS tracker unit to track its real-time location.

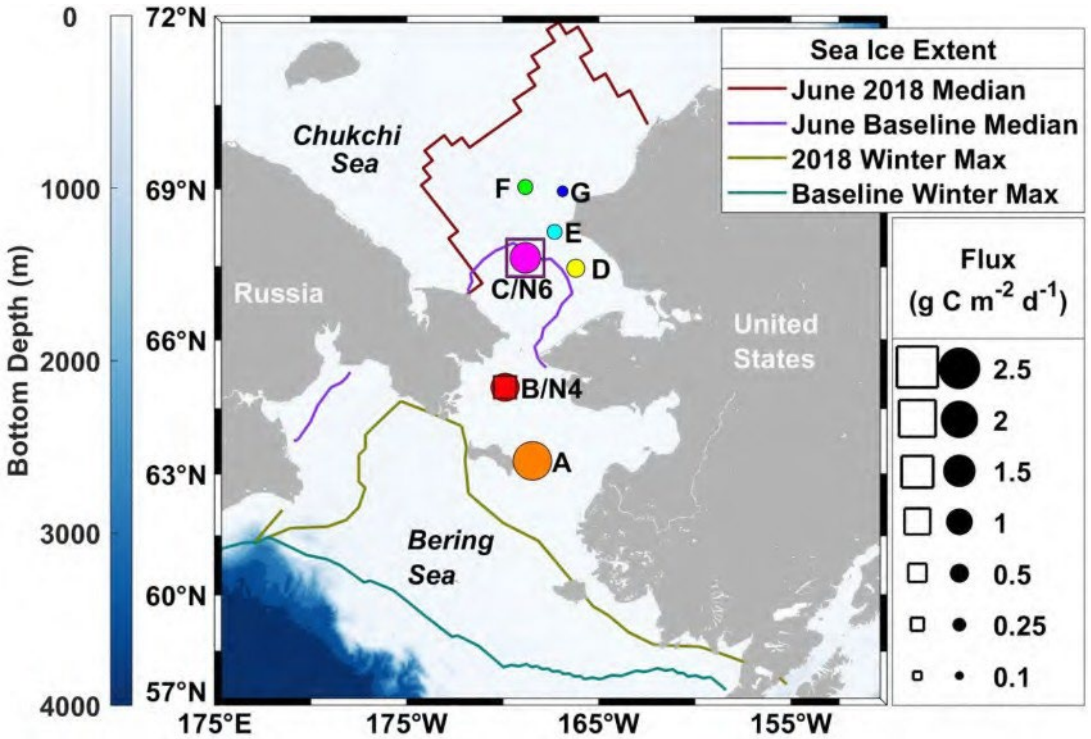

FIGURE 1 Spatial patterns of sinking particulate organic carbon fluxes on the Pacific Arctic shelf in June 2018. Drifting sediment trap measurements are depicted relative to the diameters of the circles, while moored sediment traps fluxes are shown as the length of the squares. Colored lines represent sea ice extent (Fetterer et al., 2017), where the 2018 June median ice extent (maroon) is compared with the 1981–2010 median June baseline (purple) and the record breaking 2018 maximum ice extent (olive) is compared with the 1981–2010 median winter maximum (teal).

Flux Rate Measurements

Sinking particles collected in the drifting sediment trap were used to determine POC fluxes. Once the trap was recovered, the following steps were performed as quickly as possible in an environmental chamber that fluctuated in temperature from 3 to 5°C in order to maintain as close to *in situ* conditions for particle-associated microbes as possible. Overlying water was siphoned using a vacuum pump down to a boundary layer above the settled particles at the bottom of all four tubes. In the two bulk particle collection tubes, the material that remained in the tubes after siphoning was quantitatively split into four subsamples using a Folsom plankton splitter. Three subsamples were used for triplicate analytical flux measurements. These subsamples were filtered onto pre-combusted 25-mm Whatman GF/F filters and placed in a dehydrator at 60°C for 12 h. Once dried, the filters were sealed in Petri dishes until further analysis (See section "Elemental POC/PN/$\delta^{13}C$/$\delta^{15}N$ Analysis" for details). Particulate organic carbon values were converted to daily fluxes depending on the deployment period and the collecting area (g C m^{-2} day^{-1}).

Respiration Rate Measurements

One subsample from each of the two drifting sediment trap tubes was used to estimate particle-associated microbial respiration rates. This material was homogenized by swirling the container and pipetted with a wide-bore pipette into eight replicate

2-mL glass vials (Batch PSTS-1721-01) fitted with Pre-Sens Oxygen Optode Sensor Spots (Regensburg, Germany) per drifting sediment trap tube, totaling 16 experimental samples. Filtered seawater controls were obtained from a Niskin bottle closed at 30 m depth during a CTD cast upon recovery of the drifting sediment trap. Water for the control samples was filtered (0.3 μm) to remove particles and particle-associated microbes. The filtrate was pipetted into eight replicate vials that were identical to the experimental vials. All 24 vials were checked for air bubbles, and vials were then placed inside a sealable, clear, plastic water-bath and placed on top of a PreSens SDR SensorDish Reader The water-bath was located inside a dimly lit cold room that varied from 3–5°C and connected to a Fisherbrand Isotemp 500LCSU Circulator, now referred to as a chiller, which maintained temperature at precisely 4.0°C during the incubation. The concentration of oxygen in each vial and temperature in the incubation chamber were recorded every 30 s for the duration of the incubation using PreSens – Sensor Dish Reader Version 4 Software. Incubations lasted for between 3 and 12 h. After the incubations, the remaining material from each vial was filtered onto individual GF/F filters and treated the same as the flux measurement samples.

A few modifications were made to the methods used for measuring particle-associated microbial respiration rates during the course of the study in order to try to improve the accuracy of our measurements. During the first incubation at station A, a low-oxygen micro-environment formed around the sensor spot, located at the bottom of the vial. For all subsequent incubations, the entire incubation chamber was repeatedly inverted for 5 s every 3 min to mix the sample. Additionally, we noticed the concentration of oxygen increased over time in a few of the experimental samples (i.e., at stations A, C, and E), suggesting photosynthetic activity. During the last two incubations at stations F and G, a black cloth was used to cover the incubation chamber in order to prevent any light from reaching the samples, theoretically preventing light reactions associated with photosynthesis. However, it should be noted that dark reactions associated with photosynthesis can continue for several hours after the removal of light in cold water.

The data recorded by the PreSens software were downloaded and analyzed using the following steps in Matlab 2017a computing software. Data collected before the incubation temperature stabilized were trimmed so that only the time during which the incubation temperature remained stable was analyzed. The first 188 min of data after temperature stabilization was used to determine respiration rates. Linear regression analysis was performed on the oxygen concentration data from each vial. The average and standard deviation of the eight replicate control slopes ($r_{control}$) was taken, and for each of the two experimental samples. Then the average slopes for each of the experimental incubations were averaged together and the error was propagated (r_{exp}). We calculated the carbon-specific particle-associated microbial respiration rate (R_PAM) using a 117:170 organic carbon to oxygen molar respiratory quotient ($V_{OC:O2}$), assuming a one to one relationship with organic carbon degradation and carbon dioxide production (Anderson and Sarmiento, 1994), an incubation volume (vol) of 2 mL, and the final concentration of POC at the end of the incubation ([POC]) (Eq. 1).

$$R\_PAM = \frac{(r_{exp} - r_{control}) \times vol \times V_{OC:O2}}{[POC]} \quad (1)$$

The average R_PAM ± 1 standard deviation was compared with those from other studies (Ploug and Jorgensen, 1999; Ploug and Grossart, 2000; Iversen and Ploug, 2010; Collins et al., 2015; McDonnell et al., 2015; Belcher et al., 2016a,b) at different locations.

Sinking Particle Visualization

Collecting particles in polyacrylamide gel kept sinking particles intact and allowed for particle imaging and identification (Ebersbach and Trull, 2008; McDonnell and Buesseler, 2010; Durkin et al., 2015). The contents of the cups were photographed within 6 h of sediment trap recovery using a 42.4 MP digital camera equipped with a 90 mm macro-lens and a flash unit. A length to pixel relationship was determined for each image in Adobe Photoshop CS6. These samples were used to qualitatively determine sinking particle type.

Primary Productivity Rate Measurements

^{13}C-^{15}N dual-isotope tracer technique was used to measure integrated rates of primary productivity at the seven stations following a standard protocol (Dugdale and Goering, 1967; Hama et al., 1983). For primary productivity rate measurements, water was collected at six depths corresponding to the 100, 50, 30, 12, 5, and 1% light levels. The 1% light level is estimated to be the minimum amount of light necessary for photosynthesis to occur, i.e., the bottom of the euphotic zone. The incubations lasted between 4 and 7 h, and measurements were extrapolated to daily production by adjusting to total daylight for each incubation site. At the end of the experiment, contents in each incubation bottle were filtered onto pre-combusted GF/F filters and frozen at −80°C until further analysis. These depth-specific rates were then integrated over the entire depth of the euphotic zone to determine total water column primary productivity rates in units of g C m^{-2} day^{-1}.

Elemental POC/PN/$\delta^{13}C$/$\delta^{15}N$ Analysis

All dried or frozen GF/F filters were processed in the Alaska Stable Isotope Facility at the University of Alaska Fairbanks's Water and Environmental Research Center. Filters were acidified with 10% hydrochloric acid for 24 h to remove particulate inorganic carbon (PIC). The filters were pelletized in tin cups. Stable isotope data were obtained using continuous-flow isotope ratio mass spectrometry. Stable isotope ratios were reported in δ notation as parts per thousand (0) deviation from the international standards VPDB (carbon) and air (nitrogen). Typically, instrument precision was <0.20.

Moored Sediment Trap Sampling

Two 24-cup Hydro-Bios sediment traps were moored at stations B south of Bering Strait (trap depth 37 m, bottom depth 49 m) and C north of Bering Strait (trap depth 35 m, bottom depth

50 m) from June 2017 to June 2018 (see **Table 2** and **Figure 1** for location of traps). Sample cups were filled with a hypersaline (salinity 38) 5% formalin solution in filtered seawater to preserve samples during and after deployment (Lalande et al., 2020). The carousel rotated at pre-programmed intervals ranging from seven to 40 days.

As the trap at station B was recovered before the end of its rotation, the material in the last open cup was excluded from analysis. Subsamples from each cup were filtered onto pre-combusted (500°C overnight) GF/F filters (0.7 μm), exposed to 1 N hydrochloric acid overnight for removal of inorganic carbon, and dried at 60°C overnight before encapsulation for POC measurements (Lalande et al., 2020). Particulate organic carbon measurements were conducted on a Perkin Elmer CHNS 2400 Series II elemental analyzer. Particulate organic carbon measurements were converted to daily flux rates depending on the open cup duration of each sample.

Instruments measuring physical and biological parameters in tandem with sinking POC flux were deployed on the moorings at stations B and C. A 300 kHz RDI workhorse ADCP measured bottom current velocity ~5 m off the seafloor at each site. Lowpass-filtered bottom current velocity were plotted overlaid with a 12-h smoothing. A Seabird SBE16plus unit coupled with a Wetlabs fluorometer measured temperature, salinity and fluorescence at 27 m at station B and 25 m at station C.

Remote Sensing

Daily sea ice concentrations were retrieved from the National Snow and Ice Data Center satellite records for the deployment period at both mooring sites (Fetterer et al., 2017). Wind velocity was obtained from modeled wind reanalysis for the deployment period at both mooring sites (European Centre for Medium-Range Weather Forecasts, 2019). Twenty-four hour smoothing was performed on wind data.

RESULTS

Environmental Conditions

Sea surface temperatures ranged from 1 to 10°C during the ASGARD expedition in June 2018, with the warmest water temperature above 8°C observed south of Nome and west of Norton Sound. These warm waters were characteristically fresher, with salinities ranging from 30 to 30.5, consistent with Alaska Coastal Water (ACW) characteristics and a shift to wind direction from the south (see **Supplementary Figure 1** for a map depicting regional currents in the study area). Wind speed ranged from 0 to 36 kt during the course of the cruise as measured by a vessel-mounted anemometer corrected for ship motion. Throughout the water column, temperatures ranged from −0.5 to 10°C and salinities ranged from 30 to 33.5. Chlorophyll fluorescence ranged from 0 to 15 μg L^{-1} while nitrate concentration ranged from 0 to 20 μmol L^{-1} and was highest along the northernmost Cape Lisburne line. SUNA-derived nitrate concentration measurements were confirmed with bottle-derived nitrate concentration measurements. Sea ice was absent during the cruise. A salinity of 31 delimited stations A, B, and C into the Bering Shelf/Anadyr Waters (BSAW) (salinity > 31) and stations D, E, F, and G into ACW waters (salinity < 31) (**Figure 2**).

Drifting Sediment Trap Flux Rate Measurements

The depth of the water column varied little at our seven stations, ranging from 41 to 51 m and averaging 47 m, 17 m deeper than the drifting sediment traps sampling depths at 30 m (1% Photosynthetically Active Radiation (PAR)). The actual 1% PAR varied from between 16 and 30 m, except for station F having a 1% PAR reaching 38 m (**Table 3**). The overall average depth of the euphotic zone was 26 m, comparable to POC export measurements at 30 m. Sinking POC fluxes were high (up to 2.2 g C m^{-2} day^{-1}) but spatially variable. Bering Shelf/Anadyr Waters were associated with higher fluxes (1.2–2.2 g C m^{-2} day^{-1}) at stations A, B, and C, while lower fluxes (0.2–0.5 g C m^{-2} day^{-1}) were characteristic of ACW at stations D, E, F, and G (**Figure 2**). For stations in the BSAW, sinking particles consisted mostly of aggregated diatoms and viable diatom cells while the ACW stations contained more diverse particles including fecal pellets, zooplankton, and diatom cells (**Figure 3**).

The particulate nitrogen (PN) flux ranged from 0.03 to 0.47 g N m^{-2} day^{-1}. Both the highest and lowest PN flux were measured in the ACW (**Table 3**). PN flux was slightly, though not significantly, higher in the BSAW (0.27 g N m^{-2} day^{-1}) than in the ACW (0.15 g N m^{-2} day^{-1}). Delta ^{13}C ranged from −24.03 to −19.940 with no clear distinction in $\delta^{13}C$ values between the ACW and BSAW. Both the least negative and most negative $\delta^{13}C$ values were located at stations in the ACW. A similar pattern was true for $\delta^{15}N$ values with values ranging from 5.63 to 8.50. There was no spatial pattern in $\delta^{15}N$ values and both the highest and lowest $\delta^{15}N$ values were found in stations in the ACW.

Respiration Rate Measurements

Overall carbon specific particle-associated microbial respiration ranged from −13.7 to 12.8% day^{-1} (**Table 4**). Negative

TABLE 2 Location and duration of moored sediment traps.

Station name	Trap name	Sampling period	Trap depth (m)	Bottom depth (m)	Latitude (degrees decimal minute)	Longitude (degrees decimal minute)
B	N4	June 26, 2017 to June 08, 2018	37	49	64° 55. 7′	−169° 55.1′
C	N6	June 17, 2017 to June 08, 2018	35	50	67° 40.2′	−168° 44.7′

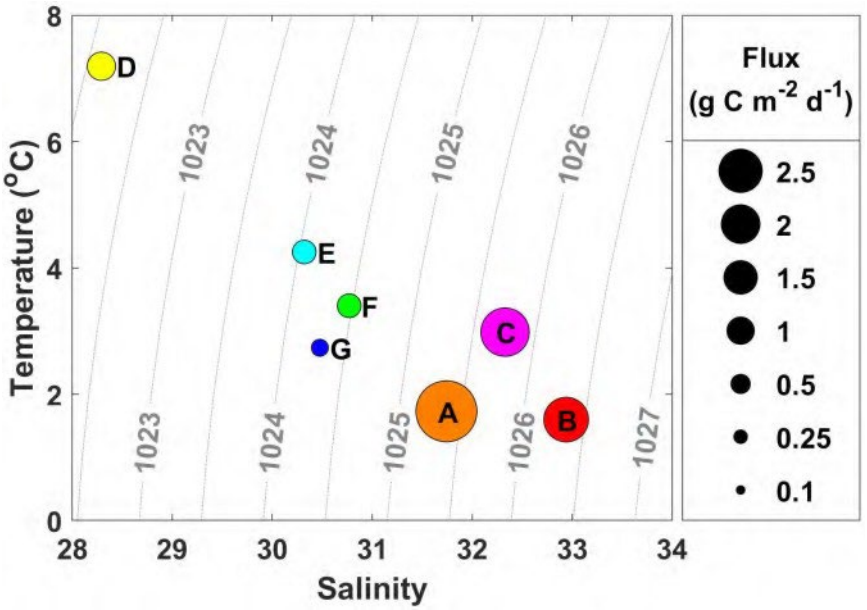

FIGURE 2. Water mass characteristics from each station where drifting sediment traps were deployed. The size of the circle is indicative of the amount of particulate organic carbon (POC) flux, labeled with station name. Warmer, fresher water characteristic of Alaska Coastal Water (ACW) has lower flux values compared with cooler, more saline water characteristic of Bering Shelf/Anadyr Water (BSAW), which has higher flux values.

Pacific Arctic's extraordinary carbon fluxes.

carbon specific particle-associated microbial respiration indicates net respiration of carbon while positive values indicate net production of carbon. Five of the seven stations had carbon specific particle-associated microbial respiration that were indistinguishable from zero where carbon specific particle-associated microbial respiration could not be distinguished from free living microbial respiration. The two respiration measurements that were distinguishable from zero were from stations B (−13.7 ± 10.5% day^{-1}) and C (12.8 ± 6.7% day^{-1}), both of which are in BSAW. Therefore, all carbon specific particle-associated microbial respiration from stations in ACW were indistinguishable from zero. Average carbon specific particle-associated microbial respiration from BSAW stations (3.1 ± 14.6% day^{-1}, average ± 1 standard deviation), ACW stations (1.7 ± 2.9% day^{-1}), as well as all stations combined (2.3 ± 8.7% day^{-1}) were indistinguishable from zero. Additionally, there was no statistical difference in carbon specific particle-associated microbial respiration between the ACW and BSAW.

Primary Productivity Rate Measurements

Primary productivity rates were spatially variable with an overall range of 0.23–4.24 g C m^{-2} day^{-1}. Station A had the highest rate of primary productivity and had the highest fluorescence signal of the seven stations (full depth CTD profiles are shown in **Supplementary Figure 2**). Here, a slight chlorophyll-*a* maximum of 10 mg m^{-3} fluorescence was present at 5 m depth and the water column was well-mixed. More pronounced, though lower chlorophyll-*a* maximums occurred at stations C

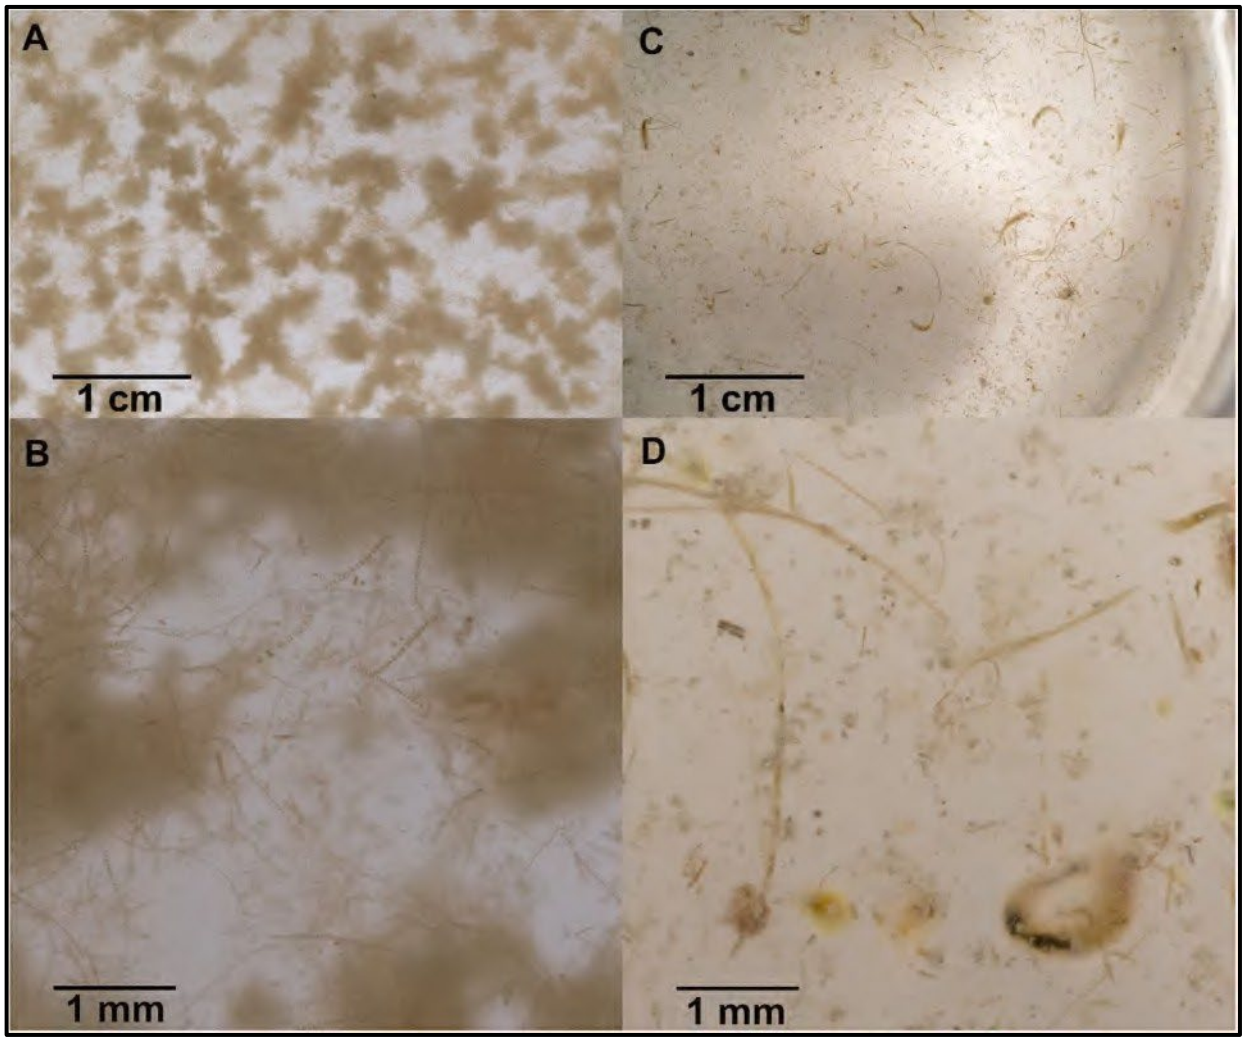

FIGURE 3 Sinking particles collected in polyacrylamide gel traps at station A (A,B) and station D (C,D). Sinking particles at station A are characteristic of Bering Shelf/Anadyr Water stations and consist exclusively of fluffy aggregates made of diatoms and viable diatom chains. Sinking particles at station D are characteristic of Alaska Coastal Water stations and consist of a more diverse set of particles, including fecal pellets, zooplankton swimmers, as well as still viable and senescent diatoms.

(30 m) and F (38 m). Station F had the deepest 1% PAR depth of 38 m, co-occurring with the chlorophyll-a maximum, but had the second lowest rate of primary productivity of 0.34 g C m^{-2} day^{-1}. Overall, primary productivity was higher in the BSAW (0.87–4.24 g C m^{-2} day^{-1}) than in the ACW (0.23–0.74 g C m^{-2} day^{-1}). All three stations in the BSAW had

less stratified water columns, while all four stations in the ACW had more stratified water columns.

Export Ratios

Export ratios are a metric that characterizes the efficiency of the biological carbon pump, calculated using Eq. 2.

$$\text{export ratio} = \frac{\text{flux}}{\text{primary productivity}} \quad (2)$$

Higher export ratios indicate a more efficient biological carbon pump and lower ones less efficient. Export ratios ranged from 0.45 to 1.36 with the lowest export ratio observed at station E and the highest at station B (**Table 3**). There was no significant difference in export ratios between water masses (BSAW: 0.84 ± 0.45 and ACW: 0.81 ± 0.27 mean ± 1 SD). Three stations (B, D, and F) had export ratios at or above 1 and the overall study average export ratio was 0.82 ± 0.32 (mean ± 1 SD).

Moored Sediment Trap Time Series Flux Rate Measurements

Moored sediment trap-derived POC fluxes provide independent measures to compare with the fluxes observed with drifting sediment trap sampling. Drifting sediment trap sampling at stations B and C took place three and six days following the end of the moored sediment trap sampling, respectively. Particulate organic carbon fluxes of 0.8 and 1.2 g C m^{-2} day^{-1} at station B and 2.3 and 1.4 g C m^{-2} day^{-1} at station C were obtained with the moored and drifting sediment traps, respectively (**Table 3** and **Figure 4**).

At station B, POC fluxes were generally low (<0.25 g C m^{-2} day^{-1}) from June through October 2017 with brief periods of elevated POC fluxes (0.6–1.3 g C m^{-2} day^{-1}) occurring around the same time as peaks in fluorescence (**Figure 5**). Particulate organic carbon fluxes increased along with wind speed during November and December 2017 (0.9–1.4 g C m^{-2} day^{-1}), decreased during January 2018, and remained relatively low (<0.65 g C m^{-2} day^{-1}) when sea ice was present from January through late April 2018. Fluorescence remained low from mid-October 2017 through April 2018. Sea ice melted at the end of April 2018 and the highest POC fluxes were observed about one month later during late May 2018 (1.5 g C m^{-2} day^{-1}).

At station C, high POC fluxes were recorded from June to mid-July 2017 (1.2–1.7 g C m^{-2} day^{-1}), followed by a period of low POC fluxes from mid-July through mid-October 2017 (<0.5 g C m^{-2} day^{-1}) (**Figure 5**). Spikes in fluorescence occurred sporadically from June until early October 2017. Particulate organic carbon fluxes increased starting in mid-October 2017 and were elevated throughout November and December 2017 (0.9–1.2 g C m^{-2} day^{-1}). Particulate organic carbon flux dramatically decreased when sea ice formed during January 2018. A period of low POC fluxes was observed between January and May 2018 (<0.5 g C m^{-2} day^{-1}), while sea ice was consistently present. The highest POC fluxes were measured at the beginning of June 2018 (2.3 g C m^{-2} day^{-1}), at the same time as the highest peaks of fluorescence soon after sea ice retreated from this station.

The moored sediment trap time series indicates that POC flux had recently peaked at station B before drifting sediment trap sampling took place during early June 2018, but was likely at or near the period of peak annual flux at station C (**Figure 5**). The composition of the material collected in the moored sediment trap samples during June 2018 indicated the occurrence of a pelagic phytoplankton bloom at station B, reflected by the export of the exclusively pelagic centric diatoms *Chaetoceros* spp. and *Thalassiosira* spp. that usually dominate spring blooms on Arctic shelves (Degerlund and Eilertsen, 2010; Lalande et al., 2019). Diatom fluxes, composed of several pennate and centric diatom groups, were nearly three times higher at station C than at station B, reflecting a large diatom bloom.

DISCUSSION

The overall objectives of this study were to characterize the strength and efficiency of the biological carbon pump on the Pacific Arctic shelf during a warm, low-ice year in order to shed light on potential current and future changes in carbon cycling in this region. We addressed this by considering three major aspects of relevance: primary productivity, sinking POC flux, and particle-associated microbial respiration during June of 2018.

Regional Spatial Trends

The largest distinction of regional spatial trends occurred between the two water masses present in this region (ACW and BSAW). Consistent with previous studies, the ACW was warmer and fresher with lower nutrients than the BSAW during June 2018 (Walsh et al., 1989; Springer and McRoy, 1993). Both regions were warmer than normal for this time of year and had experienced much less sea ice than normal (Danielson et al., 2020; Huntington et al., 2020).

We measured consistently lower POC flux rates in ACW than BSAW. These results support the previously untested hypothesis that POC fluxes would be higher in the BSAW compared to ACW (Grebmeier and McRoy, 1989). This distinction in primary productivity and POC flux between the ACW and BSAW could partially be attributed to differences in stratification between these regions; we found a less stratified water column in the BSAW, which could contribute to nutrient input to the surface and allow for higher primary productivity rates. Well-mixed water could also help facilitate POC mixing out of the euphotic zone, however it is more likely that this material could be brought back up to the surface through the same mechanism. The differences in primary productivity and POC flux cannot be fully explained by differences in water column stratification. The two regions were characterized by different types of sinking particles: more uniform aggregated diatoms and viable diatoms were found in the BSAW, while more processed material like fecal pellets and zooplankton were found in the ACW in addition to living diatoms. This distinction suggests more processing of POC by zooplankton or heterotrophic bacteria in the ACW. However, there was no difference in export ratio or particle-associated microbial respiration between

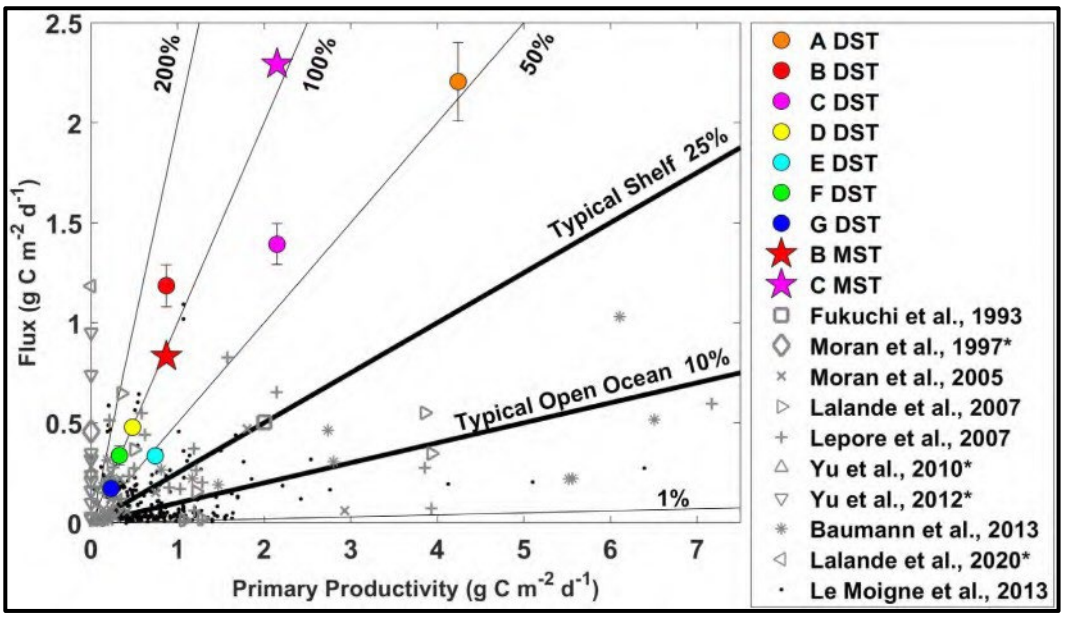

FIGURE 4 Sinking particulate organic carbon fluxes and primary productivity rates with contours of the export ratio between these two parameters measured during June 2018 on the Pacific Arctic shelf. The circles represent flux measurements from the drifting sediment trap. The stars represent the final flux measurement from the moored sediment traps (values plotted against the same primary productivity rates). Gray markers provide regional (Fukuchi et al., 1993; Moran et al., 1997, 2005; Lalande et al., 2007, 2020; Lepore et al., 2007; Yu et al., 2010, 2012; Baumann et al., 2013) and black markers global context (Le Moigne et al., 2013). *No corresponding productivity data with Moran et al., 1997 (Moran et al., 1997), Yu et al. (2010, 2012), and Lalande et al., 2020 (Lalande et al., 2020).

the two water masses, indicating that POC fluxes are mostly regulated by primary production rates rather than heterotrophic processing. The spatially uniform particle associated microbial respiration rates we measured do not support the postulation that the ACW would have higher particle-associated microbial respiration rates (Andersen, 1988; Grebmeier and Barry, 1991). Nonetheless, the higher primary productivity and POC fluxes in the BSAW demonstrate a stronger biological carbon pump in the BSAW region.

PN, $\delta^{13}C$, and $\delta^{15}N$ values were not significantly different between the BSAW and the ACW. Higher PN in sinking material are associated with more nutritious food for the benthos (Grebmeier et al., 1988). Less negative $\delta^{13}C$ values tend to indicate a larger influence of ice algae or a marine signature while more negative $\delta^{13}C$ values tend to indicate a more coastal or terrigenous signature (Wooller et al., 2007). Larger $\delta^{15}N$ values were associated with material that is higher on the food chain (i.e., secondary and tertiary producers), while lower $\delta^{15}N$ values are associated with material lower on the food chain (i.e., primary producers) (Post, 2002).

The ACW had lower primary productivity than the BSAW. This regional pattern has been well described previously (Walsh et al., 1989; Springer and McRoy, 1993) and is attributed to the lower nutrient concentrations in ACW compared with BSAW (Danielson et al., 2017). Primary productivity values in both water masses fell within a typical range for these regions (Lee et al., 2007; Arrigo et al., 2014; Hill et al., 2018). However, a primary productivity rate of 16 g C m^{-2} day^{-1} has been previously observed in the Pacific Arctic Shelf (Walsh et al., 1989; Springer and McRoy, 1993), much higher than what we measured and what is typically measured. If these higher production rates were associated with export ratios similar to what we observed here, then the associated fluxes would be even more remarkable than the values we observed with the DSTs and MSTs during this study.

Stations with higher rates of primary productivity tended to have higher rates of POC flux. However, there was not a perfect relationship between primary productivity and POC flux, which caused some variations in the export ratios. The stations with export ratios over 1 and the high average export ratio indicate an extremely efficient biological carbon pump or temporal or spatial decoupling between primary production and flux.

While the dominant regional patterns were associated with water masses, we also expected some patterns falling along a latitudinal gradient. It is difficult to separate the signal of water mass from latitude because most of the stations that were classified as BSAW were located south of the stations classified as ACW. We found higher daily primary productivity rates and POC fluxes at the southern stations in the BSAW than at the northern stations in the ACW. The annual POC flux was higher at station C (215 g C m^{-2} $year^{-1}$) than at station B (204 g C m^{-2} $year^{-1}$), indicating an increase in POC flux with latitude. However, an annual POC flux lower than these (145 g C m^{-2} $year^{-1}$) was measured at about 200 miles north of our study area (Lalande et al., 2020). Drifting sediment trap sampling at more stations in the southern portion of the ACW and moored sediment trap sampling in the ACW are needed to better

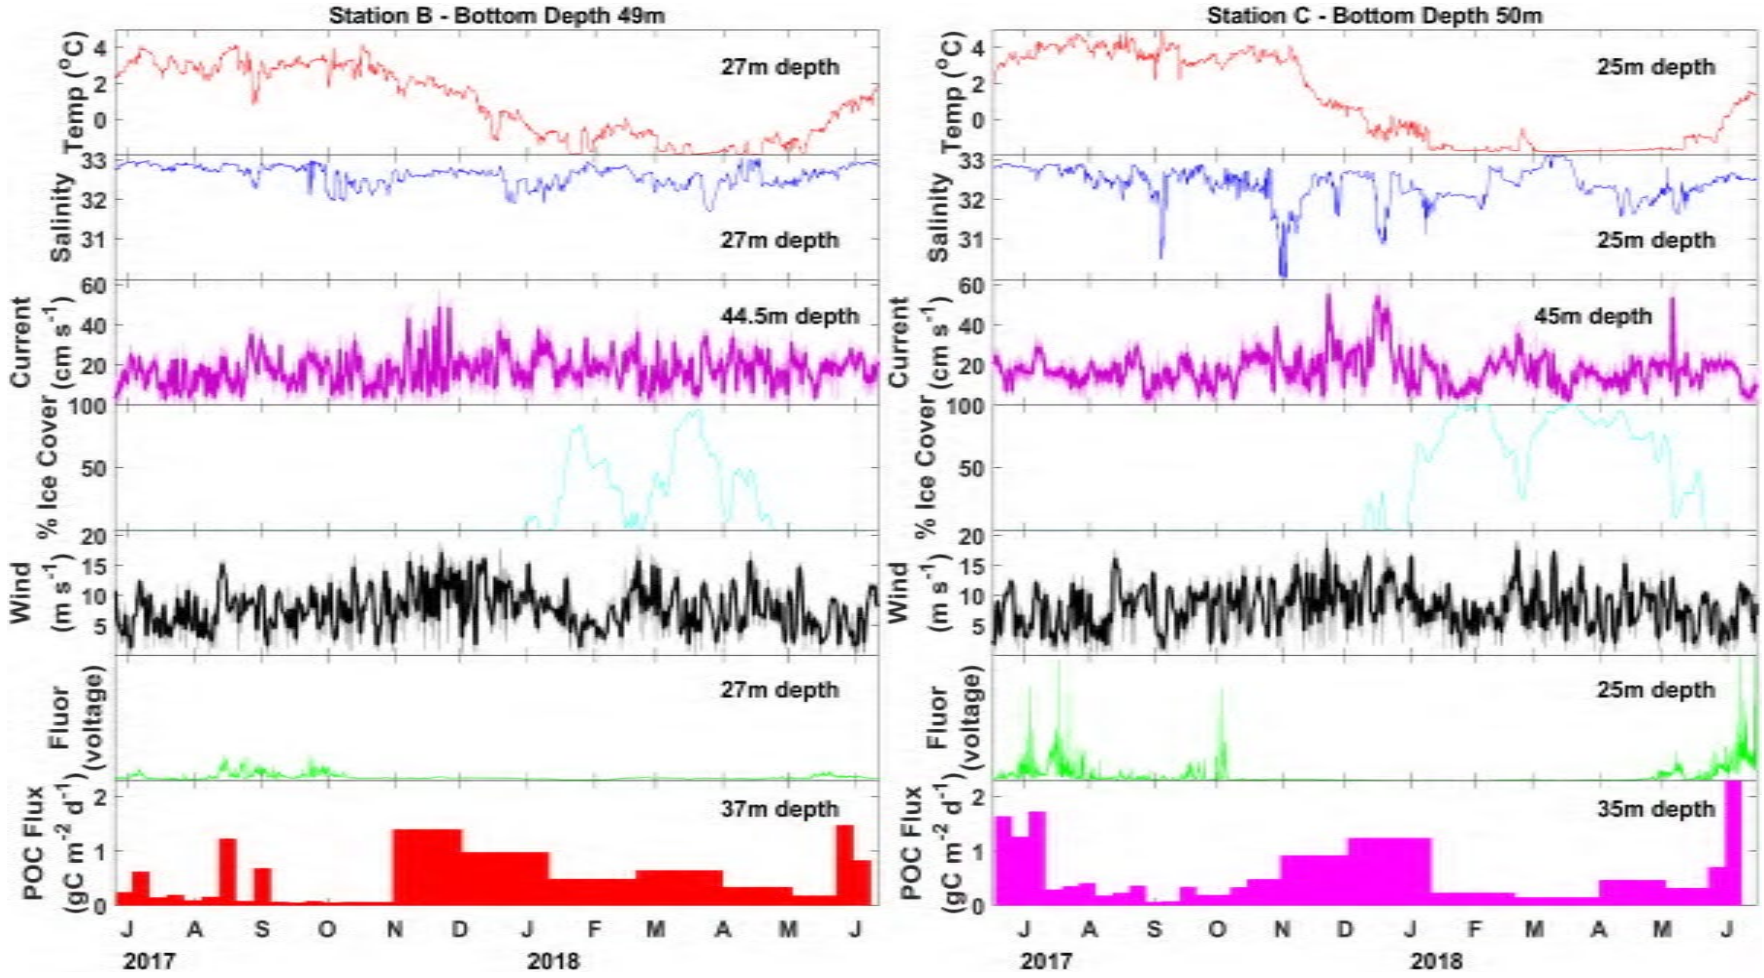

FIGURE 5 Particulate organic carbon flux (colored bars) measured with moored sediment traps at stations N4 and N6 between June 2017 and June 2018. Sea ice percent cover (cyan line) taken from NSIDC satellite records (Fetterer et al., 2017). Wind velocity (black line) taken from modeled wind reanalysis (European Centre for Medium-Range Weather Forecasts, 2019). Twenty-four hour smoothing is shown with the thick black line. Lowpass-filtered current velocity (magenta line) taken from AD, with 12 h smoothing shown with the thick magenta line, temperature (red line), salinity (blue line), fluorescence (green line) taken from seabird SBE16plus unit coupled with a WetLabs fluorometer on each of the moorings.

tease apart the differences associated with latitude and water mass in this region.

The annual pattern of POC flux shows some latitudinal distinction between the more northern station C and the more southern station B. The peak annual flux occurred during early June 2018 at station C, while the peak annual flux occurred a couple of weeks earlier at station B (late May 2018). The spring peak flux was higher at station C (2.3 g C m^{-2} day^{-1}) compared to station B (1.5 g C m^{-2} day^{-1}). Increased POC flux measurements occurred in the absence of peaks in fluorescence at both stations from November 2017 to January 2018 strongly suggesting episodic resuspension events during fall. Particulate organic carbon fluxes decreased in the presence of sea ice, reducing wind mixing and resuspension. This is particularly evident at station C under higher sea ice concentrations. It is likely that these fall high flux events do not represent increased net flux, as they are likely partly the result of material that previously fell to the seafloor being resuspended and collected in the moored sediment trap again.

Role of Heterotrophy in the Water Column

Bacterial production largely controls how much exported POC reaches the seafloor and might increase in Arctic waters under more acidic, warmer, and lower-ice conditions (Garneau et al., 2009; Vaqué et al., 2019), which could result in higher pelagic community carbon demand (Sala et al., 2010). One factor that has received a lot of thought for the Pacific Arctic shelf region is how a reduction in ice algae relative to to pelagic phytoplankton as primary producers might impact the benthic-pelagic coupling, with the prediction that smaller pelagic phytoplankton will have slower sinking rates and will therefore be more likely to be consumed by zooplankton or bacteria in the water column, resulting in less material reaching the seafloor (Carroll and Carroll, 2003; Grebmeier, 2012; Moore and Stabeno, 2015). A slower particle sinking rate will give more time for bacteria to both colonize and degrade sinking particles. In our study, we mostly collected pelagic diatoms in the drifting sediment traps rather than species associated with ice. However, our direct measurements of microbial respiration rates associated with sinking particles were mostly indistinguishable from zero. This is not unprecedented in high latitude regions (McDonnell et al., 2015).

Conducting a comparison of measured particle-associated microbial respiration rates from around the globe, we found that particle-associated microbial respiration generally decreases with increasing latitude (**Figure 6**). In our study, the rate of particle-associated microbial respiration was 2% day^{-1} on average, with a 95% confidence interval ranging from −24.2 to 34.3% day^{-1}. Given the shallow nature of the Pacific Arctic shelf (20 m average distance from base of euphotic zone to seafloor) and rapid sinking velocity of material caught in the traps (greater than 100 m day^{-1}), even under the fastest respiration rate (−24.2% day^{-1}) we calculated that less than 5% of the exported organic carbon would be remineralized within the water column before being deposited on the seafloor. Considering our conservative estimates, the true consumption is likely much smaller than this value. We conclude that particle-associated microbial respiration does not play a large role in recycling POC below the euphotic zone in this region, implying that most of the material that is exported from the euphotic zone will likely reach the shallow seafloor.

One mitigating factor in how much organic matter is deposited on the seafloor is the role zooplankton and free-living heterotrophic microbes play in consuming organic matter in the water column. Historically, zooplankton have not consumed large proportions of organic matter in the water column (Ashjian et al., 2003; Campbell et al., 2009; Hopcroft et al., 2010; Kitamura et al., 2017; Lalande et al., 2020), but it is possible they may play a larger role in the future. One study from just north of our study area found that primary production rates were similar to free-living community microbial respiration rates during the summer, indicating a large proportion of primary production could be consumed by free-living microbes (Cota et al., 1996). High export ratios in the present study point to zooplankton and free-living heterotrophic microbes playing a small role in consuming organic matter within the euphotic zone. It is possible that zooplankton and bacteria may play a larger role in consuming POC later in the summer. We suggest measuring export ratios and particle associated microbial respiration rates in August on the Pacific Arctic shelf to answer this remaining question.

Comparison of Drifting and Moored Sediment Trap POC Fluxes

The POC flux measurements measured with the drifting and moored traps at stations B and C, while of similar magnitude, were not the same. Many factors potentially caused variations between POC flux values obtained with drifting and moored traps. One reason is the different sampling times as POC fluxes may have changed on time scales much shorter than three or six days. In addition, the moored sediment trap measured flux over eight days, while the drifting sediment traps measured flux for six and a half hours and station B and five and a half hours at station C. If there is a diurnal cycle in flux regulated by zooplankton or phytoplankton it can be captured in the drifting sediment trap sampling and masked in the moored sediment trap sampling. Our study took place on a shallow Arctic shelf over the summer solstice. It is unlikely there was a diurnal cycle of primary production due the nearly 24 h of sunlight that were present. Additionally, due to the shallowness of the shelf, zooplankton in this region are not know to exhibit diel vertical migration (Ashjian et al., 2003; Campbell et al., 2009). It is unlikely that any differences in POC flux are a result of any changes in flux as a diurnal cycle, and, if present, are likely due to changes in the rate of primary production controlled by variable cloud cover and nutrient availability. Finally, the locations of the moored sediment trap and drifting sediment trap sampling did not perfectly overlap, although the drifting sediment traps were deployed within half a mile of the moored sediment traps.

Even if the sampling of these two traps perfectly overlapped in time and space, it is unlikely that they would produce the same

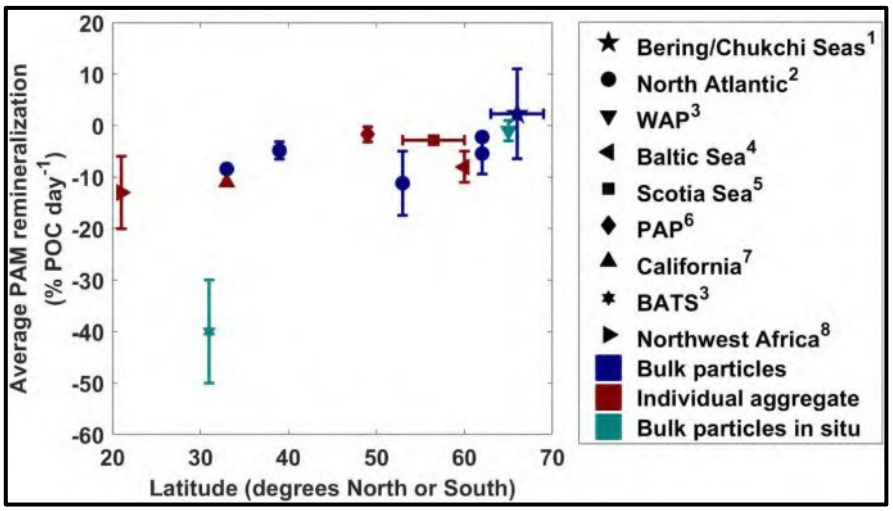

FIGURE 6 Average particle-associated microbial respiration rates (with one standard deviation plotted as vertical error bars) from this study along with previous measurements at other latitudes. Symbols colored with navy indicate bulk particle respiration measurements, teal indicate measurements taken with RESPIRE *in situ* incubator, and maroon indicate rates measured from individual aggregates. WAP, Western Antarctic Peninsula; PAP, Porcupine Abyssal Plain; BATS, Bermuda Atlantic Time Series. Measurements were taken from this study[1], Collins et al. (2015)[2], McDonnell et al. (2015)[3], Ploug and Grossart (2000)[4], Belcher et al. (2016a)[5], Belcher et al. (2016b)[6], Ploug and Jorgensen (1999)[7], and Iversen and Ploug (2010)[8].

POC flux values. One reason is because the moored sediment traps sample with a Eulerian framework, being moored in one location sampling various water masses as they flow, while drifting sediment traps sample with a Lagrangian approach, staying with one parcel of water and sampling it continuously as it moves with the currents. Another reason is that each of these trap designs have their own individual biases. In high current environments moored sediment traps can tilt to the side, affecting the collection of sinking particles. However, no tilt occurred at stations B and C based on CTD data. In contrast, drifting sediment traps may reduce the vertical shear in high current environments by floating freely within the water column. Additionally, we minimized other hydrodynamic concerns by using a bungee to dampen surface motion, tubes with a high aspect ratio, and bottom weighted tubes to keep them upright (Butman et al., 1986; Nodder et al., 2001, Buesseler et al., 2007). However, sinking POC flux may be incorrectly measured with drifting sediment traps because the tubes are open during deployment and recovery, contrary to the moored sediment traps (Buesseler et al., 2007). This source of error is minimized by deploying the drifting sediment traps at a shallow depth (i.e., 30 m).

With these sources of error, it is helpful to have two independent measurements of POC flux using different methods. The overall range of POC flux values in June 2018 was 1.48 to 2.29 g C m^{-2} day^{-1} with the moored sediment traps and 0.17 to 2.20 g C m^{-2} day^{-1} with the drifting sediment traps. Comparable maximum flux magnitudes from these two different methods minimize the concerns of collection biases common with sediment traps and provide some supporting evidence of the validity of POC fluxes of this magnitude.

Comparing POC Flux, Primary Productivity, and Export Ratios

Primary productivity rates, sinking flux, and export ratios were compared with previous measurements from the same study area (Fukuchi et al., 1993; Moran et al., 1997; Yu et al., 2010, 2012; Lalande et al., 2020), the broader Bering and Chukchi shelf system (Moran et al., 2005; Lalande et al., 2007; Lepore et al., 2007; Baumann et al., 2013), the greater Arctic area (**Supplementary Table 1**), and from a global compilation (Le Moigne et al., 2013; **Figure 4**, and **Supplementary Figure 2**). The upper range of our POC flux measurements (2.2 g C m^{-2} day^{-1} from drifting sediment trap and 2.3 g C m^{-2} day^{-1} from moored sediment trap) was unprecedentedly high compared to other measurements in this region and among the highest recorded in the surrounding areas, the broader Arctic, and globally.

Five previous studies report particulate flux estimates for the Bering and Chukchi shelves (Fukuchi et al., 1993; Moran et al., 1997; Yu et al., 2010, 2012; Lalande et al., 2020), two based on sediment trap measurements. A moored sediment trap deployed (36 m water depth, 49 m bottom depth) from late June to late September 1988, about 500 miles south of Bering Strait, measured flux ranging from 253 to 654 mg C m^{-2} day^{-1} (Fukuchi et al., 1993). More recently, a moored sediment trap deployed (37 m water depth, 45 m bottom depth) from August 2015 to July 2016, about 200 miles north of our most northern stations on the Chukchi shelf, measured POC fluxes ranging from 72 to 1184 mg C m^{-2} day^{-1} (Lalande et al., 2020). An estimate of 456 mg C m^{-2} day^{-1} (36 m water depth, 49 m bottom depth) was calculated using the $^{234}Th/^{238}U$ disequilibrium method on the Chukchi Sea shelf in August 1994 (Moran et al., 1997). Yu et al. (2010) measured a POC flux value of 243.8 mg C m^{-2} day^{-1}

(40 m water depth, 50 m bottom depth) using the $^{234}Th/^{238}U$ disequilibrium method sometime between July and September on the Chukchi shelf within the bounds of our study area. Finally, during a study on the Chukchi shelf from July to September, a POC flux measurement of 951.1 mg C m^{-2} day^{-1} (30 m water depth, 40 m bottom depth) was made using the $^{234}Th/^{238}U$ disequilibrium method within the bounds of and to the north of our study area (Yu et al., 2012). We selected the peak annual POC flux value from Lalande et al. (2020) and the flux measurement from Moran et al. (1997) and Yu et al. (2010, 2012) and plotted them directly on the y-axis indicating no known corresponding primary productivity value (**Figure 4**). The spatial extent of these studies are shown along with that of this study in **Supplementary Figure 3**. It should be noted that the $^{234}Th/^{238}U$ disequilibrium method for calculating sinking POC flux has its own biases, especially in areas with non-steady state flux events and advection and dispersion processes (Buesseler et al., 2007), such as on a shallow Arctic shelf. The measurements of POC flux we made in this study were the same or higher than previous measurements made in this region.

We expanded our region of comparison to include the Bering and Chukchi shelf breaks. Particulate organic carbon flux has been estimated more frequently on the Bering and Chukchi shelf breaks, with a maximum flux value at the base of the euphotic zone of 1.381 g C m^{-2} day^{-1} reported slightly south of our study area on the Bering Sea shelf break (40 m water depth, >125 m bottom depth) in July 2010 (**Figure 6**; Baumann et al., 2013). Additionally, our average regional flux for the BSAW, 1.59 ± 0.54 g C m^{-2} day^{-1} (mean ± 1 SD) is much higher than previous average regional flux estimates from the shelf breaks just north and south of this region, which range from 34 mg C m^{-2} day^{-1} (50 m water depth, bottom depth average 1275 m, May and June sampling period) to 376 mg C m^{-2} day^{-1} (50 m water depth, bottom depth average 838 m, May and June sampling period) (Moran et al., 2005, 2012; Lalande et al., 2007; Lepore et al., 2007; Baumann et al., 2013). Although individual measurements of export ratios approaching 1 are somewhat common (Lepore et al., 2007; Baumann et al., 2013), our average export ratio of 0.82 ± 0.32 (mean ± 1 SD) is very high. These observations illustrate the exceptional efficiency and strength of the biological carbon pump in the shallow Pacific Arctic shelf and shelf breaks.

Sinking POC flux and primary productivity values were also compared with a global review of POC flux measurements obtained using the $^{234}Th/^{238}U$ disequilibrium method (Le Moigne et al., 2013). We plotted all values with both POC flux and primary productivity rate measurements from Le Moigne et al. (2013), along with previous measurements from the broader Pacific shelf system, and our specific study area with the values we measured in this study from the drifting sediment traps and the last values of POC flux from the moored sediment traps (**Figure 4**). When available, sinking POC flux measurements at the base of the euphotic zone were selected, a metric shown to be comparable at sites with different bottom and euphotic zone depths (Buesseler et al., 2020). From this analysis, it is evident that the primary productivity rates from this study mostly fall within the upper range of what has been measured in this region before. Flux measurements at the BSAW stations (0.8–2.3 g C m^{-2} day^{-1}) are very high compared to what has been measured previously (0–1.4 g C m^{-2} day^{-1}).

In addition to the global review by Le Moigne et al. (2013), we compiled POC fluxes, primary productivity rates, and export ratios from other high latitude studies. The results of this review can be found in **Supplementary Table 1**. We categorized the studies by region, including the Baffin Bay, Baltic Sea, Barents Sea, Beaufort Sea, Bering Sea, Canadian Archipelago, Chukchi Sea, Fram Strait, Greenland Sea, Hudson Bay, Kara Sea, Labrador Sea, Laptev Sea, North Atlantic, North Sea, White Sea, as well as the high Arctic. We considered studies that measured sinking POC flux rates using drifting, moored, or neutrally buoyant sediment traps, marine snow catchers, or $^{234}Th/^{238}U$ disequilibrium. When possible, we selected samples from as close to the euphotic zone as possible. Primary productivity rates ranged from 0 to 2.6 g C m^{-2} day^{-1} and export ratios ranged from 0.03 to 1.67. These ranges are consistent with the primary productivity and export ratios measured in this study. Out of 79 studies, only nine measured rates of POC flux greater than 1 g C m^{-2} day^{-1} that were measured in the Baffin Bay (Michel et al., 2002), the Barents Sea (Andreassen and Wassmann, 1998; Olli et al., 2002; Lalande et al., 2008; Gustafsson et al., 2013), the Bering Sea (Baumann et al., 2013), the Beaufort Sea (Amiel and Cochran, 2008), the Chukchi Sea (Lalande et al., 2020), and the North Atlantic (Buesseler et al., 1992). The highest POC flux measurement of 2.5 g C m^{-2} day^{-1} was measured in the Beaufort Sea near the Makenzie River drainage in June at 50 m depth and 230 m water depth (Amiel and Cochran, 2008). The second highest POC flux measurement of 1.5 g C m^{-2} day^{-1} was measured in the Barents Sea in May at 30 m depth and 239 m bottom depth (Olli et al., 2002). We also selected some studies of POC flux from known high productivity and/or high flux regions from around the world (**Supplementary Table 2**). These POC flux values ranged from 1 to 620 mg C m^{-2} day^{-1}. Two POC flux values recorded in the present study were among the highest ever recorded at the base of the euphotic zone (2.20 g C m^{-2} day^{-1} at station A with a drifting sediment trap and 2.29 g C m^{-2} day^{-1} at station C with a moored sediment trap). With individual flux values from different methods at different stations ranking among the highest ever recorded, it is clear that the Pacific Arctic shelf exported a massive amount of organic carbon out of the euphotic zone, even in an anomalously warm year with low sea ice.

Limitations and Implications

Even with strong efforts in place to study the processes on the Pacific Arctic Shelf with the ASGARD program, there is still a lack of available data. While POC flux and water column oceanographic measurements are being obtained more frequently with moored sediment traps, temporally overlapping primary productivity rate measurements are not often available, notably later in the summer or earlier in the spring, when production is highest. Previous primary productivity measurements obtained later in the summer (Springer and McRoy, 1993; Lee et al., 2007; Hill et al., 2018) may no longer be representative of current conditions. Additionally, particle-associated microbial respiration rates are likely variable

throughout the spring, summer and fall and therefore cannot be extrapolated beyond spring. Therefore, there are still many unknowns regarding how the Pacific Arctic is responding and will respond to climate change. It is possible that only after many years of consistently warm and low-ice conditions changes in the strength and efficiency of the biological carbon pump on the Pacific Arctic shelf will become apparent.

It has been hypothesized that the strength of the biological carbon pump in the Arctic may weaken with climate change due to increased duration of the open-water period for primary production and enhanced nutrient limitation (Piepenburg, 2005; Wassmann and Reigstad, 2011; Grebmeier, 2012). Warmer waters have been predicted to increase metabolic rates of pelagic grazers and heterotrophic bacteria and potentially favor smaller phytoplankton and faster-growing grazers that more rapidly recycle organic matter within the water column (Wassmann and Reigstad, 2011; Neeley et al., 2018). We postulate that high nutrient concentrations, the shallow nature of the Pacific Arctic shelf, and the large-celled, fast-sinking phytoplankton that dominate pelagic productivity create conditions unique to this Arctic shelf (Springer and McRoy, 1993; Gradinger, 2009). Nutrients are unlikely to become more limited, especially in the BSAW, because of the consistent influx of the Anadyr Current, which is nutrient replete from Pacific upwelling. High nutrient concentrations favor large-cell phytoplankton (Li et al., 2009). Therefore, it is possible the Pacific Arctic shelf will not experience as dramatic of a shift from large cells to small cells with warming conditions when compared to other Arctic shelves. Finally, the Pacific Arctic shelf is shallower than most other Arctic shelves (averaging only 50 m deep). It will never take very long for sinking material leaving the euphotic zone to reach the seafloor, as it only has to sink about 20 m. Even if there is some increased heterotrophy in zooplankton or bacteria or decrease in cell size, the shallow nature of the shelf will allow for a higher proportion of organic matter to reach the seafloor than over deeper shelves, such as the Canadian Arctic Archipelago and European Arctic shelf. Increased frequency of storms are predicted with a changing Arctic (Slats et al., 2019). This could have major implications for the long-term carbon storage that historically has occurred on the Pacific Arctic shelf. Hauri et al. (2013) found that significant portions of carbon once thought to be stored in sediments on the Chukchi shelf are mixed up during fall storms. Given these features, we speculate that this system may retain strong coupling between the pelagic and benthic realms, continue to support highly productive pelagic and benthic ecosystems, and act as a strong sink for atmospheric carbon dioxide, possibly mediated by increased frequency of fall and winter storms. If these results prove to be a sustained feature of the rapidly changing Pacific Arctic, the biological carbon pump could represent an important element of resilience for regional ecosystems and biogeochemical cycles.

CONCLUSION

Measurements from both drifting and moored sediment traps indicate that fluxes of sinking POC on the Pacific Arctic shelf in June 2018 ranged from 0.8 to 2.3 g C m^{-2} day^{-1} in BSAW, making them amongst the highest fluxes ever documented in the global oceans. This region was also characterized by high export ratios and low rates of particle associated microbial respiration. These observations indicate that the biological carbon pump on the Pacific Arctic shelf is exceptionally strong and efficient despite a recent multi-year shift to warmer and relatively ice-free conditions (Fetterer et al., 2017; Stabeno and Bell, 2019; Danielson et al., 2020; Huntington et al., 2020). While the majority of the fluxes we observed during June 2018 were unprecedented relative to the limited number of historical flux measurements from this region, the data are still insufficient to determine whether functioning of the biological carbon pump has changed significantly relative to earlier, colder, and ice-replete years. Nonetheless, our observations do not provide supporting evidence for the common prediction that a weaker biological carbon pump and increased pelagic heterotrophy will prevail on the Pacific Arctic's continental shelves under future change.

Abstract

Unusually warm conditions recently observed in the Pacific Arctic region included a dramatic loss of sea ice cover and an enhanced inflow of warmer Pacific-derived waters. Moored sediment traps deployed at three biological hotspots of the Distributed Biological Observatory (DBO) during this anomalously warm period collected sinking particles nearly continuously from June 2017 to July 2019 in the northern Bering Sea (DBO2) and in the southern Chukchi Sea (DBO3), and from August 2018 to July 2019 in the northern Chukchi Sea (DBO4). Fluxes of living algal cells, chlorophyll *a* (chl *a*), total particulate matter (TPM), particulate organic carbon (POC), and zooplankton fecal pellets, along with zooplankton and meroplankton collected in the traps, were used to evaluate spatial and temporal variations in the development and composition of the phytoplankton and zooplankton communities in relation to sea ice cover and water temperature. The unprecedented sea ice loss of 2018 in the northern Bering Sea led to the export of a large bloom dominated by the exclusively pelagic diatoms *Chaetoceros* spp. at DBO2. Despite this intense bloom, early sea ice breakup resulted in shorter periods of enhanced chl *a* and diatom fluxes at all DBO sites, suggesting a weaker biological pump under reduced ice cover in the Pacific Arctic region, while the coincident increase or decrease in TPM and POC fluxes likely reflected variations in resuspension events. Meanwhile, the highest transport of warm Pacific waters during 2017–2018 led to a dominance of the small copepods *Pseudocalanus* at all sites. Whereas the export of ice-associated diatoms during 2019 suggested a return to more typical conditions in the northern Bering Sea, the impact on copepods persisted under the continuously enhanced transport of warm Pacific waters. Regardless, the biological pump remained strong on the shallow Pacific Arctic shelves.

Introduction

The Pacific Arctic marine ecosystem is extremely productive due to the persistent flow of nutrient-rich waters fueling high primary production on the shallow northern Bering Sea and Chukchi Sea shelves [1]. Recently, the region showed signs of a warming trend, including

and A91-00a) awarded to AMD and SLD. The CEO project was funded under NPRB Long Term Monitoring program (NPRB grant numbers 1426 and L36) awarded to SLD. JMG received support from the NSF Arctic Sciences Division (OPP grant number 1917469). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Competing interests: The authors have declared that no competing interests exist.

drastic reductions in sea ice extent and an increase in the transport of warm Pacific waters delivering more heat and freshwater, and potentially more nutrients and biota, into the Arctic Ocean through the Bering Strait [1–8]. Amid this long-term warming trend, anomalously warm conditions were observed in the Pacific Arctic from 2017 into 2019, including an unprecedented loss of sea ice, even in the context of other recent warm years [1, 9, 10]. Sea ice cover barely extended south of Bering Strait in early January 2017 and remained well below the long-term average during the entire winter [1, 11]. The reduced sea ice cover enhanced oceanic heat uptake during spring months [6] and led to exceptionally high near-bottom ocean temperatures (~4˚C) in the Bering Strait in June 2017 [1]. The anomalously elevated water column heat content combined with winds from the south delayed sea ice formation to late December 2017 and contributed to the highest northward transport of Pacific waters during winter 2017–2018 [1, 6, 12]. Warm winds from the south also contributed to the record-breaking low sea ice extent and concentrations observed in the Pacific Arctic region in February 2018 and to the northern Bering Sea region being mostly ice-free by late March 2018 [1, 13–15]. The early sea ice retreat and reduced input of freshwater from melting sea ice in 2018 delayed the onset of stratification and the spring bloom [14, 16–18], and induced a shift in the composition of the phytoplankton community toward a high abundance of small diatoms [14]. Meanwhile, low abundance of large, lipid-rich copepods and high abundance of small copepods with low lipid content were reported in the northern Bering Sea during 2018 [1, 14–16], affecting the distribution of fish as well as the reproduction and survival of marine birds and mammals [14]. Nevertheless, flux measurements obtained using sediment traps deployed in the Bering Strait region during June 2018 highlighted remarkably high POC fluxes during the warm period [19]. Similar to 2017, accumulated residual heat reflected by record high sea surface temperatures during autumn 2018 [20] delayed freeze-up until December, while unusual southerly winds again forced a large ice retreat in February 2019 that led to the second lowest winter sea ice extent on record during 2018–2019 [1, 13].

While results from several snapshot studies clearly indicated that a sudden shift of the Pacific Arctic ecosystem occurred during the anomalously warm 2017–2019 period, most biological measurements were limited to summer months [1]. To complement these snapshot observations, sinking particles and plankton collected with moored sediment traps deployed at three sites of the Distributed Biological Observatory (Grebmeier et al., this issue) were used to monitor spatial and temporal variations in export fluxes and community composition in the Pacific Arctic region. Continuous flux measurements were obtained at the DBO2 and DBO3 sites from June 2017 to July 2019 and at the DBO4 site from August 2018 to July 2019 (Fig 1). This monitoring effort using sequential sediment traps follows the first time-series flux measurements obtained on the shallow Pacific Arctic shelves at the Chukchi Ecosystem Observatory (DBO4) from August 2015 to July 2016 [21]. Fluxes of living algal cells (with chloroplasts), chlorophyll *a* (chl *a*), total particulate matter (TPM), particulate organic carbon (POC), and zooplankton fecal pellets were measured to monitor carbon export and the seasonal development of the algal bloom in relation to the drastic changes observed during the warm anomaly period. Zooplankton and meroplankton collected in the sediment traps were also identified to track spatial and temporal variations in the composition and development of these communities. The deployment of moored sediment traps represents an invaluable contribution to the DBO as they provided time-series integrative measurements of biological and biochemical parameters at a high temporal resolution during a period of rapid changes in the Pacific Arctic. As warm events are likely to increase in frequency under the current global warming scenario, time-series export fluxes measurements obtained during the 2017–2019 warm period contribute to a better understanding of conditions to expect for the highly productive marine ecosystems of the northern Bering Sea and Chukchi Sea.

Material and methods

Remote sensing

Daily averaged sea-ice concentrations above each mooring site were retrieved at a 12.5-km resolution from the Centre ERS d'Archivage et de Traitement (CERSAT) service of the French Research Institute for Exploitation of the Sea (http://cersat.ifremer.fr/). Daily sea-ice concentrations were averaged for a 44 x 44 km region above each mooring site (Fig 1; DBO2: 64.7–65.1˚N; 169.3–169.8˚W; DBO3: 67.1–67.5˚N; 168.5–169.0˚W; DBO4: 71.4–71.8˚N; 161.4–161.9˚W).

Mooring

Sequential sediment traps (24 cups, Hydro-Bios, Germany) were deployed at the DBO2 (N4) and DBO3 (N6) sites from June 2017 to July 2019 and at the DBO4 (Chukchi Ecosystem Observatory; CEO) site from August 2018 to July 2019 (Fig 1 and Table 1). No national or

international permitting was required as part of the sample collection efforts, and the field studies did not involve endangered or protected species. At CEO, year-round measurements capture physical and biogeochemical parameters in addition to measures of fish, zooplankton, marine mammals, and other ecosystem components [e.g. 22–24]. Moorings were deployed and recovered from the R/V *Sikuliaq* in June 2017 and June 2018 and recovered from the R/V *Ocean Starr* in July 2019. Sediment trap sample cups were filled with filtered seawater adjusted to a salinity of 38 with NaCl and fixed with formalin (4% final solution) to preserve samples during deployment and after recovery. The carousel holding the sample cups rotated at pre-programmed intervals ranging from one week to one month. As the mooring was recovered before the last rotation of the carousel at DBO2 in June 2018, the sample cup that was open upon recovery was excluded from analysis. Seabird SBE 16plus units were deployed to measure water temperature at three depths at DBO2 and DBO3 and at one depth at DBO4. The unit deployed at the upper depth on each mooring was coupled with a WETStar fluorometer or WET Labs ECO triplet fluorometer to measure fluorescence (Table 1).

Laboratory

In the laboratory, zooplankton and meroplankton were removed from subsamples with forceps and identified to the lowest taxonomic level possible using a dissecting microscope. Sample cups were gently mixed before subsamples (0.1–3 ml) were taken with a modified micropipette to enable the collection of large particles for measurements of chl *a*, algal cells, fecal pellets, TPM, and POC. Subsamples for chl *a* measurements were filtered onto GF/F filters (0.7 μm), extracted in acetone for 24 h at -20˚C and measured on a Turner Design fluorometer following the methods outlined in Welschmeyer [25]. Samples were kept cool and in the dark prior to chl *a* measurements, but may have experienced some degradation. For the enumeration of algal cells, subsample volumes were adjusted to 3 ml with filtered seawater before being placed in an Utermo¨hl chamber. A minimum of 300 algal cells were counted and identified by inverted microscopy at 100X, 200X or 400X depending on cell size according to the Utermöhl method [26]. Using a dissecting scope, the length and width of fecal pellets (broken or intact) were measured with an ocular micrometer and fecal pellet volumes were calculated according to their shape. Cylindrical pellets were attributed to calanoid copepods while ellipsoidal pellets were attributed to appendicularians [27]. Fecal pellet volumes were converted to fecal pellet carbon (FPC) using a volumetric carbon conversion factor of 0.057 mg C mm^{-3} for copepod pellets and 0.042 mg C mm^{-3} for appendicularian pellets [27]. Subsamples for TPM measurements were filtered in triplicate onto pre-combusted (500˚C overnight) and pre-weighed GF/F filters (0.7 μm), rinsed with distilled water to remove salt, dried at 60˚C overnight, and weighed on a microbalance. The filters were then exposed to 1N HCl overnight for removal of inorganic carbon and dried once again at 60˚C overnight before encapsulation for POC measurements. POC was measured using a PerkinElmer CHNS 2400 Series II

Table 1. Mooring and sediment trap deployment information.

Site	Mooring name	Latitude (N)	Longitude (W)	Sampling start date	Sampling end date	Water depth (m)	Sediment trap depth (m)	Fluorometer depth (m)	CTD depth (m)
DBO4	CEO	71˚35	161˚31	August 7 2018	July 30 2019	46	39	33	33
DBO3	N6	67˚40	168˚44	June 17 2017	June 8 2018	50	35	26	26, 35, 45
				June 16 2018	July 13 2019	50	35	25	26, 46
DBO2	N4	64˚55	169˚55	June 26 2017	June 8 2018	49	37	27	27, 35, 44

elemental analyzer. All measurements were converted to daily fluxes depending on sampling duration and integrated to annual fluxes.

Results

Sea ice concentrations

While sea ice was first detected in December 2017 at DBO2 and DBO3, a lasting sea ice cover only formed in January 2018 and sea ice concentrations temporarily decreased in February 2018 at both sites (Fig 2). At DBO2, sea ice concentrations decreased again in early April before complete sea ice melt was observed at the end of April 2018. Sea ice melt was observed one month later at the end of May 2018 at DBO3. Sea ice formed again in early December 2018 at DBO2 and DBO3, two to three weeks earlier than when sea ice formed during 2017. Sea ice concentrations frequently decreased throughout winter 2018–2019, especially at DBO2. At DBO4, sea ice formed in November 2018, two to three weeks earlier than at the other sites, and sea ice concentrations remained >65% throughout winter. Sea ice breakup was observed in early May 2019 at DBO2, a few days later at DBO3, and mid-May at DBO4. While sea ice melted approximately three weeks later in 2019 than in 2018 at DBO2, it disappeared approximately two weeks earlier in 2019 than in 2018 at DBO3.

Water temperatures

Mooring-derived water temperatures were above 2˚C from June to November at all depths sampled at DBO2 and DBO3 (Fig 3). Water temperatures frequently peaked between 6˚C and

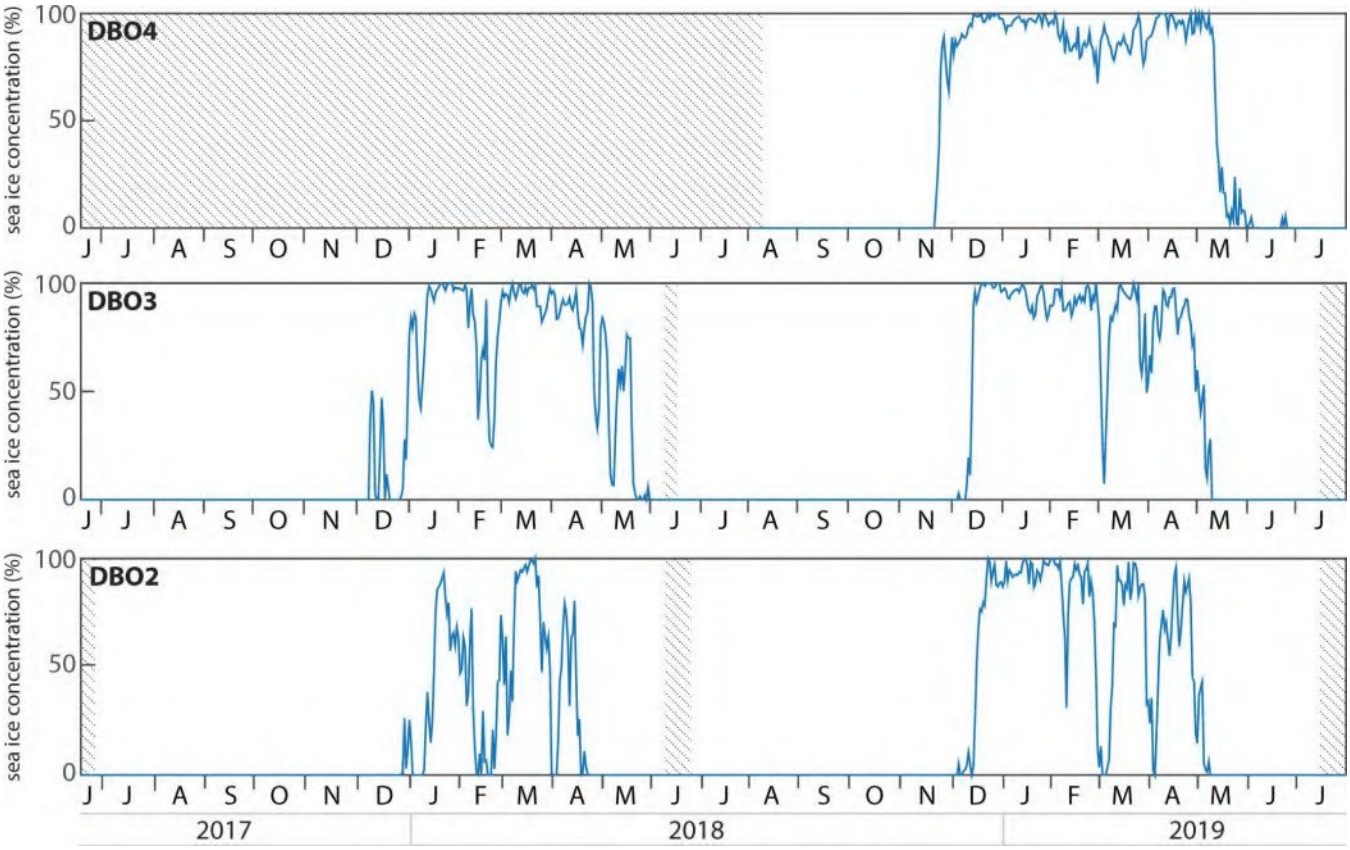

Fig 2. Daily sea ice concentration retrieved for a delimited region above each mooring site. Shaded areas represent periods without data.

https://doi.org/10.1371/journal.pone.0255837.g002

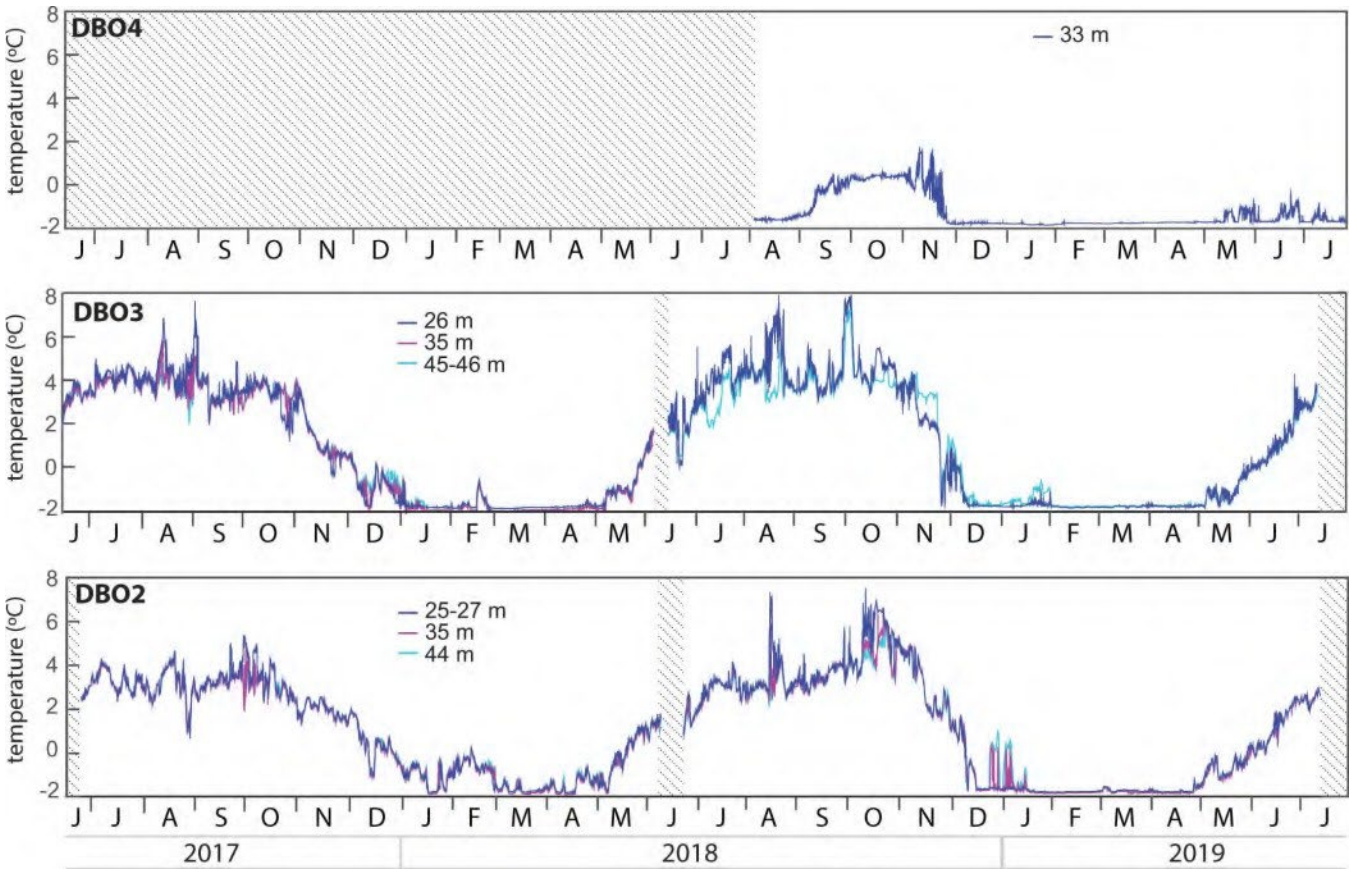

Fig 3. Water temperatures at each mooring site. There are no available data at 35 m for the 2018–2019 cycle at DBO3. Shaded areas represent periods without data.

https://doi.org/10.1371/journal.pone.0255837.g003

8˚C at both sites during late summer and autumn, except at DBO2 in 2017 where they remained below 6˚C. At DBO2, water temperatures slowly decreased to near-freezing point (-1.8˚C) only during very short periods of January, March and April 2018, while in 2019, they decreased more rapidly and remained near the freezing point from January until the end of April. At DBO3, water temperatures were almost continuously near the freezing point from January to early May 2018 and from December 2018 to early May 2019. At DBO4, water temperatures exceeded 0˚C but remained below 2˚C from September to November 2018 and were near the freezing point from the end of November 2018 to May 2019.

Chlorophyll a concentrations and fluxes

While enhanced chl *a* fluxes often coincided with increased suspended chl *a* concentrations recorded by the fluorometer 6 to 10 m above the traps, there were also notable differences between the two measurements (Fig 4). Peak chl *a* fluxes were observed at the end of May and/or early June for every deployment cycle, reaching values >10 mg m^{-2} d^{-1} at DBO2 and DBO3. During 2017, short periods of enhanced chl *a* fluxes were observed in August at DBO2 and during June and July at DBO3. Although there was a period without sampling due to the timing of the mooring turnaround in 2018, elevated chl *a* fluxes (>5 mg m^{-2} d^{-1}) were sustained during approximately five weeks in 2018 and 2019 at DBO2, and during two weeks in 2018 and nine weeks in 2019 at DBO3. At DBO4, relatively low chl *a* fluxes peaked in early June

https://doi.org/10.1371/journal.pone.0255837.g004

2019 (4.3 mg m^{-2} d^{-1}) and remained above >1 mg m^{-2} d^{-1} until the end of the deployment in late July 2019.

Diatom fluxes

Temporal variations in fluxes of diatom cells with chloroplasts were remarkably similar to chl *a* fluxes, with peak diatom fluxes observed at the end of May and/or early June for every deployment cycle (Fig 5). Whereas diatom fluxes were higher at DBO3 than DBO2 during summer 2017, the composition of the fluxes was similar at both sites, with the centric diatoms *Chaetoceros* spp. and *Thalassiosira* spp. and the pennate diatoms *Pseudo-nitzschia*/*Nitzschia* spp. contributing a large proportion of the fluxes. Low fluxes of the pennate diatom *Thalassionema nitzschioides* and the centric diatoms *Leptocylindrus* spp. and *Proboscia* spp. were also frequently observed during summer and autumn 2017. At DBO2, enhanced diatom fluxes with large proportions of the pennate diatoms *Fragilariopsis* spp. and *Neodenticula seminae* in early May 2018 were followed by extremely large fluxes nearly exclusively composed of *Chaetoceros* spp. and *Thalassiosira* spp. during late May and early June 2018. At DBO3, enhanced fluxes during May 2018 were first composed of the pennate diatoms *Pauliella taeniata* and *Fossula arctica* before *Fragilariopsis* spp. and *Thalassiosira* spp. dominated the peak in diatom export in early June 2018. Diatom fluxes at both DBO2 and DBO3 were much lower after mooring turnaround during June 2018, gradually shifting to diatom fluxes dominated by *Thalassiosira* spp. during summer 2018. At DBO4, low diatom fluxes during summer 2018 were mostly composed of *Fragilariopsis* spp., *Pseudo-nitzschia*/*Nitzschia* spp., *Cylindrotheca*

closterium, and *Chaetoceros* spp. Diatom fluxes increased again during May 2019 at DBO2 and DBO3 and in early June 2019 at DBO4. The magnitude and composition of the fluxes during spring 2019 was very similar at the three DBO sites, with *Fragilariopsis* spp., *Thalassiosira* spp., *Fossula arctica*, *Navicula* spp., *Pseudo-nitzschia*/*Nitzschia* spp., and *Chaetoceros* spp. contributing to the elevated fluxes.

Zooplankton and meroplankton

Copepods, copepod nauplii, and meroplankton were the most numerous animals collected in the sediment traps, with the highest abundances observed during June or July at DBO2 and DBO3 and during late September at DBO4 (Figs 6–8). As morphological separation of all life stages of several dominant copepod species in the Pacific Arctic is difficult, most species were aggregated and reported at the generic level (e.g. *Calanus glacialis*, *C. marshallae*; *Neocalanus plumchrus*, *N. flemingeri*; *Pseudocalanus minutus*, *P. acuspes*, *P. mimus*, and *P. newmani*), with the exception of *N. cristatus* that is recognizable due to its large size compared to its congeners [28]. A distinct dominance of the Pacific copepods *Neocalanus* was observed at DBO2 and DBO3 from June to August 2017 (Fig 6). The composition of the copepod community shifted to a dominance of *Pseudocalanus* at all sites during spring and/or summer 2018, with varying abundances of *Metridia*, *Calanus*, and *Oncaea* among sites.

Whereas few nauplii of the genera *Calanus*, *Metridia*, and *Pseudocalanus* were collected during summer 2017, large numbers of them were collected during summer 2018 and 2019, especially at DBO3 (Fig 7). At DBO2 and DBO3, nauplii of all stages were often collected simultaneously from May to October, with a larger proportion of nauplii stages N1 and N2

collected during April and May and peaks in nauplii abundance recorded in June. At DBO4, a large proportion of stages N5 and N6 was recorded during August and September 2018. Nauplii of all stages were again collected during June 2019 and peaked in abundance at the end of July 2019.

Meroplanktonic stages were dominated by polychaete larvae during summer 2017 at DBO2 and DBO3, while high abundances of bivalve veliger, polychaete larvae, and barnacle larvae blended from spring to autumn 2018 and during spring and early summer 2019 (Fig 8). At DBO4, barnacle larvae contributed to the vast majority of meroplankton collected from August to November 2018, but were absent during June and July 2019 when few bivalve veliger and polychaete larvae were collected.

Particulate organic carbon and total particulate matter fluxes

POC and TPM fluxes displayed similar temporal variations at DBO2 and DBO3 (Fig 9). At DBO2, POC and TPM fluxes increased simultaneously except during spring when TPM fluxes remained relatively low. At DBO3, the highest POC fluxes of the Pacific Arctic region (>2 g m^{-2} d^{-1}) were observed in early June 2018 and from May to July 2019, except for a week at the end of May 2019. At DBO4, peak POC (~1 g m^{-2} d^{-1}) and TPM fluxes (>50 g m^{-2} d^{-1}) were recorded during the second half of May 2019. High POC and TPM fluxes were also observed during autumn and winter at all sites, often in November and/or December. FPC fluxes contributed most to POC fluxes between June and November at all sites, and sporadically contributed to the complete POC flux between August and October 2017 at DBO3 (Fig 9).

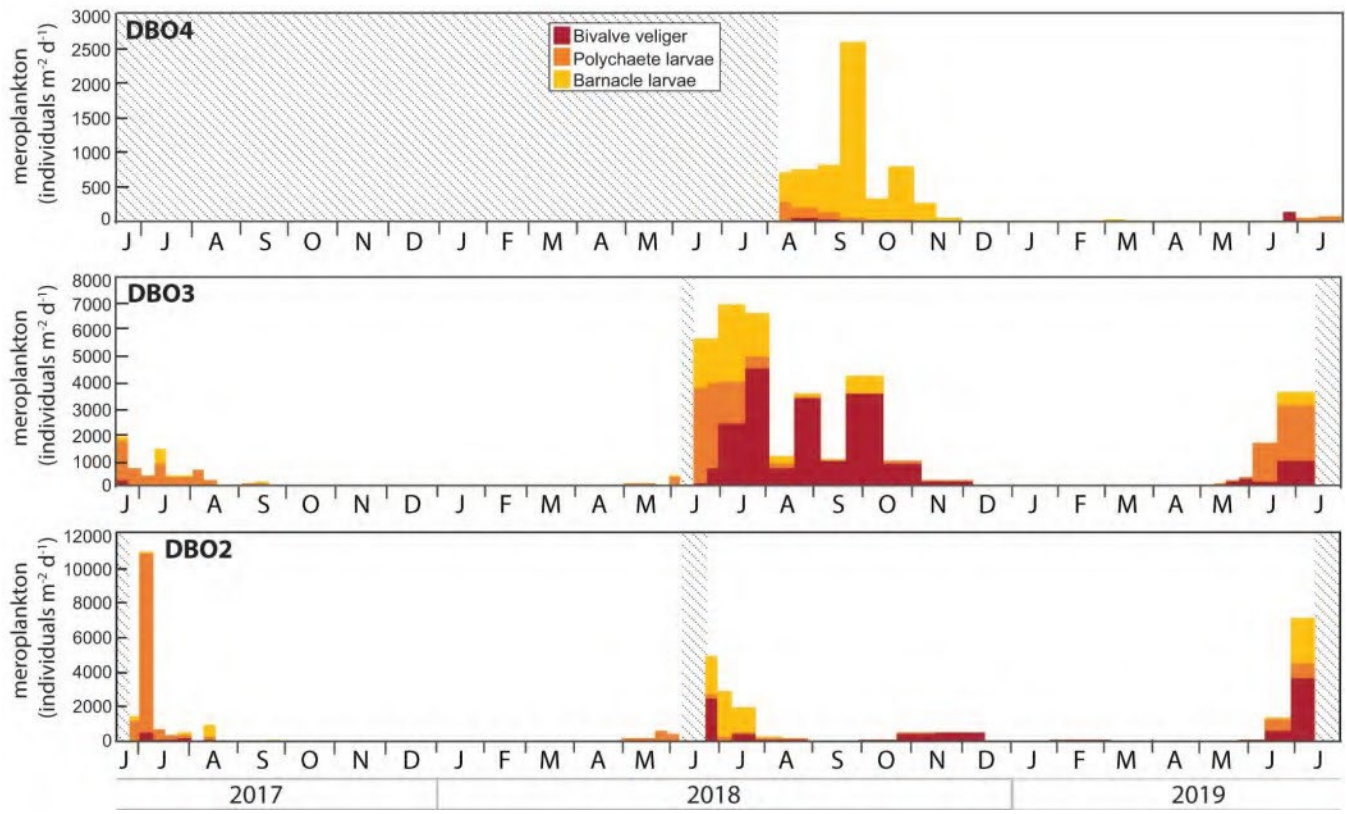

Fig 8. Meroplankton larvae collected in the sediment trap at each mooring site. Note the different scales. Shaded areas represent periods without data.

https://doi.org/10.1371/journal.pone.0255837.g008

Annual fluxes

Annual fluxes of TPM, POC, FPC, chl *a*, and diatoms all increased during the 2018–2019 cycle at DBO2 (Fig 10). Annual fluxes were also higher during the 2018–2019 cycle than during the 2017–2018 cycle at DBO3, except for a lower annual FPC flux. At DBO4, annual TPM, POC, and FPC fluxes obtained from August 2018 to July 2019 were higher than previously measured under extended sea ice cover at the same site from August 2015 to July 2016 [21], while annual chl *a* and diatom fluxes were lower during 2018–2019 than during 2015–2016 [21].

Discussion

A combination of downward export, lateral advection, and resuspension of particles contributed to the fluxes recorded at the three mooring sites of the shallow Pacific Arctic region. As typically observed on Arctic shelves [29, 30], TPM and POC fluxes were strongly correlated ($R^2 = 0.82$, $p<0.01$) at the DBO sites, with POC fluxes consistently contributing to <7% of the TPM fluxes. Whereas enhanced fluxes in April or May most likely resulted from the release of particulate matter from the melting ice [21], algal export contributed to the elevated POC fluxes during May and June. Diatoms usually dominate phytoplankton abundance and biomass in the northern Bering Sea and Chukchi Sea [31–34] and typically represent the most important component of algal fluxes across the Arctic Ocean due to their rapid sinking velocities [21, 30, 35, 36]. Diatoms also dominated algal export during spring at the three DBO sites, contributing to daily POC fluxes that were among the highest ever documented in the global oceans [19].

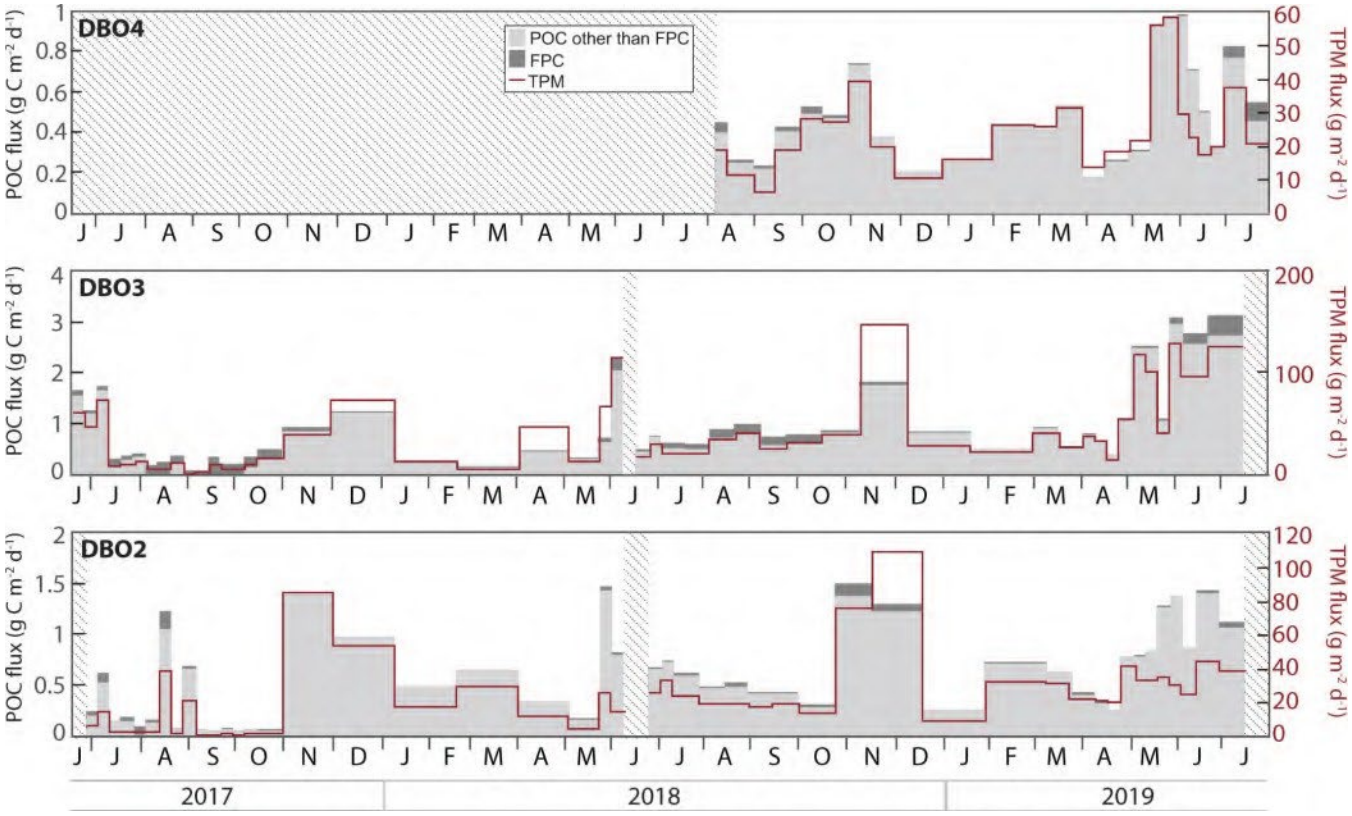

Fig 9. Particulate organic carbon (POC), fecal pellet carbon (FPC), and total particulate matter (TPM) fluxes at each mooring site. Note the different scales. Shaded areas represent periods without data.

https://doi.org/10.1371/journal.pone.0255837.g009

Zooplankton continuously collected at fixed depths indicated a strikingly similar composition of the dominant copepods at the three DBO sites, consistent with the large influence of advection on seasonal zooplankton dynamics in the Pacific Arctic [37, 38]. Copepod grazing certainly reduced diatom fluxes during summer, as supported by enhanced FPC fluxes. Similar to copepod and copepod nauplii abundances, benthic larvae abundance generally increased after the onset of the algal bloom, with large numbers of bivalve veliger, polychaete larvae, and barnacle larvae contributing to the grazing pressure on diatoms during summer and autumn. The lasting presence of planktonic larvae of benthic animals indicated productive conditions conducive to reproduction during several weeks at all sites. While copepod fecal pellets enhanced POC fluxes during summer and autumn, elevated TPM and POC fluxes during autumn and winter likely resulted from wind-induced resuspension and dispersion of sediments, as current speeds reached velocities >40 cm s^{-1} during autumn 2017 at DBO2 and DBO3 [19]. Short-lived increases in chl *a* concentrations, chl *a* fluxes, and diatom fluxes sporadically observed during late summer and autumn further support wind-induced resuspension and dispersion of sediments containing diatoms and chl *a* at the DBO sites. These observations are in agreement with enhanced near-bottom chl *a* concentrations observed during wind-induced high turbidity events during autumn near Bering Strait [39, 40], and with low fluxes of the sympagic diatom biomarker IP_{25} and of diatoms containing chloroplasts throughout the polar night on the northeast Chukchi shelf [21, 41]. In addition to reflecting the seasonal processes influencing the export of particulate matter in the region, the nearly continuous measurements obtained at a high temporal resolution from June 2017 to July 2019

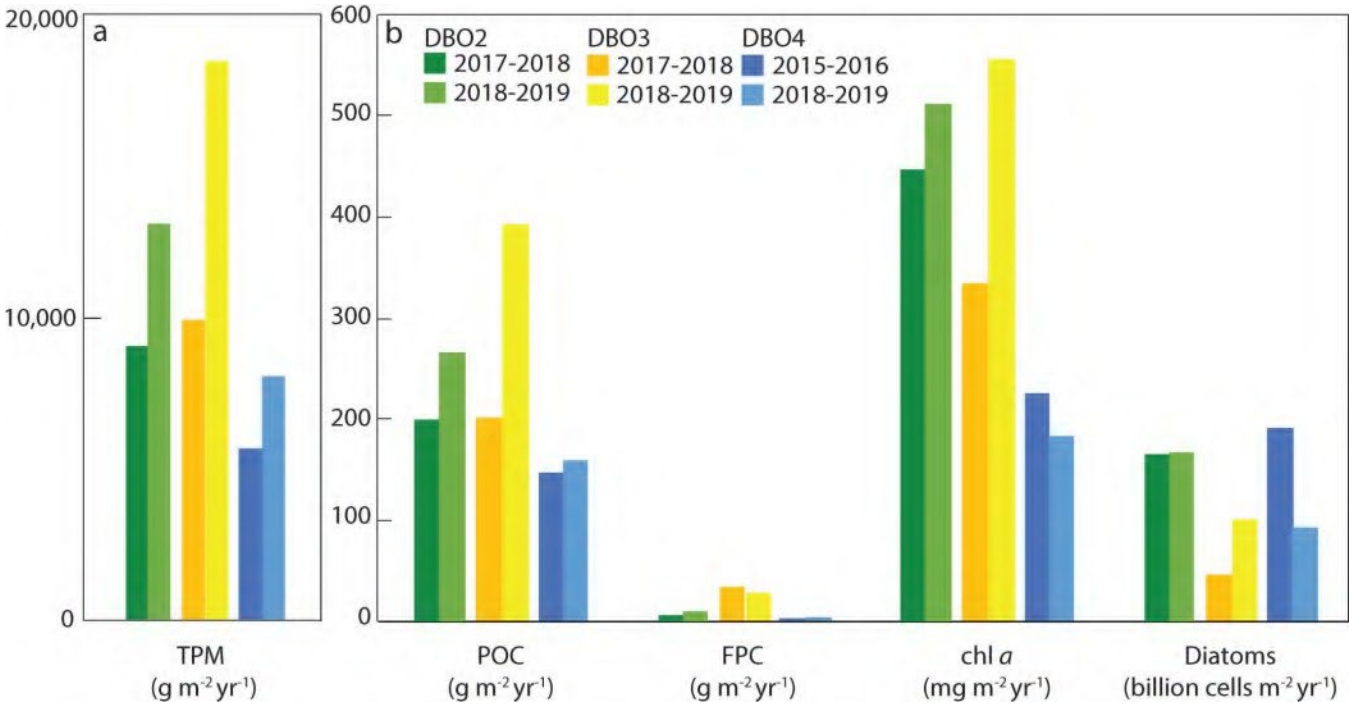

Fig 10. a) Annual total particulate matter (TPM) fluxes, and b) annual particulate organic carbon (POC), fecal pellet carbon (FPC), chlorophyll *a* (chl *a*), and living diatom fluxes at the three mooring sites in the Pacific Arctic region.

were used to assess the impact of the enhanced transport of warmer Pacific waters and shorter ice-covered duration on the Pacific Arctic marine ecosystem.

June 2017—June 2018

An earlier onset of warming and later onset of cooling in recent years lengthened the warm (±0˚C) water duration to more than 6 months in the Pacific Arctic region [7]. In 2017, the warm period lasted over 7 months and mean June temperatures were 2˚C warmer than climatology when the sediment traps were deployed [7]. A spring bloom probably occurred prior to the onset of sampling at both sites, as indicated by elevated near-bottom chl *a* concentrations revealing the occurrence of a spring bloom during May 2017 at a nearby mooring site in the southern Chukchi Sea [17, 39]. However, relatively high diatom fluxes mostly composed of the exclusively pelagic diatoms *Chaetoceros* spp. and *Thalassiosira* spp. indicated that a pelagic bloom occurred in the DBO3 region during late June and July 2017. The subsequent frequent collection of the boreal diatoms *Proboscia* spp., cosmopolitan diatom *T*. *nitzschioides*, and endemic North Pacific diatom *Neodenticula seminae* [31, 33, 42, 43] during summer and autumn reflected the enhanced inflow of warm Pacific waters across Bering Strait during 2017.

Although zooplankton community composition and distribution have been shown to vary with water properties and the volume of Pacific water transported to the northern Bering Sea and Chukchi Sea [38, 44–47], the most abundant groups are generally found throughout the region and differences between communities often depend on the presence or absence of indicator species [4]. Accordingly, peaks in copepod abundance dominated by the Pacific copepods *Neocalanus* during late June and early July 2017 highlighted an enhanced transport of warm Pacific waters, in agreement with concurrent observations of high abundance of Pacific copepods associated to the inflow of Anadyr Water during June and July 2017 in the northern

Bering Sea [44]. The very low numbers of nauplii collected during 2017 reflected the low abundance of the three copepod groups for which nauplii were identified in the trap samples. In particular, the absence of *Calanus* copepodites and nauplii indicated their decline under warm conditions, as supported by the report of a remarkably low abundance of *Calanus* in the Pacific Arctic during 2017 [1]. The nearly exclusive presence of polychaete larvae during 2017 also suggested their transport with the enhanced inflow of Pacific waters.

Residual heat from the elevated summer water temperatures delayed sea ice formation to December 2017 at both sites [6]. At DBO2, this delay reduced the rejection of salty, cold, and dense brine that typically sinks to the bottom to form a cold water layer, thereby limiting the cooling of the water column during winter and contributing to significant heat input into the Arctic Ocean [13]. At DBO3, oceanic heat loss was sufficient to reduce water column temperature at the freezing point during winter. As oceanic heat flux through Bering Strait triggers the onset of ice melt in the shallow Pacific Arctic region [7], the enhanced heat input during winter presumably contributed to the early ice breakup observed at DBO2 during spring 2018. High chl *a* and diatom fluxes dominated by the exclusively pelagic diatoms *Chaetoceros* spp. and *Thalassiosira* spp. in late May clearly indicated the occurrence of a large open water bloom following the early sea ice breakup in the northern Bering Sea. While biofouling may explain the concurrent low chl *a* concentrations recorded at DBO2 at the end of May, high chl *a* and diatom fluxes at that time were in agreement with the peak near-bottom chl *a* concentrations recorded at a nearby mooring on May 20 2018 [17]. The early collection of low numbers of the ice-associated pennate diatoms *Fragilariopsis* spp., *F. arctica*, and *Navicula* spp. during the sea ice breakup period (sea ice concentration <50%) hinted at a limited ice algae production while ice still drifted in the region in April, inhibiting the seeding of the spring bloom [48] and likely contributing to the shift in the composition of the diatom fluxes. Peak diatom fluxes at the end of May 2018 occurred approximately seven weeks after sea ice breakup at DBO2, likely due to weaker stratification following the extremely low winter sea ice extent and concentration, as observed during July 2018 in the northern Bering Sea [18]. Hence, the early sea ice breakup inhibited the ice-edge bloom and resulted in a large open water bloom in the northern Bering Sea, similar to previous observations following early sea ice breakup in the southeastern Bering Sea [17, 49, 50]. At DBO3, the coincident sea ice breakup and export of ice-associated pennate diatoms in early May was followed approximately three weeks later by a peak in chl *a* and diatom fluxes composed of ice-associated and pelagic diatoms during early June, indicating that colder water temperatures, later sea ice melt, and stronger stratification led to an ice-edge bloom in the southern Chukchi Sea in contrast to the northern Bering Sea. The highest near-bottom chl *a* concentrations recorded in late May and early June 2018 at a nearby mooring in the DBO3 region [17] confirmed that most of the bloom occurred before mooring turnaround in 2018. In response to the enhanced diatom fluxes, the abundances of copepods, copepod nauplii, and polychaete larvae increased at both sites during May 2018.

June 2018—June 2019

Low chl *a* and diatom fluxes mostly composed of *Chaetoceros* spp. and *Thalassiosira* spp. when sampling was resumed during June 2018 at DBO2 and DBO3 indicated a declining pelagic bloom at both sites. From July to September, the centric diatoms *Thalassiosira* spp. dominated the low diatom fluxes, a sharp contrast with fluxes composed of pennate diatoms *Pseudo-nitzschia*/*Nitzschia* spp., *C. closterium*, *Fragilariopsis* spp., *F. arctica*, and centric diatoms *Chaetoceros* spp. collected during the previous summer. This shift in flux composition concurs with a lower abundance of *Chaetoceros* spp. observed during July 2018 than during July 2017 in the Bering Strait region [49]. The large proportion of *Thalassiosira* spp. in the low diatom fluxes

during July 2018 possibly reflected a rapid depletion of nutrients during the large open water bloom taking place in the northern Bering Sea weeks earlier.

Peaks in copepod abundance during late June at DBO2 and early July at DBO3 probably contributed to the low diatom fluxes observed in early summer through grazing pressure. Most of the copepods collected during June and July 2018 consisted of *Pseudocalanus* while the abundance of *Neocalanus* and *Calanus* remained relatively low at both sites. As *Pseudocalanus* copepods are approximately three times smaller than *Neocalanus* and *Calanus*, their dominance supports observations of a zooplankton community dominated by small copepods during 2018 [15]. While small copepods *Pseudocalanus*, *Acartia*, and *Oithona similis* often dominate copepod abundance, large *Calanus* copepods often dominate biomass in late summer in the southern Chukchi Sea [38]. As *C. glacialis* females exploit ice algae to fuel their maturation and egg production [51, 52], the abundance and biomass of *C. glacialis* usually increase under colder conditions in the Bering and Chukchi Seas [53, 54]. The dominance of small copepods in 2018 therefore resulted from a low abundance of *C. glacialis* under warmer conditions. The presence of the Pacific copepods *Neocalanus*, *Eucalanus bungii* and *Metridia pacifica* [32, 44–46] from June to October 2018 further illustrated the influence of warm Pacific waters.

At DBO4, low diatom fluxes composed of *Fragilariopsis* spp., *C. closterium*, *Pseudo-nitzschia/Nitzschia* spp., *Navicula* spp., *Thalassiosira* spp., and *Chaetoceros* spp. at the onset of sampling in August 2018 corresponded to the ice-associated and pelagic diatom groups reported to dominate phytoplankton biomass during summer in the northern Chukchi Sea [33, 55–59], albeit with variations in the relative contribution of each group. Despite the absence of measurements prior to August 2018, the distinct composition of diatoms commonly observed during summer near Hanna Shoal suggests that local algal production was not affected by the anomalous 2018 conditions observed south of Bering Strait. Previous diatom flux measurements at the DBO4 site showed very large fluxes of *C. closterium* from August to October 2015 during a period of strong winds with frequent direction reversals [21]. Similarly, a strong wind event in September 2013 at a nearby site in the Chukchi Sea induced sufficient vertical mixing to enhance phytoplankton productivity and led to high abundances of *C. closterium* and *Leptocylindrus danicus* [60, 61]. However, although high water temperatures recorded at depth during November 2018 indicated storm conditions mixing the water column at DBO4, *C. closterium* fluxes remained low during autumn 2018 when sunlight was sufficient to induce primary production in the region. Peaks in copepod abundance recorded during late August and late September 2018 at DBO4 were dominated by small *Pseudocalanus*, similar to DBO2 and DBO3. The dominance of small copepods in the northern Chukchi Sea also resulted from a low abundance of *C. glacialis* under warmer conditions, as confirmed by *Calanus* that were ~5 times more abundant at DBO4 during August 2015 than during August 2018 while the abundance of *Pseudocalanus* was similar during both years [21]. The collection of Pacific copepods *E. bungii* and *M. pacifica* during August and September further illustrated the transport of warm Pacific waters into the Chukchi Sea. Most meroplankton collected during summer and autumn 2018 consisted of barnacle larvae, in agreement with observations of barnacle larvae contributing to the largest meroplankton biomass from 2008 to 2010 in the northeastern Chukchi Sea [62].

Despite higher water temperatures during summer and autumn 2018, coinciding with record high surface seawater temperatures in the Pacific Arctic [20], water temperatures rapidly decreased and sea ice quickly formed in November at DBO4 and in early December at DBO2 and DBO3, leading to the prolonged presence of cold water at all sites during winter 2018–2019 and to a later sea ice breakup at DBO2 in 2019. Cells of the ice-associated diatoms *Fragilariopsis* spp. were first collected simultaneously to sea ice breakup at the end of April at DBO2 and DBO3 and during mid-May at DBO4, indicative of the latitudinal delay in sea ice

breakup. Peak diatom fluxes were consistently observed approximately three weeks after sea ice breakup, resulting in a 2-week delay between the diatom bloom in the northern Bering Sea (DBO2) and in the northern Chukchi Sea (DBO4). Regardless of the delay in the onset of the bloom, the composition of the diatom fluxes was strikingly similar at the three sites during 2019, with *Fragilariopsis* spp., *F. arctica*, *Navicula* spp., *Pseudo-nitzschia/Nitzschia* spp., *Thalassiosira* spp., and *Chaetoceros* spp. composing most of the fluxes. These observations indicate that algal production was likely back to normal in the northern Bering Sea.

Whereas Pacific copepods were not collected in 2019 despite the enhanced transport of Pacific waters observed until September 2019 across Bering Strait [7], the sustained inflow of warmer waters resulted in the near absence of *Calanus* at DBO2 and DBO3 during June and July 2019. While the majority of *Calanus* copepods present in the Chukchi Sea are believed to originate from the Bering Sea [38], their increasing abundance at DBO4 in July 2019 suggested an alternate source of *Calanus* on the northern Chukchi shelf during summer 2019 [63]. No clear peaks in copepod abundance were observed during June or July 2019, consistent with high seasonal and interannual variability in the Pacific Arctic region [62]. By contrast, peaks in nauplii abundance recorded during June 2018 and 2019 at DBO2 and DBO3 revealed a steady timing in copepod reproduction despite variations in the timing of sea ice breakup. Finally, the concurring absence of diatoms and copepods of Pacific origin at the DBO sites during 2019 suggested that less productive conditions further south may have limited their advection into the region that year.

Less ice led to generally lower annual export fluxes

A comparison of annual fluxes obtained for each deployment cycle highlights the large-scale impact of an early sea ice breakup on export in the Pacific Arctic region. In the northern Bering Sea, lower annual TPM, POC, chl *a*, and diatom fluxes during the June 2017-June 2018 cycle than during the June 2018-July 2019 cycle, despite the export of a large pelagic bloom at the end of May and early June 2018, indicated that elevated fluxes were sustained over a longer period when ice breakup occurred a few weeks later during 2019. It is reasonable to assume that annual fluxes would have been higher for the 2017–2018 cycle without the interruption in sampling during June 2018. However, it is unlikely that these annual fluxes would have been higher than during 2018–2019 as decreasing near-bottom chl *a* concentrations recorded at a close-by mooring indicated a declining bloom during June 2018 [17]. Lower annual chl *a* fluxes during 2017–2018 may have also partly arisen from the dominance of the generally small-sized *Chaetoceros* cells with lower chl *a* content during the 2018 spring bloom. The large abundance of copepodites and nauplii during summer 2018, together with the larger annual FPC flux during 2018–2019, suggest that the massive pelagic bloom enhanced secondary production and grazing pressure in the northern Bering Sea, supporting the hypothesis of a transition to a pelagic-dominated ecosystem under warmer conditions [64]. The dominance of small-sized diatoms and copepods under higher water temperatures and reduced ice cover in the northern Bering Sea concurs with observations in the Atlantic Arctic sector where a shift in the composition of the phytoplankton and zooplankton communities was observed during a period of anomalously warm Atlantic Water inflow and absence of sea ice cover in the eastern Fram Strait [65]. These observations therefore suggest a similar impact of warmer conditions on the Arctic marine ecosystems influenced by the inflow of Pacific and Atlantic waters. Lastly, lower annual TPM and POC fluxes during 2017–2018 along with similar autumn and winter peaks in daily TPM and POC fluxes during both cycles suggest that the intensity and frequency of resuspension events did not significantly increase during the period of unprecedented sea ice loss during 2017–2018 in the northern Bering Sea.

In the southern Chukchi Sea, annual fluxes were also lower during the 2017–2018 cycle than during the 2018–2019 cycle, except for a slightly higher annual FPC flux. The lower chl *a* and diatom fluxes collected at DBO3 during 2017–2018, despite sea ice breakup actually occurring later during 2018 than during 2019, highlighted the influence of advected waters from the northern Bering Sea. Indeed, a shorter period of lower diatom fluxes at DBO3 during May 2018 possibly resulted from a reduced inflow of nutrients into the southern Chukchi Sea following the massive pelagic bloom that occurred during the prior weeks in the northern Bering Sea. Whereas higher annual FPC flux during 2017–2018 may be the result of larger fecal pellets produced by larger copepods during summer 2017, the highest copepod abundance during summer 2018 also contributed to relatively high FPC fluxes at DBO3 during the 2018–2019 cycle, further supporting a transition to a pelagic-dominated ecosystem under warmer conditions [64]. Although annual TPM and POC fluxes were approximately half as high during the 2017–2018 cycle as during 2018–2019, mostly due to the enhanced daily TPM and POC fluxes sustained during the bloom period from May to July 2019, the high springtime POC fluxes recorded during both years when compared with POC fluxes from around the world [19] indicate a persistently strong biological pump in the region due to the highly productive and shallow nature of the shelves.

By contrast to the DBO2 site where sea ice conditions were heavier during 2018–2019 than during 2017–2018, sea ice breakup at the DBO4 site took place more than two months earlier during 2019 than when the same site was previously sampled during 2016 [21]. Considering that the day of sea ice breakup on the Chukchi shelf ranged from mid-May to mid-August between 2010 and 2017 [66], sea ice breakup occurred relatively early during mid-May 2019 at DBO4. This early sea ice breakup led to lower annual chl *a* and intact diatom fluxes during 2018–2019 than under longer lasting sea ice cover during 2015–2016 [21]. While Waga and Hirawake [67] reported an increasing occurrence of fall blooms using satellite remote-sensing data from 2003 to 2017 for the Chukchi Sea, the absence of large diatom fluxes during autumn 2018 in contrast to autumn 2015 partly explains the lower annual chl *a* and diatom fluxes recorded during 2018–2019. However, the lower annual chl *a* and diatom fluxes observed near Hanna Shoal also resulted from the short-lived and smaller peak in diatom fluxes recorded after sea ice melt during spring 2019, while elevated diatom fluxes were sustained during several weeks in the presence of ice cover during spring and summer 2016 [21]. Therefore, a loss of sea ice resulted in a shorter period of enhanced springtime diatom fluxes during 2019 at DBO4, similar to observations during spring 2018 at DBO2 and DBO3. By contrast, annual TPM and POC fluxes were higher during 2018–2019 than during 2015–2016 at DBO4 [21], principally due to high daily TPM and POC fluxes following sea ice melt during spring and summer 2019. Elevated TPM and POC fluxes at a time of lower chl *a* and diatom fluxes during summer 2019 suggest that enhanced resuspension under reduced ice cover likely contributed to these fluxes.

Conclusions

Overall, earlier sea ice breakup resulted in shorter periods of elevated chl *a* and diatom fluxes following sea ice melt at the three DBO sites on the shallow Pacific Arctic shelves. While POC fluxes represent diverse sources of particles, such as material released from the ice, resuspension events, and lateral advection, chl *a* and intact diatom fluxes more reliably reflect the impact of reduced sea ice conditions on the biological pump. Chl *a* and diatom fluxes obtained during the two-year sediment trap time-series therefore suggest that the recent loss of sea ice and ensuing weaker stratification reduced the strength of the biological pump in the Pacific Arctic region. In addition, the sustained transport of warm Pacific waters [7] led to the low

abundance or absence of *Calanus* copepods at the three DBO sites during the study period. The abundance of smaller *Pseudocalanus* copepods instead either increased or decreased FPC fluxes and the efficiency of the biological pump at the DBO sites, highlighting the need for additional export flux measurements to determine long-term trends. As warming of the Arctic and sub-Arctic continues, major ecosystem changes are expected to occur more frequently in the Pacific Arctic region [14]. In this context, sediment trap time-series provided valuable, nearly uninterrupted measurements of biological parameters at a high temporal resolution to complement the other repeated observations made as part of the DBO. Routine sediment trap deployments would help determine if the changes observed under enhanced transport of warmer Pacific waters and shorter ice-covered duration represent an anomalous period or a new normal for the Pacific Arctic marine ecosystem.

Acknowledgments

We would like to thank the Captain and crews of the R/V *Sikuliaq* and R/V *Ocean Starr*. We also thank Thibaud Dezutter, Gabrielle Nadaï, Marie Parenteau, Jade Paradis-Hautcoeur and Julien Claveau for their respective contribution to analyses. This is a contribution to the Arctic Shelf Growth, Advection, Respiration, and Deposition rates measurement (ASGARD) and the Chukchi Ecosystem Observatory (CEO) projects. This manuscript is NPRB Publication ArcticIERP-42.

Abstract

In a rapidly changing Arctic, benthic functional traits remain understudied, and baseline metrics of benthic ecosystem function are lacking. Polychaetes are often numerically dominant within the macrofauna and serve essential roles in benthic ecosystem function, such as impacts of sediment oxygenation, organic matter burial, and remineralization within sediments. Macrofauna were collected from 12 stations in June 2017 and 11 stations in June 2018 from the northern Bering and southern Chukchi Sea continental shelves as part of the Arctic Shelf Growth, Advection, Respiration, and Deposition (ASGARD) project. Polychaetes were identified to family level and assigned a functional guild based on feeding mode, motility, and feeding structures. Four clusters of polychaete functional guilds were identified, and a conceptual model was developed to link habitat characteristics to ecosystem function. Sandy stations had a relatively high abundance of selective-feeding, tube-dwelling suspension and surface deposit feeders, reflecting the advective system with rapid current speeds and low deposition. The abundance of tube-dwellers likely results in increased oxygenation of the sediment. The second group of stations displayed characteristics that suggest impacts of fluctuations between high deposition of organic matter and disturbance from scouring. A third group of muddy, offshore Chukchi Sea stations contained large bivalves and large carnivorous polychaetes, promoting high bioturbation rates. The macrofauna at the coastal Chukchi Sea stations in the fourth group were concentrated in the surface layer, and with little bioturbation, anaerobic microbial remineralization of organic matter likely dominates. Overall, polychaete functional composition and vertical distribution reflected the quality and quantity of organic matter input and the depositional environment inferred from grain size, with subsequent impacts on biogeochemical and carbon cycling within the sediment.

Keywords: macrofauna, polychaetes, functional traits, ecosystem function, Pacific Arctic

[1] Charrier, B.R., and S.L. Mincks. Linking polychaete functional traits and benthic ecosystem function to habitat characteristics on a shallow Arctic shelf. *In preparation*.

Introduction

The benthos accounts for a substantial portion of total production in the Pacific Arctic (Walsh et al., 1989). Ecologically important hotspots of high benthic biomass (Grebmeier et al., 2015) serve as critical feeding grounds for marine mammals (Fay, 1982) and birds (Lovvorn et al., 2003). However, the Pacific Arctic is undergoing rapid environmental change (Huntington et al., 2020), with unprecedented environmental conditions in 2017 and 2018 (Baker et al., 2020; Grebmeier et al., 2018). Record low sea ice persistence coincided with low concentrations of ice algae biomarkers in the sediment and high concentrations of pelagic biomarkers (Koch et al., 2020). Emerging evidence also indicates that environmental change has influenced the distribution of macrofaunal biomass (Goethel et al., 2019; Moore et al., 2018) and caused shifts in community structure and composition (Grebmeier, 2012; Waga et al., 2020), likely impacting benthic organic matter consumption and carbon demand (Jones et al., 2021).

Given the rapid environmental change occurring in the Pacific Arctic, it is critical to characterize current benthic ecosystem function to monitor and assess future change. Ecosystem models can be used to predict the impacts of environmental change on ecosystem structure and function (e.g., Lovvorn et al., 2016; Whitehouse et al., 2014) and to inform adaptive ecosystem management and policy decisions. Well-constrained ecosystem models for this region should include quantitative descriptions of spatial patterns in macrofaunal abundance and biomass (Grebmeier et al., 2015) but also functional characteristics of the benthic community (Liu et al., 2019; Sutton et al., 2020). The vertical distribution of macrofauna within the sediment is also critical in understanding biogeochemical, nutrient, and carbon cycling within the benthos (Deng et al., 2020). However, the benthos is often oversimplified in ecosystem models due to a lack of available information, aggregated as the whole benthos or higher taxonomic levels that do not account for differences in functional roles among taxa within these major groups (Whitehouse et al., 2014). For instance, in a Bering Sea modeling study, polychaetes were categorized as deposit-feeders or carnivores (Lovvorn et al., 2016). Yet, the burrowing activities of surface and subsurface deposit feeders have different impacts on important ecosystem functions such as sediment stabilization, oxygenation, organic matter burial, and remineralization in sediments (Aller, 1982; Jumars and Nowell, 1984; Lopez and Levinton, 1987; Rhoads, 1974). Additionally, various types of deposit feeders consume different quality and freshness of organic material (Josefson et al., 2002). For example, tentacle feeders generally select high-quality particles, while non-selective deposit feeders feed on lower quality, diffuse food sources. Consequently, carbon cycling in an area dominated by selective surface feeders will be different from an area dominated by non-selective subsurface deposit feeders.

While taxonomic composition of benthic communities is of interest in understanding biogeographic patterns and drivers of community structure, functional trait analysis elucidates the roles of communities in ecosystem processes. Biological traits can describe ecosystem functions (Degen et al., 2018), such as the ability to avoid disturbance (Hinchey et al., 2006), bioturbation (Mermillod-Blondin et al., 2004), and organic matter and nutrient cycling (Norling et al., 2007). Additionally, taxonomic diversity does not necessarily equate to functional diversity (Snelgrove, 1998). While communities may differ in taxonomic composition, they can share common functional traits, which has been shown in other Arctic benthic communities (Rand et al., 2018; Sutton et al., 2020). Different species often perform similar functions, and the loss of one species can be compensated for by an increase in the abundance of other species that perform similar ecological roles (Bremner et al., 2006; Snelgrove, 1998).

Sediment substrate type, sediment transport, and water depth are critical structuring forces of macrobenthic functional traits in Arctic systems (Liu et al., 2019; Włodarska-Kowalczuk et al., 2012). While taxonomic and functional diversity may follow similar large-scale spatial patterns, functional analyses in the Arctic have revealed additional patterns in the partitioning of ecological niche space and improved understanding of how disturbance may cause ecosystem shifts (Kokarev et al., 2017; Liu et al., 2019; Sutton et al., 2020). Variation in community structure of macrofauna has also been directly linked to differences in ecosystem function in Arctic sediments (e.g., Link et al., 2013; McTigue et al., 2016). Studies have also shown low functional redundancy in some Arctic shelf systems, implying vulnerability to a changing climate (Kokarev et al., 2017; Liu et al., 2019).

Polychaetes are often numerically dominant in the macrofauna (Gontikaki et al., 2011; Gunton et al., 2015) and serve essential roles in the benthic ecosystem (reviewed by Hutchings, 1998). The feeding and bioturbation activities of polychaetes have critical effects on carbon and biogeochemical cycling, such as oxygenation of sediment, reworking of organic material, and alteration of habitat for other infaunal or microbial communities (Aller, 1994; Hutchings, 1998; Pinto and Austen, 2006). Functional trait databases of polychaete families have been established based on morphology and taxonomy (Jumars et al., 2015), making polychaetes an ideal taxonomic group for functional trait analyses. The overall objective of this study was to characterize spatial patterns in macrofaunal communities across the northern Bering and southern Chukchi Sea shelves, with an emphasis on polychaete functional traits. Based on the distribution of polychaete functional guilds, we identified four distinct assemblages in different locations. We present an overview of the major patterns in macrofaunal community structure among these areas and describe differences in functional composition of polychaete assemblages that may influence ecosystem processes. We also examine relationships between polychaete functional traits and environmental characteristics, which may be used to extrapolate functional information to broader areas with similar environmental conditions.

Methods

Study area and sampling

Macrofaunal samples were collected from the northern Bering and southern Chukchi Seas in June 2017 and 2018 from the *R/V Sikuliaq* as part of the Arctic Shelf Growth, Advection, Respiration, and Deposition (ASGARD) project (Table 1; Figure 1). Some sampling locations correspond to long-term monitoring stations in the Distributed Biological Observatory (DBO) regions 2 and 3, also known as the Chirikov and SECS hotspots, respectively (Grebmeier et al., 2015, 2010). The northern Bering and southern Chukchi Sea continental shelves are shallow, seasonally ice-covered, and highly productive. The shelves are characterized by the net northward movement of cold, nutrient-rich Anadyr-Bering Sea Water in the west and warm, more nutrient-poor Alaska Coastal Water in the east (Danielson et al., 2017). Currents accelerate as flow is constricted through Bering Strait (Danielson et al., 2014), promoting water column mixing that locally enhances pelagic primary productivity (Walsh et al., 1989). Downstream of this constriction, the water column fans out over the wide and shallow Chukchi shelf, resulting in the decline of the current speed and allowing suspended particulate material to settle to the seafloor (Grebmeier et al., 2015).

Intact sediment cores were retrieved from 12 stations in 2017 and 11 stations in 2018 using an MC-800 multi-corer with 10-cm diameter tubes (Ocean Instruments, San Diego). Nine stations were sampled in both years (Table 1). Sampling stations ranged from 32 to 59 m in water depth.

The average near-bottom water temperature was 2.02 ± 1.35 °C (ranging from -1.2 to 3.96 °C) in 2017 and 1.15 ± 0.88 °C (ranging from -0.6 to 2.4 °C) in 2018, measured from CTD deployments (Table 1). Given the interdisciplinary nature of the field sampling program, weather constraints, and limits on wire time, statistical replicates for macrofaunal community structure analysis were not collected at all stations. For most stations, at least two intact cores from different multi-core deployments (i.e., sampling replicates) were sectioned into 0-1 cm, 1-5 cm, and 5-10 cm depth intervals and sampled for macrofauna. At some stations, multiple cores were processed from the same deployment (i.e., sampling pseudo-replicates). These pseudo-replicates were averaged into a single mean value for that deployment before combining with other true sampling replicates to calculate a station average. Pseudo-replicates were included to better constrain sampling error, given that the area sampled by a single multi-core tube is relatively small (78.5 cm^2). In 2017, a single core was retrieved at stations CPL8 and DBO2.3. Additional sampling coverage was achieved by including cores used for other purposes, including grain-size analysis and shipboard oxygen-flux incubations. Due to the differences in depth strata sampled in these additional cores, broad-scale spatial patterns in community structure were analyzed using data summed across the upper 10 cm of sediment. We also present more detailed results on the depth distribution of infauna for cores with 0-1, 1-5, and 5-10 cm sections. All cores used for macrofaunal analyses were gently washed over 500-µm mesh using filtered seawater and preserved in 10% buffered formalin.

Macrofauna and polychaetes

Preserved macrofaunal samples were stained with Rose Bengal and transferred to 70% isopropanol for sorting. Macrofauna were generally identified to phylum, class, or order level, counted, and wet mass was determined to 0.1 mg. Polychaetes were identified to family. Higher-level taxonomy was sufficient to meet ASGARD objectives of quantifying total abundance and biomass and examining functional roles of dominant species, which can be assessed based on family-level taxonomy in polychaetes (Jumars et al., 2015).

Polychaete taxa were classified into functional guilds based on feeding mode (microphage, macrophage/carnivore, or omnivore), motility (motile or discretely motile), and feeding structures (tentacles or palps, non-muscular eversible pharynx, or muscular eversible pharynx), according to Jumars et al. (2015; Table 2). Microphage feeders were further classified as suspension-, surface deposit-, or subsurface deposit-feeders. Motility was further distinguished by tube-dwelling, burrowing, crawling, or swimming behaviors. Polychaetes are considered motile if they exhibit burrowing, crawling, or swimming behavior. Discretely motile polychaetes are individuals that actively construct burrows or are tube-dwelling and can rebuild, extend, or move their tubes. Polychaete families can display multiple traits within individual taxa, so only the most common trait or traits were selected (Table 2).

Environmental parameters

Individual multi-core tubes were taken from the same deployments as the macrofaunal cores and allocated for analyses of sediment environmental parameters. One core from each station was allocated for grain-size analysis. Sediment was collected by inserting a 60-cc plastic syringe (6-cm diameter) with the tip cut off into the core surface to a depth of 5 cm. Samples were frozen in Whirl-Pak bags at -20°C until analyzed. Grain size was determined through a combination of wet and dry sieving. Sediment was thawed and homogenized by kneading the bag. To break up sediment aggregates, 20 mL of 2 g L^{-1} sodium hexametaphosphate and 30 mL of reverse osmosis water were added to 30 to 40 g of sediment and stirred for three minutes. The sample was wet

sieved through stainless steel 2-mm and 63-µm sieves. The material retained on each sieve and the <63-µm fraction (silt/clay) was collected into separate glass beakers and dried at 90°C until a constant mass was achieved. The material retained on the 63-µm sieve was then dry sieved through a set of brass stacked sieves on a shaker for 10 min (#18, 35, 60, 120, and 230 mesh sizes). Material retained on each sieve was weighed. The silt/clay fraction was weighed, rehydrated with reverse osmosis water, and 30% hydrogen peroxide (H_2O_2) was added to the sample until effervescence ceased to remove the organics. The beaker was held at 70°C on a block heater for one hour to decompose the H_2O_2 and then stirred for three minutes. The material was dried at 90°C until a constant mass was achieved. Mean phi and sorting coefficient were calculated using the Grain Size Distribution and Statistics (GRADISTAT v.8.0) package (Blott, 2010; Blott and Pye, 2001).

Replicate cores from different multi-core deployments at each station were allocated for analyses of sediment organic matter. Intact sediment cores were sectioned in 0-1, 1-2, 2-3, 3-4, 4-5, 5-7, and 7-10 cm layers, and each layer was then subsampled for different analyses. For chloropigment analyses, samples were sealed in Whirl-Pak bags, wrapped in foil, and frozen at -80°C until analyzed. Samples were thawed, homogenized by kneading the bag, and 1 cc of sediment was subsampled using a syringe and placed in a glass extraction tube. Samples were then suspended in 5 mL of 100% acetone, vortexed, sonicated in an ice bath for 10 minutes, and left to extract in the dark overnight at -20°C. Samples were then centrifuged for five minutes at 3,000 rpm, and the supernatant was removed and transferred to a clean glass tube. Fluorescence of the supernatant was measured using a TD-700 fluorometer (Turner Designs, San Jose, CA, USA). The fluorescence of a blank of 100% acetone was measured and subtracted from the sample fluorescence. Samples were then acidified with 0.15 mL of 0.1 N HCl, briefly vortexed, and allowed to rest for at least 90 seconds. The fluorescence was then measured again to determine phaeopigment concentrations. Each sample was extracted a second time by adding another 5 mL of acetone to the same sediment and following the procedure described above. Afterward, the sediment was dried at 60° until a constant mass was achieved. A standard curve was produced using a chlorophyll-a standard (spinach extract C5753, Sigma-Aldrich) to convert fluorescence into concentrations (adapted from Arar and Collins, 1997). Chlorophyll-a (chl-a) and phaeopigment (phaeo) concentration (µg g^{-1} dry sediment) from both extractions were then summed for each sample, and sediment inventories of chl-a and phaeo (µg cm^{-2}) were calculated for the upper 10 cm of sediment using the volume-to-dry weight conversion derived from the 1-cc sample of sediment extracted. Chloroplastic pigment equivalents (CPE) were calculated as the sum of chl-a and phaeo inventories.

Additional subsamples from these same cores were analyzed for stable carbon isotope signature of surface sediments ($\delta^{13}C$), total organic carbon (TOC) and nitrogen (TN) for the upper 1 cm of sediment (mg cm^{-2}), and carbon to nitrogen ratios (C:N). A subsample of the top 0-1 cm of intact sediment cores were collected, sealed in Whirl-Pak bags, and frozen at -80°C until they were freeze-dried. Between 5 and 10 g of freeze-dried sediment was weighed into 50-mL centrifuge tubes. To remove carbonates, the samples were rinsed with 1 N HCl until effervescence ceased. Samples were rinsed with reverse osmosis water and then freeze-dried again. Between 15 and 50 mg were weighed into 7 mm aluminum boats and submitted to the Alaska Stable Isotope Facility at the University of Alaska Fairbanks Water & Environmental Research Center. Elemental and stable isotope analyses were conducted via continuous-flow isotope ratio mass spectrometry using a Thermo Scientific Flash 2000 elemental analyzer and Thermo Scientific Conflo IV interfaced with a Thermo Scientific DeltaV Plus Mass Spectrometer. Stable isotope ratios were

reported in δ notation as parts per thousand (‰) deviation from the international standard Vienna Pee Dee Belemnite (VPDB; carbon). Typically, instrument precision is <0.2 ‰.

Data analysis

Abundance and biomass were calculated as the number of individuals and total wet weight m^{-2} for spatial comparisons and m^{-3} for comparison among sediment depth layers. The average size of individuals was calculated by dividing total biomass by total abundance (g $indiv.^{-1}$).

Multivariate analyses of community structure were conducted in PRIMER v7 (Clarke and Gorley, 2015) with PERMANOVA+ add-on (Anderson and Gorley, 2008) for macrofauna higher taxonomic levels, polychaete families, and polychaete functional guilds. Echiurans and two unidentifiable polychaetes were excluded from the polychaete analysis so that the polychaete family dataset could be directly compared to the functional guild dataset. Bray-Curtis similarity matrices were calculated on 4^{th}-root transformed data and displayed on non-metric multi-dimensional scaling (nMDS) plots to visualize similarities and differences among samples. Samples with similar taxonomic or functional composition were identified using hierarchical agglomerative clustering with group-average linking. A similarity profile (SIMPROF) procedure was used to delineate statistically significant groupings.

Relationships between polychaete functional guild composition and environmental variables were examined using a distance-based linear model (DistLM) with a stepwise selection criterion based on adjusted R^2, followed by distance-based redundancy analysis (dbRDA). After examining histograms, sediment chl-a inventory, phaeo inventory, chl-a:phaeo, and CPE were log-transformed. All data were normalized. Variables were removed prior to the analysis due to multicollinearity determined by Draftsman plots and Pearson's correlation coefficients (>0.8), including mean phi, percent sand, chl-a inventory, phaeo inventory, and surface TOC.

Univariate descriptors of polychaete functional guild diversity included Margalef's richness (d) and Pielou's evenness (J′), which were calculated using PRIMER. A functional redundancy index was calculated by dividing the number of functional guilds by the number of polychaete families. Differences in diversity indices, abundance, biomass, and size among station groups were examined using analyses of variance (ANOVA) and Tukey's post hoc test, performed in R Studio. ANOVA assumptions were checked using the Shapiro-Wilk test for normality of residuals and Cochran's C test for homogeneity of variances. When assumptions were not met, data were log-transformed.

Results

Overall, there was roughly the same proportion of major macrofaunal taxa at all sampling stations, but total abundance and biomass differed (Table 1; Supplemental Tables 1 and 2). There was no significant spatial pattern in community structure when all macrofauna were examined at higher taxonomic levels. Polychaetes composed an average of 40.2% ± 11.2% (ranging from 22 to 66%) of total macrofaunal abundance. Polychaete abundance relative to total macrofauna increased with sediment depth (67% at the 5-10 cm layer), while the relative abundance of amphipods and bivalves decreased with sediment depth.

Spatial patterns emerged when considering only polychaetes at the family level, with three significant clusters of samples identified. Further spatial structure was revealed when examining patterns based on polychaete functional guilds, yielding four significant clusters (A, B, C, and D; Figures 1 and 2). The fourth cluster (Group C) was composed of stations that had clustered with either Group B or Group D in the family-level analysis. Stations attributed to each of these four

clusters are indicated on the map in Figure 1, and these groupings are used to further explore patterns in community structure, including associations with environmental variables.

Macrofauna

There were no significant differences in total macrofaunal abundance among the four groups ($F_{3,19}$ = 2.70, = 0.07); however, C had the lowest average abundance (Table 3). Total macrofaunal biomass at sites in Group D was significantly lower than Groups B and C ($F_{3,19}$ = 4.36, p = 0.02), and the average size followed a similar pattern ($F_{3,19}$ = 3.54, p = 0.03; Table 3).

Polychaetes were the most abundant macrofaunal taxon in all groups except Group A, where amphipods were the most abundant (Table 4). Groups B and C had similar relative abundances of the major taxa but differed in total macrofaunal abundance (Tables 3 and 4). Group D exhibited different composition than the other groups, with relatively high abundance of ostracods (14%), ophiuroids (5%), echiurans (4%), and echinoids (3%). Bivalves accounted for more than 50% of the biomass in Groups B, C, and D and were particularly high (88%) at sites in groups B and C. In contrast, amphipods had the highest biomass in Group A. Polychaetes had the second-highest biomass in all groups. In all groups, total macrofauna abundance was highest in the 1-cm surface layer (Figure 3). Biomass showed a similar pattern except in Group C, where biomass was highest at the 5-10 cm layer primarily due to bivalves (Figure 3).

Polychaete community structure

Polychaete abundance was significantly different among groups, with the post hoc test revealing that abundance was significantly lower at Group C compared to Group B ($F_{3,19}$ = 5.72, p = 0.006; Table 3). There were no significant differences in polychaete biomass ($F_{3,19}$ = 0.72, p = 0.55) or average body size ($F_{3,19}$ = 0.52, p = 0.67) among the groups; however, average polychaete biomass was highest at Group A (Table 3). Additionally, Group C had a high variance in average polychaete body size.

The most abundant family was different in each group, although some families had high abundance across multiple groups, such as Capitellidae, Spionidae, and Cossuridae (Table 4). One or two families dominated most groups; however, Group C had a relatively even distribution, with many families of similar abundances. The most abundant polychaete families (>10% of relative abundance) at Group A were Paraonidae, Capitellidae, Spionidae, and Terebellidae (Table 4). Group A also had the highest proportion of Maldanidae, which otherwise only occurred among the top 10 families at sites in Group B. Polychaete abundance was highest at Group B stations, where only three families (Capitellidae, Phyllodocidae, and Spionidae) accounted for ~75% of total polychaete abundance (Table 4). Group B also had a high proportion of Polynoidae and Pectinariidae compared to the other groups. The most numerous families in the Group C polychaete assemblage included Nephtyidae, Sigalionidae, Cossuridae, and Flabelligeridae (Table 4). Group C also had low abundance of Sabellidae and Capitellidae compared to other groups, and Syllidae and Paraonidae were notably absent. Family richness was highest at Group D sites, where Cirratulidae, Cossuridae, and Capitellidae were most abundant (Table 4). Group D was the only group containing Apistrobranchidae, Magelonidae, Ophellidae, Owenidae, and Serpulidae.

Overall, 21 polychaete functional guilds were identified, with most guilds represented by only one or two families, suggesting little functional redundancy over the study region when feeding type, motility, and feeding structure were all considered (Tables 2 and 4). Groups B and C were dominated by carnivores (~40 – 45%), although different families comprised the most abundant carnivores in each group, including Phyllodocidae in Group B and Nephtyidae and

Sigalionidae in Group C (Table 4). Subsurface deposit feeders made up the next largest proportion of the polychaetes at these sites (~26 – 36%), with Capitellidae the dominant family overall in Group B and Cossuridae the third most abundant in Group C. Deposit feeders, both surface and subsurface, accounted for ~70% of the polychaetes in Groups A (e.g., Paraonidae and Capitellidae) and D (e.g., Cirratulidae, Cossuridae, and Capitellidae; Table 4). Motile burrowers were the most abundant motility type in all groups (Table 4). Group A had a large portion of tube-dwellers compared to the other stations (37%). The most common feeding structure at Group A was non-muscular eversible pharynx, followed by tentacles/palps. The most common structure at Groups B and C was muscular eversible pharynx (Table 4), followed by non-muscular eversible pharynx in Group B and tentacles/palps in Group C. In Group D, the most common feeding structure was tentacles/palps, followed by muscular eversible pharynx.

Surface and subsurface deposit-feeding motile burrowers with non-muscular eversible pharynges, including guilds I(S/B)M(B)N (Paraonidae) and I(B)M(B)N (Capitellidae and Orbiniidae), accounted for almost half of the polychaetes in Group A, and thus accounted for a large portion of the dissimilarity between groups in pairwise comparisons to other sites (Supplemental Table 3). The subsurface deposit-feeders with non-muscular eversible pharynges (I(B)M(B)N) were also abundant in Groups B and D where they accounted for roughly ~20 – 30% of polychaetes. Mobile and discreetly mobile carnivores, including a combination of burrowing, crawling, and swimming behaviors, were abundant in Group B and C. SIMPER analysis indicated that within-group similarity in Groups A and D were attributed to the five most abundant guilds at those sites, as well as carnivores of lower abundance (Table 5; Figure 4). Groups B and C were distinguished based on abundance of 4 out of 5 of the most abundant guilds. A(C)M/D(C)P (Polynoidae) in Group B and I(B)M(B)P (Cossuridae) in Group C were abundant guilds that did not contribute substantially to within-group similarity at these sites. Guilds that contributed to within-group similarity that were not in the top five of respective groups were A(C)D(B)P (Glyceridae) in all groups, I(S/B)M(B)T (Cirratulidae) in Group B, I(F/S)D(T)T (Spionidae) and A(C)M/D(C)P (Polynoidae) in Group C, and A(C)M/D(C)P (Polynoidae) and A(C)M(B/C/S)P (Nephtyidae) in Group D (Table 5).

There were no significant differences in Margalef's richness (d) of functional guilds among the groups ($F_{3,19} = 2.63$, $p = 0.08$), although Group D had the highest average richness (Table 3). Group B had a low Pielou's evenness (J′) compared to Groups C and D ($F_{3,19} = 4.62$, $p = 0.01$; Table 3). In particular, Group C had low richness but high evenness, while Group D had high richness and high evenness. Group B had low richness and evenness. Additionally, Group D had high functional redundancy (e.g., guilds I(S/B)M)B)T, I(B)M(B)P, I(B)M(B)N, and I(F/S)D(T)T each contained two families) compared to Group B ($F_{3,19} = 4.62$, $p = 0.02$; Table 3). Group A also had high functional redundancy (e.g., guilds I(B)M(B)N and I(S)D(T)T each contained two families).

Polychaete abundance gradually declined with sediment depth at Groups A and D, where abundance was about twice as high in the surface layer compared to the 1-5 cm layer (Figure 3). In contrast, polychaete abundance declined rapidly at Group B, and surface abundance was almost four times higher than the 1-5 cm layer. Group C showed relatively similar abundances in the 0-1 and 1-5 cm layers, with dominance of carnivores at all depths. Groups A and C show an opposite pattern in biomass compared to abundance trends, with biomass maxima in the 5-10 cm layer (Figure 3), primarily attributed to the large carnivore Nephtyidae and high relative abundance of mid-sized subsurface deposit feeders. The large suspension feeder Sabellidae also contributed to the biomass maxima at Group A, and the large surface deposit feeder Pectinariidae contributed to

Group C. In contrast, Group D had the greatest polychaete biomass in the surface layer (Figure 3) due to a high abundance of carnivores (Polynoidae) and a few large surface deposit feeders (Trochochaetidae). Biomass peaked in the 1-5 cm layer at Group B (Figure 3) with particularly high abundance of large carnivores (Nephtyidae) and a high abundance of small subsurface deposit feeders (e.g., Maldanidae, Capitellidae).

The surface layer at Group A had a high relative abundance of suspension and suspension/surface feeders compared to the other groups, although it was still a small portion at only 8%. There was a notably high relative abundance of carnivores at the 1-5 cm layer at Group B and the 1-10 cm layers for Group C. Groups A and D had a high relative abundance of surface/subsurface deposit feeders at depths. However, subsurface deposit-feeders made up 22% of total abundance in the surface layer in Group D and 83% in the 5-10 cm layer where capitellids were abundant. Group D also had a high relative abundance of suspension feeders at the surface layers compared to Groups B and C, but still small at only 4%.

Environmental setting

The selected DistLM model accounted for 53.6% of total variation in polychaete functional guild composition and included TN, chl-a:phaeo, percent silt/clay, depth, CPE, and salinity (Figure 6). Some of the selected environmental predictors were highly correlated with other parameters not included in the model selection. TN was highly correlated with TOC. Percent silt/clay was highly correlated with mean phi, percent sand, and TOC. CPE was highly correlated with chl-a and phaeo inventories.

The first dbRDA axis was most correlated with TN and percent silt/clay, and the second dbRDA axis was highly correlated with chl-a:phaeo, with a lower, negative correlation with depth (Figure 5). These parameters suggest that organic matter and depositional environmental (i.e., muddy vs. sandy substrate) are important correlates of polychaete functional structure. Groups A and B were distinctly separated from Group C along the first dbRDA axis, reflecting differences in sediment type between sandier substrate in the northern Bering Sea and muddier sediments in the central Chukchi Sea. In contrast, distribution of sites in Group D along axis 1 overlaps with the other groups, reflecting more variability in sediment grain size among sites (Figure 6). Stations within Groups C and D further separated from each other along the second dbRDA axis, reflecting differences in surface chl-a:phaeo, which may be driven by a recent deposition of phytodetritus observed during sampling at some Group D sites.

Group A consisted of two sites in the Chirikov basin (DBO2.2 and DBO2.3), which were characterized by sandy sediments and low chl-a:phaeo, as well as higher $\delta^{13}C$ values than the other groups (Figure 6). These latter two metrics taken together suggest freshly deposited phytoplankton detritus at the seafloor, although TOC and TN content were low. Group B included stations directly north (downstream) of the Bering Strait constriction and station CBE3 east of Saint Lawrence Island, near the Yukon River delta. Grain sizes ranged from fine sand to very coarse silt with organic matter content similar to that of Group A. CBE3 had very low salinity (Table 1), reflecting freshwater input from the Yukon River.

Groups C and D were composed of stations in the more northerly portion of the study area, characterized by muddy sediment and high TOC and TN (Figure 6). IL4 was included in Group D in 2017 and Group C in 2018. Group C stations were located in the central Chukchi Sea and included the southeast Chukchi Sea hotspot (DBO3.8, CNL5). Group D was mostly comprised of the coastal stations with lower salinity indicative of the Alaska Coastal Current. CPE inventories were variable but included higher values in Group C, whereas chl-a:phaeo ratios were higher in

Group D (Figure 6), suggesting deposition of phytodetritus in both areas, but perhaps more degradation had taken place at Group C sites by the time of our sampling. Group D stations also had higher C:N and lower $\delta^{13}C$ values, suggesting more refractory organic matter, including terrestrial inputs or material advected from further south. Group D also contained station DBO2.4 in the Chirikov Basin, which had distinct community structure compared to the nearby DBO2.2 and DBO2.3 sites that made up Group A. The temperature at DBO2.4 was comparable to the warm temperature of Groups A and B. DBO2.4 had lower chl-a:phaeo, TOC, TN, and C:N, and higher $\delta^{13}C$ than other Group D stations (Table 1).

Discussion

We identified four distinct polychaete assemblages based on functional guild composition that were associated with specific environmental conditions. Overall, the distribution of these assemblages aligned reasonably well with key benthic environmental variables, including grain size and organic matter content, and with a south-to-north gradient across the Bering Strait, typical of this advective system. Although broad-scale features of the environment, such as substrate type and water mass distribution, are known to influence benthic biomass (Bluhm et al., 2009; Grebmeier et al., 2015), an exploration of the functional characteristics of infaunal communities provides a refined view of benthic ecosystem function in these four distinct regions. For example, sediment grain-size characteristics are well-known to constrain benthic assemblage structure (Rhoads, 1974), as we observed here in the separation between the sandy, southern groups (Groups A and B) and the northern, muddy groups (Groups C and D). However, functional characteristics of infaunal assemblages indicate further differentiation among sites within sandy and muddy areas. We combined community structure and environmental information from these subregions to construct a conceptual model of ecosystem structure and function across the study area (Figure 7).

Benthic "eco-regions" in the Alaskan Arctic

Group A consisted of the two eastern DBO2 stations in the northern Bering Sea, located within the Chirikov Basin and characterized by sandy sediment. Our measurements indicated low amounts of high-quality organic matter (OM) in the sediments at these sites; however, suspended OM likely supports benthic biomass in this area. The sandy sediment suggests high current velocity and lateral advection of particles, thus low phytodetritus deposition to the benthos. Low sediment TOC concentration and low sedimentation rates support this scenario (Grebmeier, 1993). Furthermore, the relatively high proportion of suspension-feeding polychaetes in the surface layer suggests that currents are critical in structuring the macrofaunal community (Gontikaki et al., 2011; Lovvorn et al., 2020).

Characteristics of many of the benthic taxa in Group A also suggest the dependence of a large portion of the assemblage on fresh, high-quality suspended or recently deposited OM. For instance, the Chirikov Basin is a known amphipod hotspot and critical feeding ground for gray whales. Amphipods in this region have been estimated to consume nearly all available carbon (Coyle et al., 2007). Indeed, amphipods were the most abundant taxon and had high biomass at the Group A sites, especially at DBO2.2. The amphipod community in the Chirikov Basin is composed primarily of the tube-dwelling suspension-feeding Ampeliscidae family (Grebmeier et al., 1989), although we found a diverse community of amphipod taxa in our samples, including Ampeliscidae, Lysianassidae, Phoxocephalidae, Photidae, and Tryphosidae. While some ampeliscids are obligate suspension feeders, others can supplement with surface deposit-feeding or preying on small crustaceans (reviewed by Conlan et al., 2019). Group A also had a high portion of tube-dwelling

polychaetes, many of which were tentaculate or palp feeders, such as Spionidae, Terebellidae, Sabellidae, and Ampharetidae. While surface and subsurface deposit feeders were the most abundant feeding type at these sites, there was a relatively high portion of suspension (Sabellidae) and facultative suspension feeders (Spioindae) in the surface layer, both of which exhibit particle selectivity (Cavallo et al., 2007; Guieb et al., 2004; Mincks et al., 2008). Additionally, Spionids display an ontogenetic shift from feeding on labile particles like diatoms as juveniles to detrital feeders as adults (Hentschel, 1998). Suspension feeders need a specific range of current speeds to suspension feed (Bock and Miller, 1997). Many facultative species switch between suspension and deposit-feeding behaviors depending on both fluid velocities and organic composition of suspended particles, entering suspension-feeding mode when the horizontal flux of high-quality particles is sufficient (Bock and Miller, 1997). Spionids have been shown to grow faster when consuming high-quality suspended particles than when deposit feeding (Hentschel, 2004).

Group A also had a high relative abundance of surface/subsurface feeders at depth, such as Paraonidae, which primarily feed in deeper sediment layers and move to the surface to feed after a fresh food pulse (Jumars et al., 2015). Indeed, paraonids were most abundant at the 1-5 cm layer at the Group A stations and had a high relative abundance at the 5-10 cm layer, suggesting they were primarily subsurface feeding. Paraonids and others with non-muscular eversible pharynges are generally non-selective, while those with tentacles display more particle selection behavior (Magalhães and Bailey-Brock, 2017). These non-selective polychaetes likely are consuming more refractory and reworked detritus within the sediment. Similarly, capitellids and orbiniids were also common in Group A, both of which are burrowing subsurface deposit feeders with non-muscular eversible pharynges. Although capitellids are generally subsurface deposit feeders, they can respond to fresh deposits of organic-rich particles on the sediment surface (Tsutsumi et al., 2005). However, in the absence of a fresh depositional event, they are likely consuming primarily refractory material that has been reworked and degraded by bacteria (Gontikaki et al., 2011). Both capitellids and orbiniids are in the same functional group, representing an example of functional redundancy. Overall, in Group A, suspension and surface feeders may take advantage of higher quality suspended material associated with the high fluid velocity, while subsurface feeders may dominate because they can survive on the more refractory buried detritus, suggesting physical resource partitioning of OM between these groups based on vertical stratification within the sediment (Jumars, 1978; North et al., 2014; Whitlatch, 1980).

Even within the Chirikov Basin, heterogeneity existed among polychaete assemblages, illustrating the importance of considering subregional spatial scales. For instance, although also located in the Chirikov Basin, station DBO2.4 clustered with Group D. DBO2.4 had a smaller abundance of certain tube-dwellers [e.g., I(B)D(T)N, I(S)D(T)T, I(F/S)D(T)T] and a higher abundance of certain carnivores [e.g., A(C)M(B/C/S)P and A(C)M/D(B)P] and burrowing deposit feeders [e.g., I(B)M(B)P and I(S/B)M(B)T] compared to Group A stations. During sampling, DBO2.4 was solely in Anadyr Water, while the Group A stations were also influenced by Bering Shelf water (Danielson unpublished data). DBO2.4 also had a low relative abundance of amphipods and a high relative abundance of ostracods and brittle stars compared to Group A, representing Group D composition. Brittle stars have also been found in Anadyr Strait communities to the southwest of our sampling (Grebmeier, 1993).

The fourth station sampled in the Chirikov Basin (CBE3) clustered with Group B, which also included two stations with sandy substrate directly north (downstream) of Bering Strait (CNL3 and CPL8). CBE3 had similar environmental conditions to these more northerly sites, except that salinity was lower due to proximity in the Yukon River plume. The CBE region (measured at

nearby CBE1) had high export flux during the time of sampling in 2018 (O'Daly et al., 2020). The Bering Strait stations in Group B had a larger percent of gravel (1-2%) compared to other stations, suggesting high current velocity. Currents accelerate as water moves through the narrow Bering Strait constriction (Danielson et al., 2014). Currents are strong in the fall and winter, resulting in disturbance and resuspension (Abe et al., 2019). However, currents in the Bering Strait throughflow are weaker in the spring, allowing the spring bloom to settle and leading to high sediment chl-a values (Abe et al., 2019). High dominance of relatively few families, especially the classic opportunists Capitellidae and Spionidae (Rhoads et al., 1978), could suggest a disturbed environment, for example, due to scouring from the strong currents. However, the high abundance of large carnivorous polychaetes observed in Groups B would be less likely in recently disturbed areas and is likely supported by the deposition of the spring bloom during weaker phases of the currents (Abe et al., 2019).

Further north, water fans out over the wide and shallow Chukchi shelf, and velocity decreases, allowing local and advected sources of OM to settle to the seafloor (Feng et al., 2020; Grebmeier et al., 2015). These stations are influenced by the nutrient-rich, highly productive Bering Shelf and Anadyr waters with high export flux of diatom detritus and viable diatom cells (O'Daly et al., 2020). Group C was composed of muddy stations in the central Chukchi, including the benthic "hotspot" area near DBO3.8 and CNL5 (Grebmeier et al., 2015), where large amounts of labile OM are deposited. Interestingly, although Group C had large amounts of OM, it had a low abundance of total macrofauna and low abundance and biomass of polychaetes. However, it had a large biomass and average size of macrofauna. These trends may be due to the competitive advantage of a few large-bodied bivalves. Additionally, Group C was the only group with relatively high abundance of Flabelligeridae, which can feed on fresh phytodetritus, but may also target bacteria particularly in the Chukchi Sea (*Brada* spp.; Iken et al., 2010; Jumars et al., 2015).

The large amounts of sediment OM at Groups B and C supported a high relative abundance of carnivores in both groups. The dominant carnivores at Group B sites were Phyllodocidae, which burrow or crawl and feed with a muscular eversible pharynx (Jumars et al., 2015; Kedra et al., 2012; Sokołowski et al., 2014), and are known to eat other polychaetes (Michaelis and Vennemann, 2005). At Group C sites, Nephtyidae and Sigalionidae were common carnivores, both of which are motile predators with muscular eversible pharynx. Sigalionids may be active hunters or sit-and-wait predators (Jumars et al., 2015). Nephtyids consume a variety of prey, including amphipods, foraminifera, and polychaetes (Gaston, 1987; Redmond and Scott, 1989). Nephtyids were abundant throughout the upper 5 cm of sediment and often burrow right below the sediment-water interface (Jumars et al., 2015).

In contrast to Group C, the coastal Chukchi Sea stations of Group D are generally influenced by the nutrient-poor, low-productivity Alaska Coastal Water (Danielson et al., 2017; O'Daly et al., 2020). These stations likely have a high input of refractory terrestrial material or marine detritus that has been reworked during lateral transport, as suggested by depleted $\delta^{13}C$ values and high C:N (Feder et al., 2007; Iken et al., 2010). We found high chl-a:phaeo at some sites and high TOC and TN in part attributed to a visible layer of newly deposited phytodetritus. Sampling timing compared to depositional events associated with ice-cover and bloom phenology are known to influence measurements of sediment OM (Lovvorn et al., 2020), and we sampled these stations shortly after sea-ice retreat. In addition to the amount of food, the quality of food can influence benthic biomass and abundance, impacting trophic structure and ecosystem function (Campanyà-Llovet et al., 2017).

Sites in Group D had low macrofauna and polychaete biomass and small average body sizes, with the majority of individuals concentrated in the surface layer. However, this area also had the highest number of polychaete families and high functional-guild richness and evenness. This diversity may be sustained by a diversity of food sources due to inputs of both terrestrial and marine sources. Station IL4, which switched from Group D to Group C between years, may be experiencing dynamic frontal or ice-edge conditions that affect advection and deposition of organic material. In contrast to other Group D stations, DBO3.3 had a high abundance and biomass of total macrofauna, which has been found before under the ACW near Point Hope and some stations within the Chukchi Bight, likely supported by advected and resuspended organic material (Feder et al., 2007). Similar to Group A, deposit feeders were the most abundant feeding types in Group D. These tentacle feeders were concentrated in the surface layer, suggesting the predominance of particle-selective surface deposit-feeding. Many subsurface deposit-feeders were also found in the upper 1 cm.

Implications for ecosystem processes

We created a conceptual model demonstrating how substrate type and OM input related to benthic community structure and hypothesized environmental inferences from each of the eco-regions, such as bioturbation potential and remineralization pathways (Figure 7). While some generalizations can be made between the sandy and muddy stations, many essential differences are missed with this generalization. For instance, the vertical distribution of macrofauna within the sediment and their associated functional traits impact biogeochemical cycling through oxygenation and bioturbation of sediment. There was evidence of intense sediment mixing in Groups A, B, and C, which all had subsurface maxima of polychaete biomass. Large, tube-dwelling, head-down deposit-feeders such as Maldanidae (Group A) and Pectinariidae (Group B) were relatively abundant at these sites and are known to influence biogeochemical cycling through oxygenation of the sediment by flushing their tubes (McTigue et al., 2016). Group C contained stations DBO3.6 and DBO3.8, the only stations with a subsurface abundance peak of total macrofaunal abundance. Additionally, these stations had high biomass at the 5-10 cm layer dominated by bivalves. High deposition of labile OM at these stations may stimulate bioturbation by macrofauna, leading to high rates of aerobic remineralization (Aller, 1994). Vertical distribution of sediment microbial communities also suggests intense sediment mixing in these groups, with a homogenous community of aerobic microbes inhabited the upper 7 cm of sediment and evidence of a deep oxic/anoxic boundary at about 7-10 cm (Walker et al. submitted). In contrast, the Group D stations had most of the macrofauna abundance concentrated at the surface and are predicted to have low amounts of bioturbation, with primarily anaerobic remineralization of OM. Furthermore, the microbial community at Group D stations showed a shallow transition from an aerobic to an anaerobic community at 1 cm (Walker et al. submitted). The concentration of macrofauna and polychaetes in the surface layer may be due to shallow anoxic conditions at this site, where anaerobic mineralization of organic matter may be the dominant pathway.

When more than one taxa perform similar ecological roles, functional redundancy can contribute to ecological resiliency to disturbance (Bremner et al., 2006; Snelgrove, 1998), and this relationship has been demonstrated for polychaetes in a variety of settings (e.g., Magalhães and Barros, 2011). Groups A and D had the highest functional redundancy and may be more resilient to disturbance than Groups B and C. However, functional redundancy was low throughout all groups, with most functional guilds represented by only one or two polychaete families. Low functional redundancy was also determined for the whole macrobenthos in the Bering Sea (Liu et

al., 2019). Accordingly, benthic ecosystem function in the Pacific Arctic may be susceptible to species loss or shifts in community structure caused by environmental change.

Alterations in benthic biomass and community composition have already been observed in response to environmental change in the Pacific-Arctic region (Goethel et al., 2019; Grebmeier, 2012; Stabeno et al., 2020; Waga et al., 2020), with likely impacts on carbon cycling (Jones et al., 2021). A decline in phytodetrital input to the seafloor has been predicted (Lee et al., 2013; Moore and Stabeno, 2015), and model results for the Chirikov basin suggest this decline will result in a steady loss of deposit feeders followed by a decline in carnivorous polychaetes (Lovvorn et al., 2016). However, deposit-feeding polychaetes remained relatively constant under simulated declines of different magnitudes south of St. Lawrence Island, and carnivorous polychaetes declined slightly (Lovvorn et al., 2016). These regional differences demonstrate the need for local, high-resolution data to inform the modeling of ecosystem function and potential environmental change impacts. For instance, the four polychaete functional assemblages identified in our study will likely respond differently to projected changes in food input and other environmental changes.

Taxa that rely more on fresh microalgae, such as protists, meiofauna, and tunicates, are likely to be more vulnerable, especially in the short term, to declines in phytodetrital inputs (Lovvorn et al., 2016). This vulnerability might also extend to polychaetes relying on higher-quality food particles, such as suspension and surface deposit feeders (Lessin et al., 2019). Consequently, sites in the Chirikov basin and just north of Bering Strait (Groups A and B) with higher proportions these types of feeders (e.g., Spionidae, Terebellidae) may be particularly at risk. These taxa are also discretely motile tube-dwellers, which, like amphipods, rely on water currents to supply suspended OM, contributing to their likely sensitivity to declines in primary production (Coyle et al., 2007). Additionally, some juveniles rely on discrete, labile food particles. For example, juvenile spionids feed on labile particles like fresh diatoms before experiencing an ontogenetic shift to detrital feeders as adults (Hentschel, 1998). Even if the adult food source is still abundant, a reduction in labile particles could cause a bottleneck in development and a population decline. In contrast, deposit feeders may be somewhat buffered against declines in phytodetrital input by a sediment food bank of labile organic matter (Mincks et al., 2005; Pirtle-Levy et al. 2009). These differing responses to environmental change based on functional traits may indicate that specific traits will be more susceptible, with deposit feeders potentially outcompeting suspension feeders. Consequently, it is possible that large suspension feeders will decline, and these broader areas would transition to assemblages resembling Group D, with small deposit-feeders adapted to less labile food.

Changes in phytodetrital input impact trophic groups differently (Lovvorn et al., 2016). However, the benthos is often oversimplified in ecosystem modeling due to a lack of available information (Whitehouse et al., 2014). This aggregation of the benthos at higher taxonomic levels or generic functional groups likely does not reflect local ecosystem function. For instance, feeding type alone did not distinguish differences in proportional contribution of bacterial, phytoplankton, and terrestrial organic matter sources in the Chukchi Sea food web, suggesting the need to consider other traits, including motility and particle selectivity (Zinkann et al., 2021). Consequently, the differences among the four polychaete functional guild assemblage "eco-regions" identified here, which considered feeding type, feeding structure, and motility, can be used to inform ecosystem models through the Pacific Arctic.

In conclusion, we found that the depositional environment, characterized by grain size and amount and quality of OM deposition, structures the taxonomic, functional, and vertical structure of the Pacific Arctic benthos. These community composition patterns likely impact benthic trophic

food web dynamics and biogeochemical and carbon cycling within the sediment, especially rapid, short-term processing of OM. Consequently, alterations in polychaete functional traits due to changing environmental conditions will likely impact the biogeochemical and carbon cycle of the benthos. Thus, ecosystem modeling and conservation and management would benefit from including representatives of different ecosystem functional systems, such as the different polychaete functional assemblage "eco-regions" and the trophic and biogeochemical carbon cycling they represent.

Acknowledgments

This research was part of the Arctic Integrated Ecosystem Research Program (IERP; http://www.nprb.org/arctic-program/). Funding for the program was provided by the North Pacific Research Board, U.S. Bureau of Ocean and Energy Management, Collaborative Alaskan Arctic Studies Program, and U.S. Office of Naval Research. Generous in-kind support for the program was contributed by the U.S. National Oceanic Atmospheric Administration Alaska Fisheries Science Center and Pacific Marine Environmental Laboratory, University of Alaska Fairbanks, U.S. Fish and Wildlife Service, and U.S. National Science Foundation. Support for this research was also provided by the University of Alaska Dissertation Completion Fellowship. We would like to thank the Captain and crew of the *R/V Sikuliaq* for making sampling possible and Opik Ahkinga, Silvana Gonzalez, Jessica Pretty, Sarah Seabrook, and Andrew Thurber for help with sample collection. We also thank Tibor Dorsaz, Brenda Holladay, and Nana Matsui for their assistance with sample sorting; Hilary Nichols and Max Hoberg for macrofaunal identification; Timothy Howe and others at the Alaska Stable Isotope Facility; and Seth Danielson, Jeroen Ingels, Amanda Kelly, and Andrew Thurber for their guidance and valuable input.

Table 2: (a) Legend of polychaete functional guild codes. (b) Polychaete families and assigned functional guilds (based on Jumars et al. 2015). Codes that have multiple traits in parenthesis are families that are facultative feeders, display multiple modes of movement, or have common species within a family that display different traits.

(a)

Feeding		**Motility**		**Structure**
I: Microphage	(B): Subsurface	D: Discretely motile	(T): Tube	T: Tentacle/palps
A: Macrophage	(S): Surface	M: Motile	(B): Burrow	(N): Non-muscular eversible pharynx
O: Omnivore	(F): Suspension		(C): Crawl	P: Muscular eversible pharynx
	(C): Carnivore		(S): Swim	

(b)

	Detailed guild	**Families**
Macrophage carnivores:	A(C)D(B)P	Glyceridae
	A(C)M(B/C)P	Phyllodocidae
	A(C)M(B/C/S)P	Nephtyidae
	A(C)M/D(B)P	Sigalionidae
	A(C)M/D(C)P	Polynoidae
	A(C)MP	Sphaerodoridae
Microphage subsurface deposit feeders:	I(B)D(T)N	Maldanidae
	I(B)D(T)T	Pectinariidae
	I(B)M(B)N	Capitellidae, Orbiniidae
	I(B)M(B)P	Cossuridae, Sternaspidae
	I(B)M(B/S)N	Opheliidae, Scalibregmatidae
	I(B)M/D(B/T)T	Trichobranchidae
Microphage suspension feeders:	I(F)S(T)T	Sabellidae, Serpulidae
Microphage suspension/surface deposit feeders:	I(F/S)D(T)T	Oweniidae, Spionidae
Microphage surface deposit feeders:	I(S)D(B)T	Flabelligeridae
	I(S)D(T)T	Ampharetidae, Terebellidae, Trochochaetidae
Microphage surface/subsurface deposit feeders:	I(S/B)M(B)N	Paraonidae
	I(S/B)M(B)T	Cirratulidae, Magelonidae
Microphage (unspecified) feeder:	IDT	Apistobranchidae
Omnivores:	OM(B/C)P	Syllidae
	OM(C)P	Dorvilleidae

Table 3: Average macrofauna (including polychaetes) and polychaete abundance (individuals m^{-2}), biomass (g m^{-2}), and body size (g $indiv.^{-1}$) for each group (± standard deviation) for the upper 10 cm of sediment; and polychaete functional guild Margalef's richness (D), Pielou's evenness (J′), and functional redundancy index.

	Group A	**Group B**	**Group C**	**Group D**

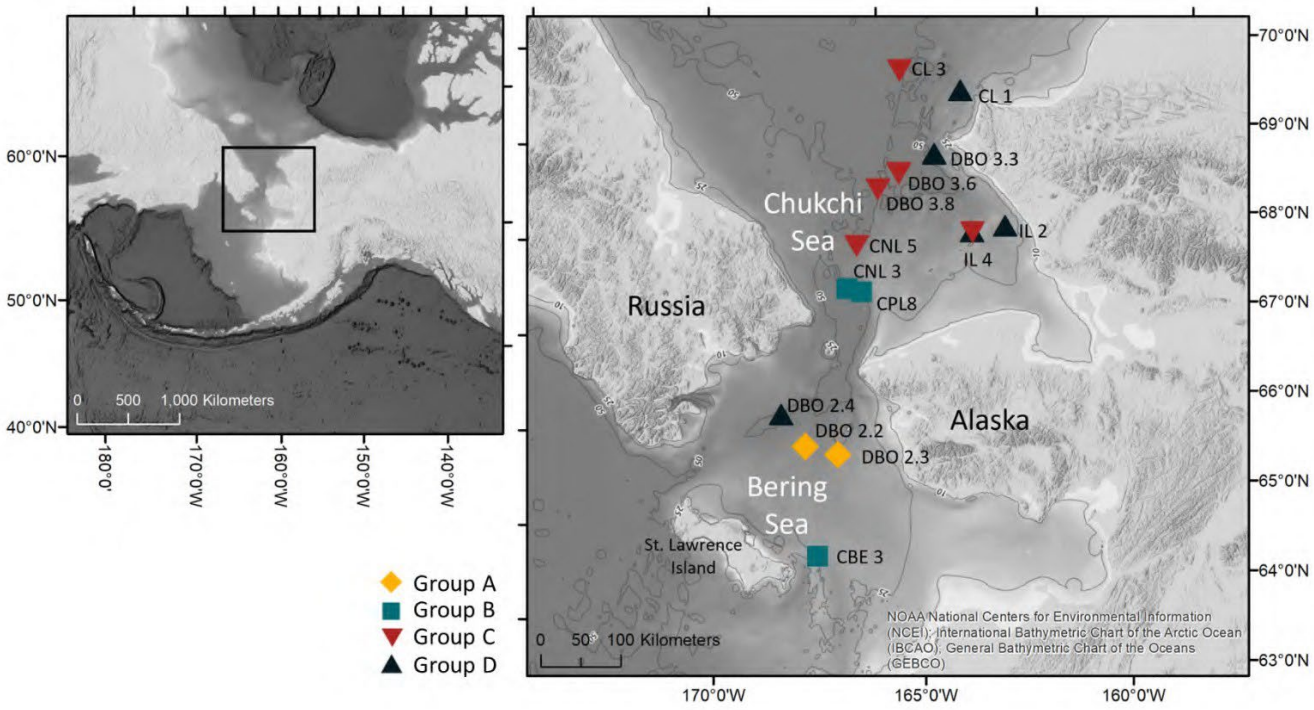

Figure 1: Macrofauna sampling locations in the northern Bering and southern Chukchi Sea in 2017 and 2018. Nine stations were sampled in both years. Symbols based on hierarchical agglomerative clustering of polychaete functional guild abundances from Figure 2. Station IL 4 clustered in Group D in 2017 and Group C in 2018.

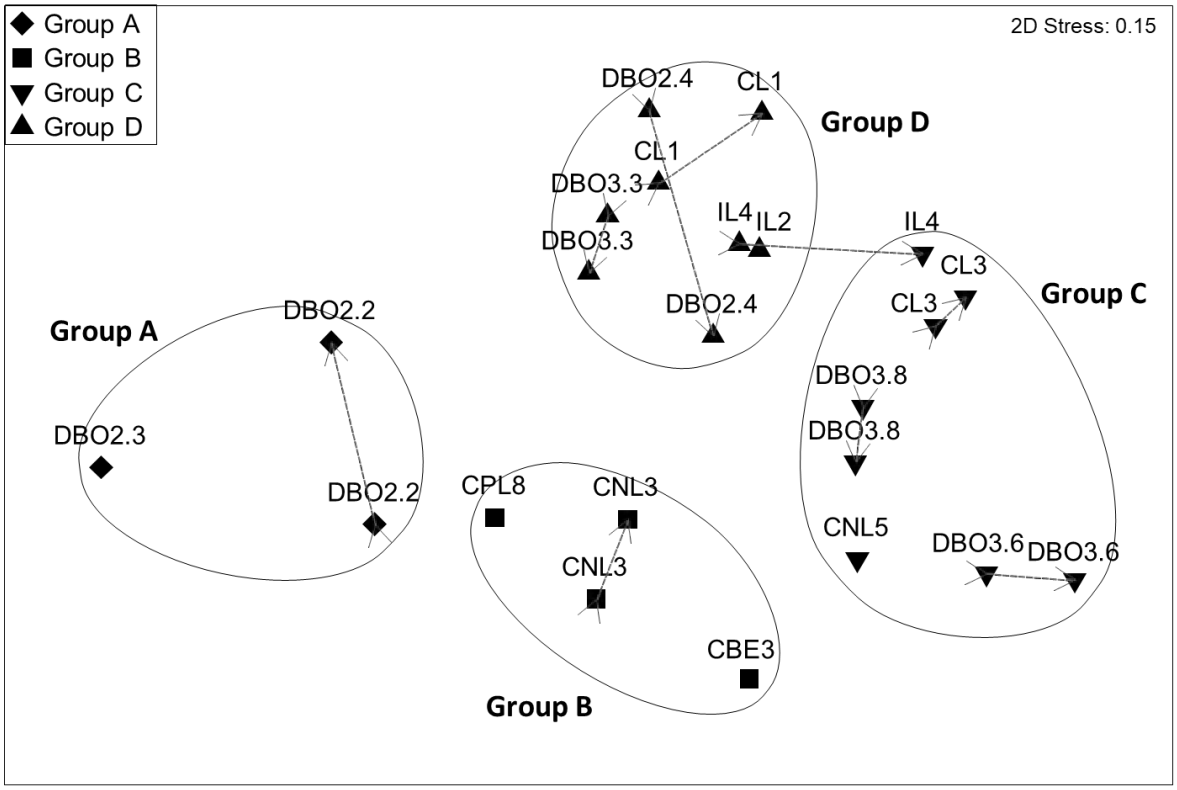

Figure 2: nMDS ordination of polychaete functional guild community structure (indiv. m^{-2}) from 2017 and 2018. Ordination based on hierarchical agglomerative clustering with group-averaged linkage on 4^{th} root transformed data and Bray-Curtis similarity. Four significant station groupings circled in black based on the similarity profile test (SIMPROF). Arrows indicate trajectories from 2017 to 2018 for stations sampled in both years.

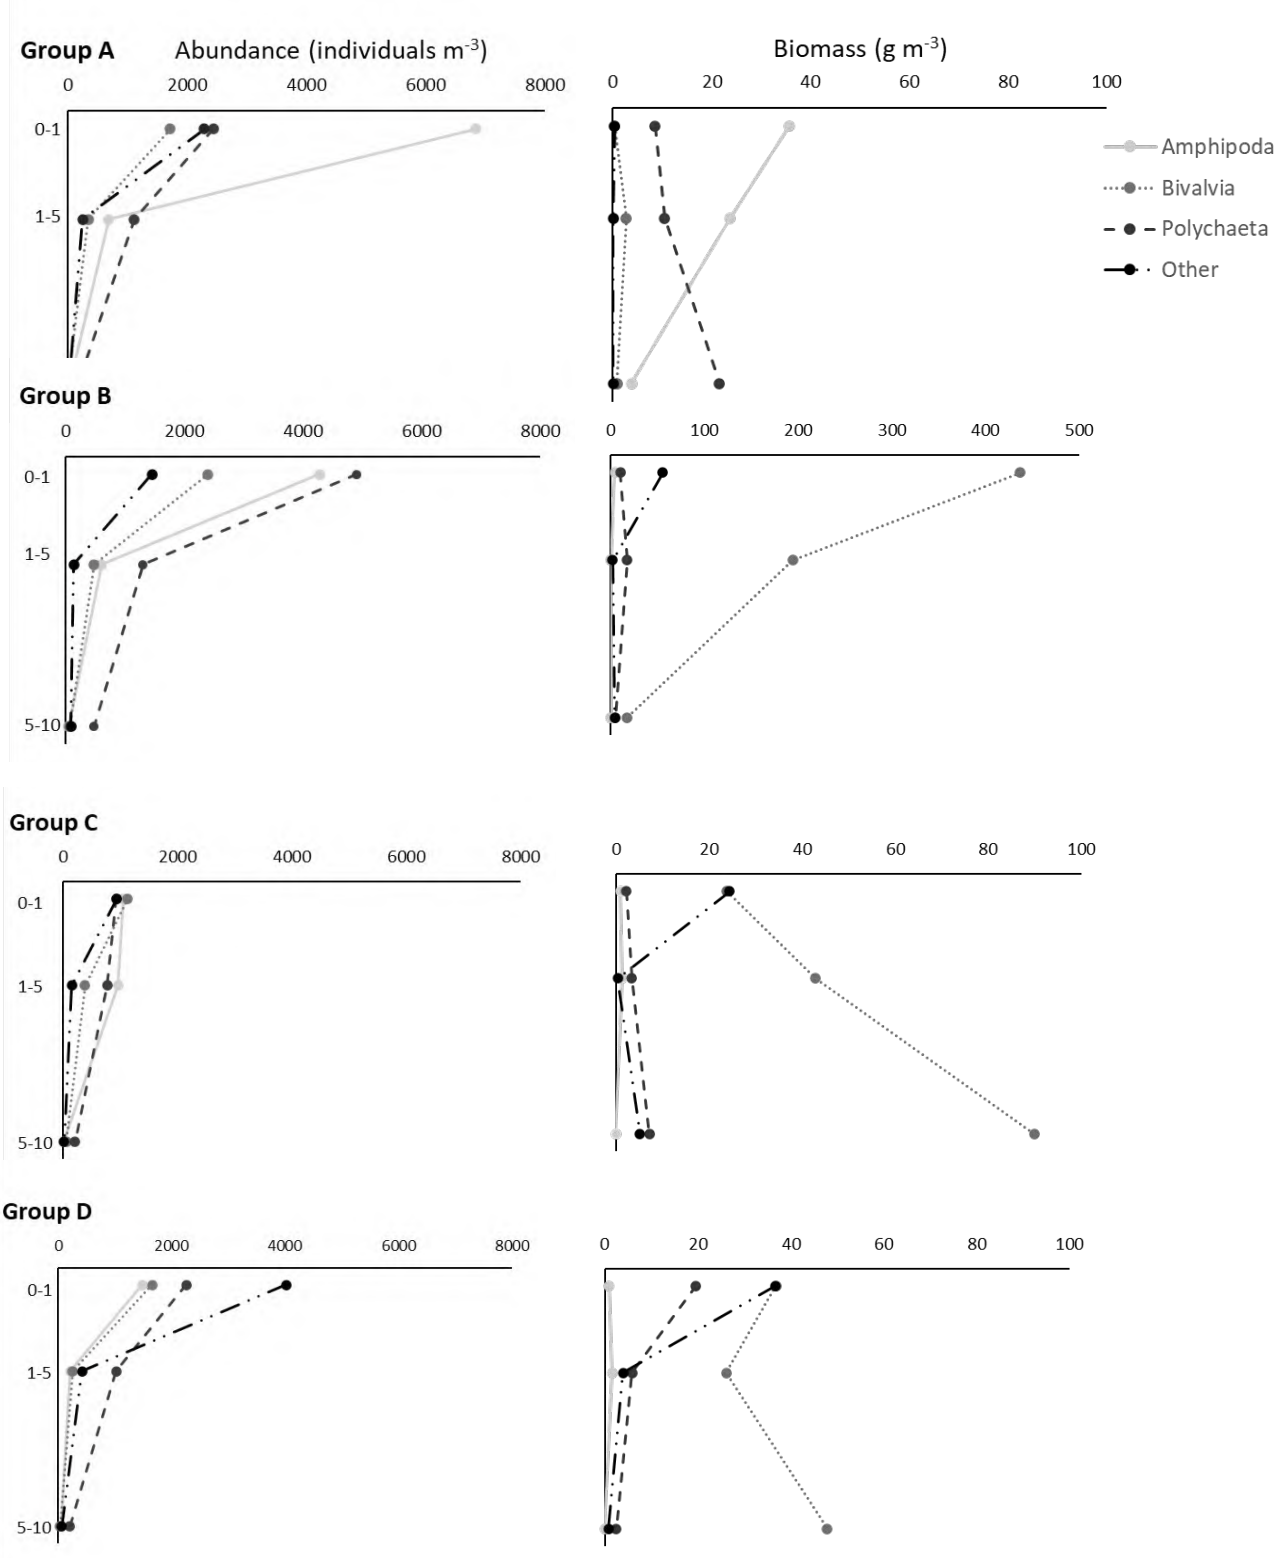

Figure 3: Average abundance (individuals m^{-3}) and biomass (g m^{-3}) within each group of Amphipoda, Bivalvia, Polychaeta, and other macrofaunal taxa for each sediment layer. Scale for Group B biomass is different from other groups. Groups based on hierarchical agglomerative clustering from Figure 2.

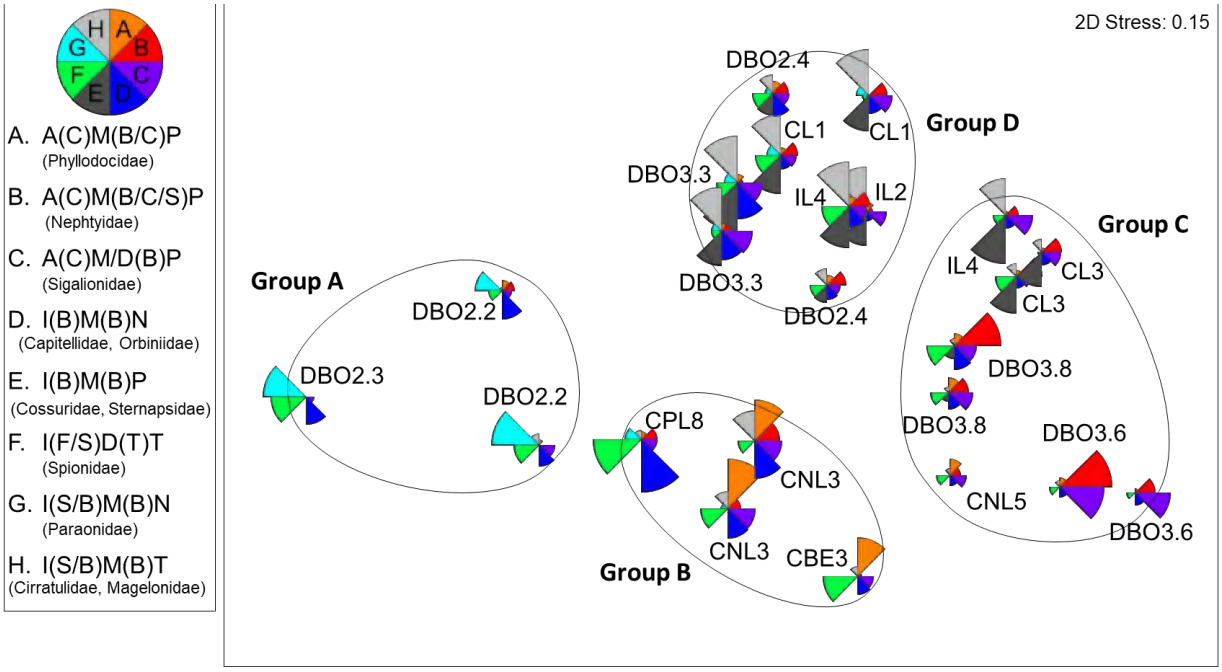

Figure 4: nMDS ordination of polychaete functional guild community structure from 2017 and 2018. Ordination based on hierarchical agglomerative clustering with group-averaged linkage on 4th root transformed data and Bray-Curtis similarity. Significant clusters circled in black based on similarity profile test (SIMPROF). Pie slices represent the abundance of polychaete functional guilds in the top three guilds contributing to within-group similarity in at least one group based on Similarity Percentages (SIMPER) procedure. The first three guilds in the legend are carnivores (A-C), followed by two subsurface deposit feeders (D-E), a suspension/surface deposit feeder (F), and two surface/subsurface deposit feeders (G-H). See Table 2 for detailed guild information.

Meiofauna community structure in Pacific Arctic shelf sediments: a comparison of meiofaunal- and macrofaunal-sized nematodes and functional traits[1]

Abstract

Meiofauna serve essential roles in benthic ecosystems, such as nutrient cycling and linking microbial and upper-trophic levels of the food web, and they serve as bioindicators of environmental change, particularly nematodes. However, in the rapidly changing Pacific Arctic shelf region, meiofauna remain poorly studied, and baseline data for assessing change is lacking. Sediment samples were collected at ten stations in the northern Bering and southern Chukchi Seas in June 2018 as part of the Arctic Shelf Growth, Advection, Respiration, and Deposition (ASGARD) project. We characterized meiofauna (63-500 µm) community structure and abundance at higher taxonomic levels and evaluated genus-level composition of nematodes in both meiofaunal (63-500 µm) and macrofaunal (>500 µm) size fractions. The nematodes were also classified by trophic feeding groups and life-history strategies. Total meiofauna abundance ranged from 1449 to 12875 ind. 10 cm^{-2} for the upper 5 cm of sediment, and the dry weight (DW) biomass of nematodes in the upper 1 cm of sediment ranged from 33 to 739 µg DW10 cm^{-2}. Four clusters of meiofaunal-sized nematode communities were identified occupying different regions of the Pacific Arctic shelves: the northern Bering shelf, Bering Strait region, central Chukchi Sea, and coastal Chukchi Sea. These nematodes assemblages reflected impacts of food availability and substrate type, and differences suggest these subregions should be considered separately in ecosystem modeling. Additionally, the meiofaunal- and macrofaunal-sized nematodes represented two distinct communities. The taxonomic composition and large standing stock of the macrofaunal-sized nematodes (2 - 215 µg DW 10 cm^{-2}) suggest they are a critical component of the infauna and merit more in-depth research to consider the ecological role they play, including benthic carbon cycling and trophic dynamics. This study provides the first genus-level characterization of nematode communities in the region and among the first measurements of meiofauna standing stock. Thus, the data presented here can serve as a baseline for assessing ecosystem shifts in a rapidly changing Arctic environment.

[1] Charrier, B.R., J. Ingels, and S.L. Mincks. Meiofauna community structure in Pacific Arctic shelf sediment: a comparison of meiofaunal- and macrofaunal-sized nematodes and functional traits. *In preparation*.

Introduction

Meiofauna play critical roles in ecosystem functioning (reviewed by Schratzberger and Ingels, 2017), including carbon and nutrient cycling (Bonaglia et al., 2014; Coull, 1999; Rysgaard et al., 2000), linking microbial and upper-trophic levels of the food web (Coull, 1990; Gee, 1989; Kennedy, 1994), and serving as bioindicators of environmental change (Ridall and Ingels, 2021). Tight pelagic-benthic coupling on Arctic shelves supplies substantial inputs of phytodetritus to the benthos (Grebmeier and Barry, 1991; Grebmeier and McRoy, 1989), often supporting abundant meiofauna communities (Górska et al., 2014). Important sources of organic matter (OM) include phytoplankton and ice algal production, and possibly riverine input of microbially processed terrestrial material (McMahon et al., 2006; Zinkann, submitted).

This tight pelagic-benthic coupling sustains high macrofaunal biomass on the Pacific Arctic shelf (Grebmeier et al., 2015). However, the Pacific Arctic meiobenthos remains poorly studied and has been identified as a critical data gap in the region, especially for constraining ecosystem models (Lovvorn et al., 2016; Nelson et al., 2014). Only a handful of meiofaunal studies have been conducted in the Pacific Arctic. One study quantified the abundance and distribution of meiofauna in the Chukchi Sea (Lin et al., 2014) but only identified specimens to higher taxonomic levels (e.g., phylum and class). Community composition and functional diversity of nematodes were not resolved any further, even though nematodes accounted for 96.6% of total meiofauna abundance in the shallow shelf region (Lin et al., 2014). Additionally, meiofaunal abundance and biomass were quantified in the Northeast Chukchi Sea (Hajduk, 2015), and nematode community structure and function were assessed, with *Sabatieria* dominating nematode assemblages (Mincks et al., 2021). However, additional research is needed on meiofauna community structure and functional diversity in the Pacific Arctic, especially in the context of the rapid environmental change and unprecedented environmental conditions observed in recent years, including high temperatures and record low sea ice persistence (Baker et al., 2020; Grebmeier et al., 2018; Huntington et al., 2020).

Nematodes are generally the most abundant metazoan meiofaunal taxa in marine sediment. Additionally, functional traits are reasonably well described for nematode genera, including feeding types and life-history strategies (Bongers et al., 1991; Wieser, 1953). Consequently, nematode communities can be useful in assessing ecosystem function and provide insights into ecological and biogeochemical processes occurring in the benthic ecosystem, such as food availability, hydrodynamic conditions, and sediment biogeochemistry (e.g., Gunton et al., 2017; Ingels et al., 2011b; Román et al., 2018).

While meiofauna, and nematodes in particular, are commonly shown to reflect environmental conditions and ecosystem processes, macrofaunal-sized nematodes are often ignored in infaunal studies. Standardized sieve sizes operationally define meiofauna as individuals that pass through an upper mesh of 300-1,000 µm and are retained on a lower 32-63 µm mesh (Giere, 2009). These size separations align with a trough in the bimodal size distribution of benthic infaunal metazoans, corresponding to a shift in optimizing life-history strategies between small, meiofaunal organisms living interstitially within the sediment and large, macrofaunal organisms actively manipulating the sediment matrix (Warwick, 1984). Thus, macrofaunal-sized nematodes are excluded from meiofaunal studies due to their large size and ignored in macrofaunal studies because they are not considered macrofaunal taxa *sensu stricto*. However, macrofaunal-sized nematodes exhibit distinct assemblage structure and functional diversity relative to meiofaunal nematodes (Baldrighi and Manini, 2015; Sharma et al., 2011) and can contribute substantially to macrofaunal abundance (Baldrighi and Manini, 2015; Gunton et al., 2017).

We characterized the spatial variability of meiofauna communities in the upper 5 cm of sediment on the northern Bering and southern Chukchi Sea shelves. Community composition, abundance, biomass, and function (as reflected by feeding mode and life-history strategy) were also assessed for meiofaunal- and macrofaunal-sized nematode genera in surface sediments, in relation to environmental characteristics. We explored differences in nematode community structure between the two size fractions and evaluated the contribution of macrofaunal-sized nematode abundance and biomass to total macrofaunal standing stock and whether critical information may be lost when they are excluded from benthic research. This study provides the first genus-level characterization and biomass estimates of nematodes in this region.

Methods

Study area and sampling

Meiofauna samples were collected from the northern Bering and southern Chukchi Seas in June 2018 from the *R/V Sikuliaq* as part of the Arctic Shelf Growth, Advection, Respiration, and Deposition (ASGARD) project (Table 1; Figure 1). This shallow shelf area is seasonally ice-covered and influenced by distinct water masses. Cold, nutrient-rich Bering Shelf-Anadyr Water (BSAW) experiences water column mixing that enhances primary productivity as current speeds accelerate through the Bering Strait constriction (Danielson et al., 2017; Walsh et al., 1989). As the BSAW fans out over the Chukchi Sea shelf, the current speed declines resulting in high deposition of suspended particulate material to the seafloor (Grebmeier et al., 2015). In contrast, the warm, nutrient-poor Alaska Coastal Water in the east is characterized by low pelagic production and high terrestrial input (Danielson et al., 2017).

Intact sediment cores with undisturbed surfaces were retrieved from ten stations using an MC-800 multi-corer with 10-cm internal diameter tubes (Ocean Instruments, San Diego, USA). Sampling stations ranged from 39 to 58 m in water depth (Table 1). Average near-bottom water temperature was 1.15°C ± 0.93°C (ranging from -0.6 to 2.4°C), measured from CTD deployments. One core from each station was selected for meiofauna sampling. The cores were sectioned into 1-cm depth intervals down to 5 cm and preserved in 10% buffered formalin.

Meiofauna analysis

Meiofauna were separated from the sediment using a decantation method (Creer et al., 2010), whereby samples were washed over a 63-µm sieve, transferred to 70% isopropanol, and stained with Rose Bengal. Prior to sorting, an upper sieve with a 500-µm mesh size was used to separate macrofaunal- (>500 µm) from meiofaunal-sized (63-500 µm) specimens. All nematodes were counted from the >500 µm samples for each sediment depth. From the surface sediment layers (0-1 cm), the first 120 nematodes were picked out for further taxonomic identification and biomass estimation. All nematodes were identified if there were fewer than 120 individuals.

The 63-500 µm samples were split using a Wet Sample Divider (WSD-10, McLane Research Laboratories, Massachusetts, USA), and 10% of each sediment layer was processed for abundance of metazoan meiofauna, identified to higher taxonomic levels (i.e., phylum, class; Giere, 2009; Higgins and Theil, 1988). For surface sediment layers (0-1 cm), 100-150 nematodes were randomly selected for genus-level identification and biomass estimation using a random number table and a gridded petri dish. This number of individuals generally reflects the composition of the whole nematode community (Soetaert and Heip, 1990), allowing for greater efficiency in taxonomic analysis.

The selected meiofaunal- (N= 1124) and macrofaunal-sized (N = 483) nematodes were transferred to anhydrous glycerin using a glycerol-isopropanol-water solution and evaporated overnight in a drying oven at 50°C (Seinhorst, 1959). Nematodes were then mounted on glass slides and identified to genus under a compound microscope using pictorial keys (Platt and Warwick, 1988) and the Nemys database (Bezerra et al., 2021). Genus-level identification is effective in detecting ecological significance (Somerfield and Clarke, 1995). Specimens that could not be identified to genus level were assigned to family.

Length and width of each mounted nematode were measured using a compound microscope and imaging software. Nematode wet weight (µg) was calculated using the equation $(L * W^2)/(1.5 * 10^6)$, where L is length (µm), and W is the maximum body diameter (µm). This equation is adapted from (Andrassy, 1956), assuming a specific gravity of 1.13 g cm^{-3} for marine nematodes (Ingels et al., 2013; Pape et al., 2013). Wet weight was converted to dry weight using a dry-to-wet weight ratio of 0.25 (Heip et al., 1985) and to carbon weight using a carbon-to-wet weight ratio of 0.124 (Jensen, 1984).

Nematode functional traits were characterized in terms of feeding type and life-history strategy. The feeding type of each nematode was assigned based on their buccal cavity morphology as classified by Wieser (1953): selective deposit feeder (1A), non-selective deposit feeder (1B), epistratum feeder (2A), and predators/scavengers or omnivores (2B). Each nematode was also assigned a life-history strategy based on c-p scores on a scale ranging from 1 (colonizer with short generation times and rapid reproductive rates) to 5 (persister with long generation times and slow reproductive rates), based on Bongers (1990) and Bongers et al. (1991, 1995).

Environmental variables

Sediment cores were collected from multi-core deployments at each station to analyze sediment characteristics (N=1 core) and OM content (N = 3 cores; except DBO2.4 N = 2 cores). Detailed methods for all analyses are presented in Charrier et al. (in preparation). Briefly, grain size analysis was conducted using a subsample of the upper 5 cm of sediment. Samples were suspended in dispersant and then separated into size fractions using a combination of wet and dry sieving. The <63-µm (silt/clay) fraction was treated with 30% hydrogen peroxide (H_2O_2) to remove organic material prior to final weighing. Mean phi was calculated with the Grain Size Distribution and Statistics (GRADISTAT v.8.0) package (Blott, 2010; Blott and Pye, 2001). Percent silt/clay and percent sand were calculated, and porosity was calculated as the ratio of water content to total sediment wet weight.

OM was measured as chloropigment content, total organic carbon (TOC), total nitrogen (TN), and carbon to nitrogen ratio (C:N). Stable carbon isotope signatures were also measured as an indication of carbon source. For these analyses, cores were sectioned in 0-1, 1-2, 2-3, 3-4, 4-5, 5-7, and 7-10 cm layers. Chloropigments were extracted in 100% acetone and analyzed as in Charrier et al. (in preparation) using a TD-700 fluorometer (Turner Designs, San Jose, CA, USA). Fluorescence was converted to concentration units based on a standard curve produced (adapted from Arar and Collins, 1997) using a chlorophyll-a standard (spinach extract C5753, Sigma-Aldrich). Each sediment sample was extracted twice, and the amount of chlorophyll yielded from each extraction was summed. Sediment chlorophyll parameters measured included chlorophyll-a (chl-a), phaeopigment (phaeo), and chloroplastic pigment equivalent (CPE; chl-a + phaeo) inventories (ug cm^{-2}). Chl-a to phaeo (chl-a:phaeo) ratio was also calculated. Stable carbon isotope signatures ($\delta^{13}C$), TOC (mg cm^{-2}), and TN (mg cm^{-2}) were analyzed at the Alaska Stable Isotope Facility at the University of Alaska Fairbanks Water & Environmental Research Center. Stable

isotope data were obtained by continuous-flow isotope ratio mass spectrometry, utilizing a Thermo Scientific Flash 2000 elemental analyzer and Thermo Scientific Conflo IV interfaced with a Thermo Scientific DeltaV Plus Mass Spectrometer. Stable isotope ratios were reported in δ notation as parts per thousand (‰) deviation from the international standard Vienna Pee Dee Belemnite (VPDB; carbon). Typically, instrument precision is <0.2 ‰.

Data analysis

Multivariate analyses of community structure were conducted in PRIMER v7 (Clarke and Gorley, 2015) with the PERMANOVA+ add-on on (Anderson and Gorley, 2008). Bray-Curtis similarity matrices were calculated on $\log_{(x+1)}$ transformed data and displayed on non-metric multi-dimensional scaling (nMDS) plots to visualize similarities and differences among samples. Samples with similar taxonomic composition were identified using hierarchical agglomerative clustering with group-average linking. A similarity profile (SIMPROF) procedure was used to delineate statistically significant groupings. The RELATE routine was used to calculate a Spearman rank correlation coefficient between the meiofaunal- and macrofaunal-sized nematode community Bray-Curtis similarity matrices. Since the abundances of the two size fractions were orders of magnitude different, relative abundances were calculated for further comparisons. A Bray-Curtis similarity matrix was calculated on $\log_{(x+1)}$ transformed relative abundances, and analysis of similarities (ANOSIM) was performed to test for differences between the communities within the two size fractions.

Relationships between meiofaunal-sized nematode community structure, environmental variables, and surface layer sediment variables were examined using a distance-based linear model (DistLM) with a stepwise selection criterion based on adjusted R^2, followed by distance-based redundancy analysis (dbRDA). All environmental data were normalized. Variables were removed prior to the analysis due to multicollinearity determined by Pearson's correlation coefficients (>0.8). Variables allowed in model selection included depth, temperature, salinity, percent silt/clay, and surface sediment layer CPE, chl-a:phaeo, phaeo, TN, and $\delta^{13}C$.

Univariate descriptors of nematode diversity were calculated in PRIMER. Hill's numbers (H_0, H_1, H_2, and H_∞; Heip et al., 1998; Hill, 1973), Pielou's evenness (J′), Shannon-Wiener diversity index (H′), and expected number of genera for 51 individuals (EG(51)) were calculated. The trophic diversity index (TDI) was calculated as the reciprocal of the trophic index (Heip et al., 1998; Ingels and Vanreusel, 2013). The maturity index (MI) was calculated as the sum of the products of the relative proportion of each genus and their c-p score (Bongers, 1990; Bongers et al., 1991; Ingels and Vanreusel, 2013).

Results

Metazoan meiofauna

Total meiofauna abundance (63-500 μm) was 1.7 times higher at the most northern station (CL3) than at any other station, due mainly to a large abundance of small nematodes in the surface layer of sediment (Table 1; Figure 2). The central, offshore Chukchi stations (DBO3.6 and DBO3.8) also had high meiofauna abundance (Table 1; Figure 2). The lowest meiofauna abundances occurred at the stations immediately north of the Bering Strait (CNL3 and CNL5) and the station off the coast of Point Hope (DBO3.3).

Nematodes were the most abundant taxon at all stations and accounted for 88% ± 14% (ranging from 49% at DBO2.4 to 98% at DBO3.8) of total meiofauna abundance (Table 1; Figure 2). Nauplii (6%) were the second most abundant taxa, followed by copepods (4%), bivalves

(0.6%), kinorhynchs (0.4%), polychaetes (0.4%), and ostracods (0.4%). Kinorhynchs were only found at the four coastal Chukchi Sea stations, while ostracods were only found at the two central Chukchi Sea stations (DBO3.6 and DBO3.8). Nauplii abundance at DBO2.4 was 4.8 times higher than at any other station (Figure 2).

Meiofaunal-sized nematodes

There was no significant spatial pattern in community structure when all meiofauna were examined at higher taxonomic levels. However, when surface nematodes (63-500 μm) were considered at the genus level, spatial patterns emerged, and four significant clusters of stations were identified (A, B, C, and D; Figure 3). Group A included stations south of Bering Strait, CNL 3 immediately north of the Strait was distinct (Group B), Group C was composed of three central Chukchi Sea stations, and Group D contained the coastal Chukchi Sea stations (Figure 1). Within-group similarity was driven by a combination of abundant and less abundant genera (Table 2; Figure 4), suggesting that rarer taxa are important in structuring differences among the nematode assemblages in this region. Additionally, some genera were highly abundant across multiple groups. For instance, *Daptonema* was in the top two most abundant genera in Groups A, B, and C (Table 2; results for each station presented in Supplemental Table 1).

Group A had high abundance and biomass of nematodes in the surface 1 cm of sediment, dominated by *Daptonema* and *Oncholaimus* (Table 2; Figure 5). The dominant feeding type in Group A was non-selective deposit feeders (1B; e.g., the Xyalidae family, including *Daptonema* and *Paramonohystera*, and *Monhystrella*), which was also the most abundant feeding type in Groups B and C (Table 3; results for each station presented in Supplemental Table 2). Predators/scavengers (2B; e.g., *Oncholaimus* and *Viscosia*) were relatively more abundant in Group A compared to the other groups, leading to the highest average trophic diversity index (Table 3). However, Group A did not have a higher taxonomic diversity compared to the other groups, demonstrating the importance of assessing both taxonomy and functional diversity. General opportunists (c-p score = 2) were dominant in all groups (Table 3), particularly in Groups B (59%; e.g., *Sabatieria*, *Daptonema*, *Paramonohystera*) and C (81%; e.g., *Daptonema* and *Paramonohystera*). Indeed, Group C consistently had the lowest taxonomic and trophic diversity values among the groups (Table 3). Groups B and C had low nematode abundance and biomass in the upper 1 cm of sediment (Figure 5).

Selective deposit feeders (1A; e.g., *Halalaimus*, *Tricoma*, *Terschellingia*) were dominant in the muddier coastal sites in Group D (Tables 2 and 3). Group D had the highest average maturity index, with a relatively large number of persisters (c-p score = 4; e.g., *Halaimus*, *Tricoma*). Group D was characterized by high abundance and biomass of small-bodied nematodes (Figure 5), although this pattern was heavily influenced by very high abundance at station CL3.

While meiofauna abundance was highest in surface sediments at six sites (Groups A and D), a subsurface abundance peak was detected at the central and southern Chukchi Sea stations (Groups B and C; Figure 6). Overall, the relative abundance of nematodes increased over the first 3 cm of sediment and then remained high at an average of 96 to 97% of total meiofaunal abundance.

Environmental correlates of nematode assemblages

The selected DistLM model for the 63-500 μm surface nematodes community structure accounted for 97.2% of total variation in nematode community structure and included $\delta^{13}C$, chl-a:phaeo, salinity, percent silt/clay, depth, TN, phaeo, and CPE (Figures 7 and 8; environmental

values for each station presented in Supplemental Table 3). Many of these parameters (e.g., $\delta^{13}C$, chl-a:phaeo, TN) suggest the freshness of OM was an important correlate of nematode community structure in this region. The first dbRDA axis was most positively correlated with chl-a:phaeo and negatively correlated with salinity and depth. The second dbRDA axis was highly correlated with $\delta^{13}C$, with a negative correlation with salinity and TN. Some of the selected environmental predictors were highly correlated with other parameters not included in the model selection. The parameter $\delta^{13}C$ was correlated with C:N. Chl-a:phaeo was correlated with chl-a. Percent silt/clay was correlated with mean phi, percent sand, porosity, and TOC. TN was correlated with TOC.

Groups C and D separated from each other along the first dbRDA axis, with higher chl-a:phaeo, lower salinity, and muddier sediments at Group D. Groups A and B fell between Groups C and D along the first axis, with Group B closer to Group C, while Group A was closer to Group D. Group A separated from the other groups along the second dbRDA axis, with higher $\delta^{13}C$ values, sandier sediment, and lower TN.

Macrofaunal-sized nematodes

Macrofaunal-sized nematodes (>500 µm) contributed a small amount to total nematode abundance in the upper 5 cm of sediment (1.1 ± 1%; 16 to 110 ind. 10 cm^{-2}) but a considerable amount to total nematode biomass (16 ± 17%), given their large size (Figure 5), with biomass contribution ranging from 0.2% at CL3 to 58% at DBO3.3. Community structure showed no significant spatial pattern (Supplemental Figure 1) but was distinct from the meiofaunal-sized nematodes (ANOSIM R = 0.356, p = 0.0002; Figure 9). However, spatial patterns of taxonomic composition among stations between meiofaunal- and macrofaunal-sized nematodes were significantly related (RELATE test: rho = 0.37, p = 0.0095), suggesting the two communities followed similar spatial patterns.

The most abundant macrofaunal-sized nematode genus at most stations was either *Paramonohystera* or *Sabatieria*, with exceptions at DBO2.2 (*Cephalanticoma* and *Mesacanthion*) and CL1 (*Setosabatiera)*; Supplemental Table 3). *Paramonohystera* was generally dominant at northern stations, while *Sabatieria* was dominant at the southern Chukchi stations and DBO2.4 (Table 2; Supplemental Table 4).

Of the 67 genera recovered in the meiofaunal size fraction, 45 were not found in the larger fraction, including *Neochromadora* and *Tricoma*, which along with abundant genera contributed to dissimilarity between the two size fractions. Ten genera were only found in the >500 µm size fraction, including *Ledovitia*, *Mesacanthion*, *Symplocostoma*, and *Thalassoalaimus*, and were mainly predators/scavengers (2B) and/or had high c-p scores (3 or 4).

Trophic diversity was lower than that of the meiofaunal nematode assemblage at all stations except CNL5 (Supplemental Table 2). However, as with the smaller size fraction, non-selective deposit feeders (1B) were the dominant feeding type except at DBO2.2, which was dominated by predators/scavengers (2B). Predators/scavengers were also abundant north of Bering Strait (CNL3 and CNL5) and at DBO3.3. At many sites, especially those in Group D, the maturity index was lower in the macrofaunal size fraction compared to the smaller size fraction (Supplemental Table 2), attributed to the high relative abundance of general opportunists (c-p score = 2), such as *Paramonohystera* and *Sabatieria*). Station DBO2.2 also had a high abundance of c-p = 3 and 4.

Discussion

This study is among the first meiobenthic studies in the Pacific Arctic. The most northern portion of our study area overlapped with that of a previous study, which presented abundance

estimates for higher taxonomic levels of meiofauna (>32 µm) down to 10 cm depth (~1200 to 4900 individuals 10 cm^{-2}; Lin et al., 2014) that are somewhat lower than our values of ~1500 to 12000 individuals 10 cm^{-2} for the upper 5 cm. These differences may be due to temporal changes in meiofaunal standing stock during the eight years between sampling events, seasonal differences (June sampling versus July to September sampling), or small-scale spatial variability. Although nematodes accounted for 96.6% of total meiofauna abundance at their shallow stations, the taxonomic and functional diversity of nematodes was not assessed (Lin et al., 2014). Further north in the Northeast Chukchi Sea (NECS), meiofaunal abundance in surface sediments (0-1 cm) was measured as ~90-1300 individuals 10 cm^{-2}, with nematodes accounting for 80.6 to 88% of meiofauna abundance (Hajduk, 2015). We observed higher abundances with 351 to 7322 individuals 10 cm^{-2}. These studies used the same sieve sizes; however, there were many other mythological differences, including sample collection (multi-core versus van Veen grab) and extraction method (decantation versus Ludox extraction).

Four distinct station groups for meiofaunal nematodes

Our study provides the first genus-level characterization and biomass estimates of nematodes in the northern Bering and southern Chukchi Seas. While no significant spatial patterns were detected in the meiofaunal community when examined at the phylum/class level, spatial patterns emerged through higher-resolution analysis of the nematodes identified to genus, demonstrating the value of meiofaunal studies for elucidating ecological patterns. Previous studies have shown that patterns of ecological impact are robust at the species and genus level but are altered at higher levels of taxonomic aggregation (Somerfield and Clarke, 1995). Our study supports this finding.

Four distinct communities of meiofaunal nematodes were identified, occupying different regions of the continental shelves associated with local environmental conditions. **Group A** comprised the Bering shelf stations (DBO2.2 and DBO2.4) within the Chirikov Basin, characterized by sandy sediment and low amounts of labile organic matter in sediments. The Chirikov Basin experiences high-speed flow resulting in low sedimentation rates (Grebmeier, 1993; Lovvorn et al., 2020). The water currents in this region accelerate as they move toward and are constricted by the narrow Bering Strait (Danielson et al., 2014). Notably, the abundance of nauplii at DBO2.4 was nearly five times higher than at any other station, suggesting a recent recruitment event, potentially in response to a pulse of OM following the retreat of the sea-ice edge and subsequent spring bloom. The nematode assemblage in Group A was indicative of a labile food source at the surface. However, while these sites had high abundance and biomass of relatively large-bodied taxa, most of the nematodes were concentrated in the upper 1 cm of sediment and declined rapidly downcore. This pattern has been observed in food-poor environments, where densities are concentrated in the upper sediment layers to access surface food availability (Górska et al., 2014; Lambshead et al., 1995). Group A also had a high relative abundance of predators/scavengers (2B; e.g., *Oncholaimus* and *Viscosia*) in both the meiofauna (18%) and macrofauna (~30-55%) size fractions. In the Northeast Chukchi and Beaufort Seas, these genera and feeding types were also more abundant at sandy nearshore sites compared to other habitats (Mincks et al., 2021). This pattern further suggests a food-limited habitat, where this facultative feeding strategy and greater mobility are advantageous (Baldrighi and Manini, 2015; Sharma and Bluhm, 2010).

Immediately north of the Bering Strait lies station CNL3, the singular station in **Group B**. CNL3 and the station off the coast of Point Hope (DBO3.3; Group D) were the only sites with

gravel (0.9% and 32%, respectively), suggesting these stations may experience hydrodynamic disturbance, such as scouring from strong currents. This disturbance may negatively impact meiofaunal abundance. At DBO3.3, the currents likely speed up as they curve around Point Hope, or the gravel may be caused by ice-rafted debris or ice scouring since this station also has a high portion of silt/clay particles (38%). CNL3 is influenced by constriction of water masses moving through Bering Strait and the deepening topography as the shallow Strait opens onto the Chukchi shelf. The nematode community composition and functional traits at CNL3 also point to a disturbed environment. CNL3 was dominated by non-selective deposit feeders (56%) and general opportunists (c-p = 2), including *Sabatieria*, *Daptonema*, and *Paramonohystera*. *Sabatieria* was the most abundant genus at CNL3 (25%) and is often abundant in disturbed areas, hydrodynamically active sites, or sediments generally under stressed environmental conditions such as low oxygen concentration (Ingels et al., 2011a, 2011b; Mincks et al., 2021). The location downstream of the Bering Strait constriction, sandy and gravelly substrate, and high abundance of *Sabatieria* support the hypothesis of a dynamic and disturbed environment at CNL3. This disturbance is further supported by the high dominance of relatively few families of polychaetes, including the classic opportunist Capitellidae family (Charrier et al. in preparation). *Sabatieria* (37.6%) was the most abundant genera in the upper 1 cm of sediment in the NECS, with the next three most abundant genera being *Daptonema* (10.7%), *Cervonema* (4.5%), and *Dorylaimposis* (3.7%; Mincks et al., 2021). In our study, *Sabatieria* was only the most abundant meiofaunal-sized nematode in Group B, whereas *Daptonema* was highly abundant in groups A, B, and C., and *Cervonema* (CL1, CL3, IL4) and *Dorylaimpsis* (IL4) were only found in Group D which included the northern, coastal stations closest to the NECS, suggesting broader regional patterns that extend beyond our study area and point to the heterogeneous nature of Pacific Arctic benthos.

Group C included three stations in the central Chukchi Sea (CNL5, DBO3.8, and DBO3.6), with muddy sediment and low chloropigment content, but high TOC and TN. Overall, these stations receive large inputs of OM (Feng et al., 2020; O'Daly et al., 2020), which result in high biomass of deposit-feeding macrofauna (Grebmeier et al., 2015) that may subduct this material through feeding activity and bioturbation. The meiofaunal and nematode community in Group C also reflects these large inputs of OM, with high meiofauna abundance in the upper five cm of sediment, especially at DBO3.6 and DBO3.8, and dominance of non-selective deposit feeders (80%) and general opportunists (c-p = 2; 81%) including members of the Xyalidae family and *Sabatieria*. In contrast to the high meiofaunal abundance of small nematodes in Group C, macrofaunal abundance was low at these stations (Charrier et al. in preparation). However, macrofaunal biomass was high and dominated by a few species of large-bodied organisms, particularly bivalves. This abundance and biomass differentiation suggests the meiofauna and macrofauna are responding differently to food input, with meiofauna responding with high abundance and low biomass, while macrofauna respond with low abundance and high biomass.

Group D contained the four coastal Chukchi Sea stations, characterized by muddy sediment with high concentrations of TOC and TN, and evidence of recently deposited phytodetritus at some sites. However, this region is influenced by Alaska Coastal Water, which is generally more nutrient-poor and less productive (Danielson et al., 2017; O'Daly et al., 2020). High C:N ratios and depleted $\delta^{13}C$ values in sediments suggest these relatively large sediment OM pools are partly comprised of refractory terrestrial material or advected particles, which enter the benthic food web in this area (Feder et al., 2007; Iken et al., 2010). This large amount of OM supports high nematode surface abundance and biomass, with meiofaunal abundance 1.7 times

higher at station CL3 than at any other station, although the community also comprised the smallest individuals on average.

The large number of small nematodes (i.e., likely dominated by juveniles) suggests that CL3 recently experienced a recruitment event, potentially in response to the spring bloom. Although other stations had higher sediment chl-a and TOC values, the sediment cores at CL3 had a thin, visible layer of flocculated phytodetritus at the surface (personal observation), suggesting a recent depositional event. Food pulses may be important in regulating nematode size distributions as food inputs can stimulate reproduction (e.g., Ingels et al., 2013). The Pacific Arctic is indeed characterized by large pulses of OM input to the seafloor associated with ice melt and release of ice algae and a strong spring phytoplankton bloom. We sampled these stations shortly after sea-ice retreat and saw evidence of freshly deposited phytodetritus at some of the more northernly stations, likely due to the settlement of the spring bloom. Small organisms, such as meiofauna, respond more rapidly to changes in OM than large organisms and may serve as important indicators of environmental change in these ice-influenced ecosystems.

The nematode and meiofauna communities at Group D stations were representative of assemblages commonly found in muddy locations with high OM. For instance, the most abundant genus was *Halalaimus*, a long, slender nematode that can occupy very fine interstitial space in fine sediments (Sharma et al., 2011). The Desmodoridae family (e.g., *Desmodora* and *Molgolaimus*) was only found at these sites and were also most abundant at muddy stations in the Southern Ocean (Ingels et al., 2006). Kinorhynchs were unique to Group D, and particularly abundant at the muddiest stations CL1, CL3, and IL4, and are generally restricted to muddy sediment with higher OM (Grzelak and Sørensen, 2019; Landers et al., 2019). Overall, these taxa suggest that the muddy substrate and OM quantity at these stations drive community composition.

Group D also had a high trophic diversity index and a high proportion of selective deposit feeders such as *Halalaimus*, *Tricoma*, and *Terschellingia*. Of particular interest is the genus *Terschellingia*, which has been found in abundance in sulphidic, shallow-water habitats and are known to be tolerant of harsh biochemical conditions (Vanreusel et al., 2010). *Terschellingia* is most likely indicative of a shallow redox boundary at Group D sites, corresponding with evidence of a transition from an aerobic microbial community in the upper 1 cm of sediments at these same sites to an anaerobic community below (Walker et al. in preparation).

Meiofauna distributions along the vertical sediment profile across stations groups

The densities of meiofauna generally decline with sediment depth; however, the rate at which this decline occurs can vary. For instance, in the Fram Strait, shallow stations with high food availability on the upper slope exhibited a gradual decrease in meiofauna density with increasing sediment depth, whereas at deeper stations with low food availability, meiofauna densities decreased rapidly to low levels with increasing sediment depth (Górska et al., 2014). Similar trends have been found at continental slope and abyssal sites (Lambshead et al., 1995; Vanaverbeke et al., 1997). These patterns of the vertical distribution of meiofauna in relation to food input align with the patterns we observed in the Pacific Arctic. Meiofauna abundance decreased slowly with sediment depth at the muddy, coastal Chukchi stations (Group D) characterized by high OM inputs and declined more rapidly at the sandy Bering Sea stations with low OM (Group A).

The vertical distribution of meiofauna can also be impacted by other factors such as predation, bioturbation, and downcore movement of OM. Although meiofauna are often concentrated in surface sediment, we found four stations with a subsurface peak of meiofauna

abundance at our southern and central Chukchi Sea stations (Groups B and C). Two of these stations also had a subsurface peak of macrofaunal abundance (Charrier et al. in preparation). Other studies have found subsurface peaks in meiofaunal abundance due to surficial predation pressure (Soltwedel et al., 2003), subsurface peaks of food availability due to bioturbation (Galéron et al., 2001), or physical disturbance (Braeckman et al. 2011). The stations in the Chukchi Sea with the subsurface peaks of meiofaunal abundance generally had a large biomass of bivalves at depth. Thus, the peaks are likely due to bioturbation activity and the subduction of OM to depth.

Role of macrofaunal-sized nematodes in the sediment food web

Macrofaunal-sized nematodes are often ignored in both macro- and meiobenthic studies. However, they have been shown to be distinct from meiofaunal nematodes in terms of taxonomic and functional diversity compared to meiofaunal-sized nematodes (Baldrighi and Manini, 2015; Gunton et al., 2017; Sharma et al., 2011). Similarly, we found that the meiofaunal- and macrofaunal-sized nematodes in the Pacific Arctic represent two distinct communities and should both be considered in future benthic studies and ecosystem modeling.

The macrofaunal-sized nematode communities comprised relatively fewer selective deposit feeders (1B) and epistratum feeders (2A) and higher proportions of non-selective deposit feeders (1B) and predators/scavengers (2B) compared to the meiofaunal-sized nematode communities. Indeed, they were dominated by non-selective deposit feeders, such as *Paramonohystera* and *Sabatieria*. *Sabatieria* was also the dominant genus in Arctic deep-sea macrofaunal-sized nematode assemblages (>250 μm), followed by *Viscosia* (Sharma and Bluhm, 2010). *Viscosia* was present at low abundance in only four of our ten samples, suggesting the taxonomic composition of macrofaunal-sized nematode assemblages is not ubiquitously uniform in the region but varies according to local conditions. Predators/scavengers contributed to a larger relative abundance in the macrofaunal-sized nematode samples compared to the meiofaunal-sized nematode samples. In addition, those genera that were exclusively found in the >500 μm communities were mainly predators/scavengers and/or persisters (c-p = 3 or 4), which tend to be larger and thus better represented in this size fraction (Baldrighi and Manini, 2015; Gunton et al., 2017; Sharma and Bluhm, 2010).

These differences in relative proportions of feeding modes between meiofaunal- and macrofaunal-sized nematodes suggest distinct roles in benthic carbon cycling due to the consumption of different food sources. Many of the meiofaunal-sized nematodes are selective feeders, targeting labile food particles such as fresh phytoplankton cells or bacteria. These nematodes likely depend on a constant supply of freshly deposited OM and would be sensitive to changes in food input (Lovvorn et al., 2016), such as a decline in fresh phytoplankton to the seafloor, which has been predicted for the region (Lee et al., 2013; Moore and Stabeno, 2015). In contrast, non-selective deposit feeders that dominate the macro-sized communities may be utilizing more refractory or reworked material that would go unconsumed and buried in their absence, and additionally are possibly making it more available to other organisms. These taxa may be buffered against declines in the input of fresh phytodetritus to the seafloor through consumption of a sediment food bank of OM (Mincks et al., 2005; Pirtle-Levy et al. 2009). In addition, the predators/scavengers prevalent in macro-sized nematode communities can consume other meiofaunal organisms or the juveniles and scavenged remains of macrofaunal organisms, adding a trophic pathway to sedimentary systems that goes unnoticed when the larger nematodes are ignored. Predators/scavengers were particularly abundant in sandier locations, potentially

because their facultative feeding type and higher mobility are successful strategies for food-limited habitats (Baldrighi and Manini, 2015; Sharma and Bluhm, 2010).

In addition to representing a unique component of the benthos in terms of taxonomic composition and ecosystem function, macrofaunal-sized nematodes contributed substantially to benthic abundance and biomass, and hence benthic carbon cycling. While they only represented 1% of total nematode abundance (16-110 individuals 10 cm^{-2} in the upper 5 cm of sediment; similar to values reported by Gunton et al., (2017)), they accounted for 16% of total nematode biomass, with a high of 58% at DBO3.3. This large biomass and their unique role in the benthic food web imply that macrofaunal-sized nematodes are a critical component of the Pacific Arctic benthic ecosystem and merit more in-depth research. Meiofaunal and macrofaunal studies that do not consider macrofaunal-sized nematodes are ignoring the ecological role they play given their unique set of functional traits, as well as the role of these large infaunal organisms with rapid turnover times in carbon cycling at the seafloor.

Macrofaunal-sized nematodes were also an important component of macrofauna, especially in terms of abundance. They composed an average of 82% ± 17% (ranging from 48% at DBO2.2 to 96% at DBO3.6 and DBO3.8) of total macrofaunal abundance in the upper 5 cm of sediment (macrofaunal data from Charrier et al. in preparation), and 3% ± 8% (ranging from 0.002% at CL3 to 26% at IL4) of macrofaunal biomass in the surface sediment. This contribution of nematodes to total macrofaunal abundance is high compared to other studies. In the Whittard Canyon, nematodes only accounted for up to 15% of total macrofaunal abundance for the upper 5 cm of sediment (Gunton et al., 2017) and between 16-40% at deep-sea sites in the Mediterranean Sea (>300 μm for upper 20 cm; Baldrighi and Manini, 2015). However, these studies counted nematodes in macrofaunal samples that were live sieved prior to preservation, while our estimates were for samples that were sieved after preservation. Sieving live reduces retention of many taxonomic groups of macrofauna, especially soft-bodied, motile polychaetes (Degraer et al., 2007). Indeed, nematode counts from our macrofauna samples that were sieved live yielded estimates of only 28% ± 19% of total macrofauna abundance, which is nevertheless a significant contribution. This discrepancy highlights the well-known potential for methodological bias when comparing results among studies.

Conclusions

The Pacific Arctic is experiencing rapid environmental change (Baker et al., 2020; Huntington et al., 2020), including warming temperatures, declining sea ice, and changes in the timing and magnitude of pelagic production (Arrigo and van Dijken, 2015; Huntington et al., 2020; Ringuette et al., 2002; Selz et al., 2018; Wang and Overland, 2015). These environmental changes impact benthic biomass distribution and community structure (Goethel et al., 2019; Grebmeier, 2012; Moore et al., 2018; Waga et al., 2020), with likely alterations in benthic carbon cycling (Jones et al., 2021). To predict potential impacts of future environmental change on ecosystem structure and function, ecosystem models must be well-constrained and representative of the current ecosystem. However, most benthic research in the Pacific Arctic has focused on the macro- or epibenthos (e.g., Bluhm et al., 2009; Grebmeier et al., 2015), even though meiofauna play critical roles in ecosystem functioning (reviewed in Schratzberger and Ingels, 2017) and achieve high densities in other marginal ice zones (Górska et al., 2014). Due to a lack of available meiofauna data, modeling studies have utilized meiofauna community metrics from other regions (Lovvorn et al., 2016; Nelson et al., 2014). Our study shows four distinct regional benthic communities (using nematodes as a representative component) in the Bering and Chukchi Seas,

providing insight into the heterogeneous nature of the Pacific Arctic sedimentary ecosystem, its distinct communities, and the environmental drivers that shape them. Additionally, the four meiofaunal-sized nematode assemblages identified in our study align well with clusters of stations identified based on polychaete functional guilds (Charrier et al. in preparation), reinforcing the distinctiveness of these "eco-regions."

The data presented here provide critical baseline community metrics for meiofauna in the region, with abundance, biomass, and community structure and function data that can serve as a baseline to assess the impact of environmental change and inform regional ecosystem models. Although more research is needed to better understand the community taxonomic and functional dynamics in the Arctic, particularly across a larger spatial scale and increased temporal resolution, our results suggest the need for small-scale sub-region ecosystem modeling units within the greater Pacific Arctic region. Our research also shows that the size-based separation for infauna (meiofauna versus macrofauna) and the traditional taxonomic focus by scientists within each group leads to exclusion of a benthic component, the macrofauna-sized nematodes, that represent a significant amount of biomass and abundance, and a distinct trophic signature. Future field, experimental, and modeling studies should take into account the potential bias when excluding macrofaunal-sized nematodes and assess their contribution to benthic ecosystem diversity and function.

Acknowledgments

This research was part of the Arctic Integrated Ecosystem Research Program (IERP; http://www.nprb.org/arctic-program/). This manuscript is Publication ArcticIERP-XX. Funding for the program was provided by the North Pacific Research Board, U.S. Bureau of Ocean and Energy Management, Collaborative Alaskan Arctic Studies Program, and U.S. Office of Naval Research. Generous in-kind support for the program was contributed by the U.S. National Oceanic Atmospheric Administration Alaska Fisheries Science Center and Pacific Marine Environmental Laboratory, University of Alaska Fairbanks, U.S. Fish and Wildlife Service, and U.S. National Science Foundation. Funding was also provided by the North Pacific Research Board Graduate Student Research Award and the University of Alaska Dissertation Completion Fellowship. We would like to thank the Captain and crew of the *R/V Sikuliaq* for making sampling possible and Opik Ahkinga, Silvana Gonzalez, and Andrew Thurber for help with sample collection. We would also like to thank Tibor Dorsaz and Alexis Walker for lab assistance, Timothy Howe and others at the Alaska Stable Isotope Facility, and Seth Danielson, Amanda Kelly, and Andrew Thurber for their valuable input and guidance.

Table 2: Relative abundance (%) of the most abundant (>1%) nematode genera per group (0-1 cm sediment layer) for the (a) 63-500 µm and (b) >500 µm size fractions. Groups are based on hierarchical agglomerative clustering and similarity profile test of meiofaunal-sized communities (SIMPROF; Figure 3). Genera highlighted in bold in table (a) contributed >70% to within group similarity based on Similarity Percentages (SIMPER) procedure (Note: Group B only contained one station so a SIMPER could not be performed for this group).

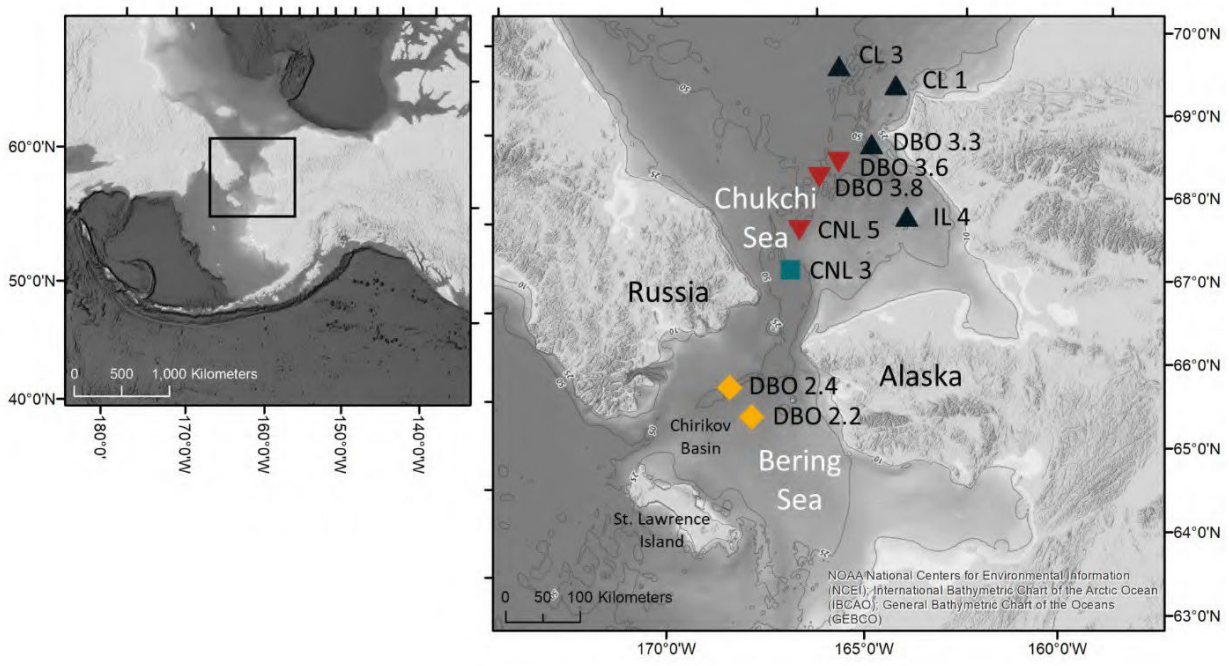

Figure 1: Ten sampling locations in the northern Bering and southern Chukchi Seas in 2018. Symbols based on hierarchical agglomerative clustering of 63-500 µm nematode communities from Figure 3. Group A = yellow diamonds; Group B = blue square; Group C = red inverted triangles; Group D = black upright triangles.

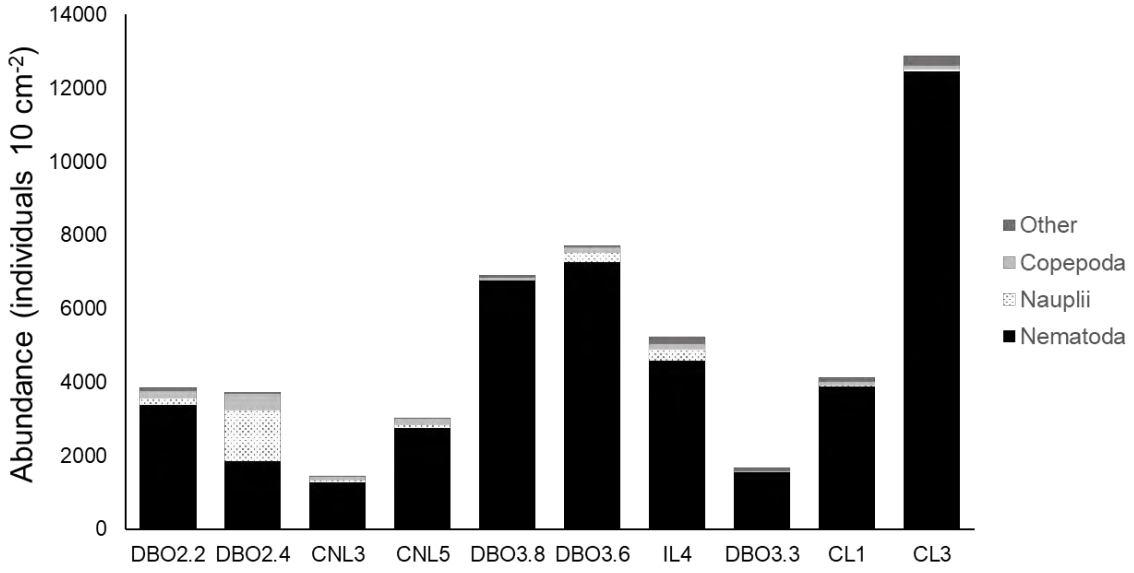

Figure 2: Meiofaunal abundance (ind. 10 cm^{-2}) in the upper 5 cm of sediment at sampling locations on the northern Bering and southern Chukchi Sea continental shelves in 2018.

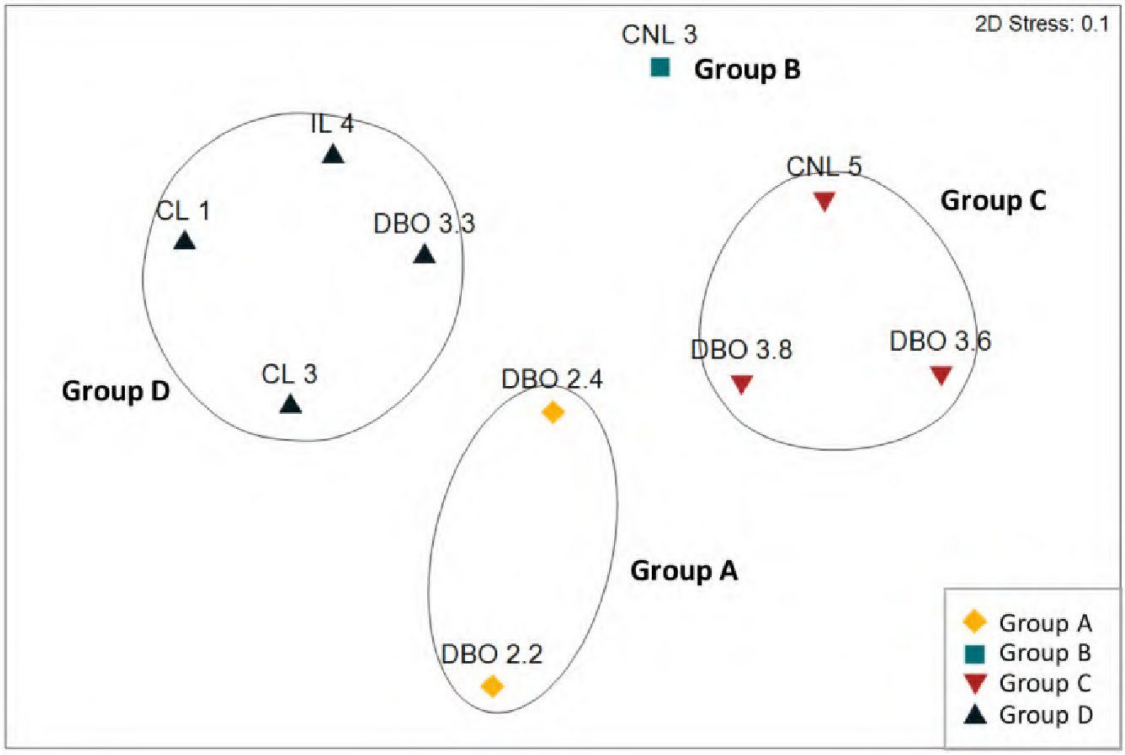

Figure 3: nMDS ordination of meiofaunal-sized (63-500 µm) nematode surface (0-1 cm) community structure (ind. 10 cm^{-2}). Ordination based on hierarchical agglomerative clustering with group-averaged linkage on $\log_{(x + 1)}$ transformed data and Bray-Curtis similarity. Four significant station groupings circled in black or as a singleton station based on the similarity profile test (SIMPROF).

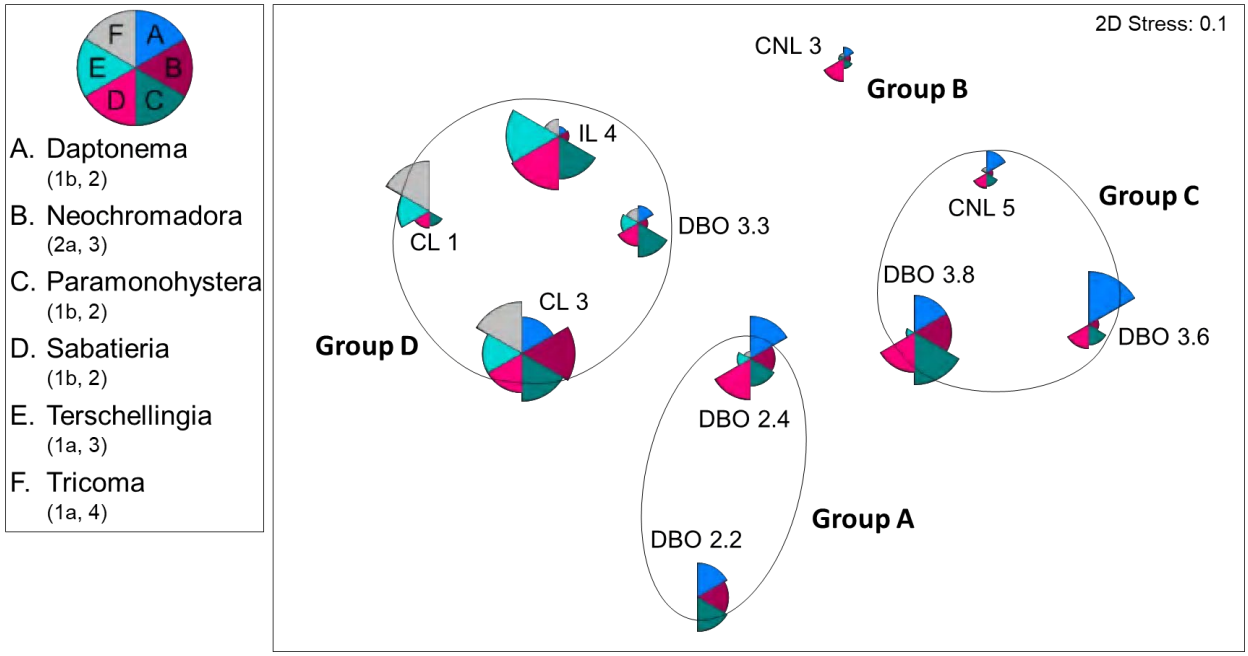

Figure 4: nMDS ordination of meiofaunal-sized (63-500 µm) nematode surface (0-1 cm) community structure (ind. 10 cm^{-2}). Ordination based on hierarchical agglomerative clustering with group-averaged linkage on $\log_{(x + 1)}$ transformed data and Bray-Curtis similarity. Four significant station groupings circled in black or as a singleton station based on the similarity profile test (SIMPROF). Pie slices represent the abundance of nematode genera that are in the top three guilds contributing to within-group similarity in at least one group based on Similarity Percentages (SIMPER) procedure. Feeding type and c-p score of genera in parentheses.

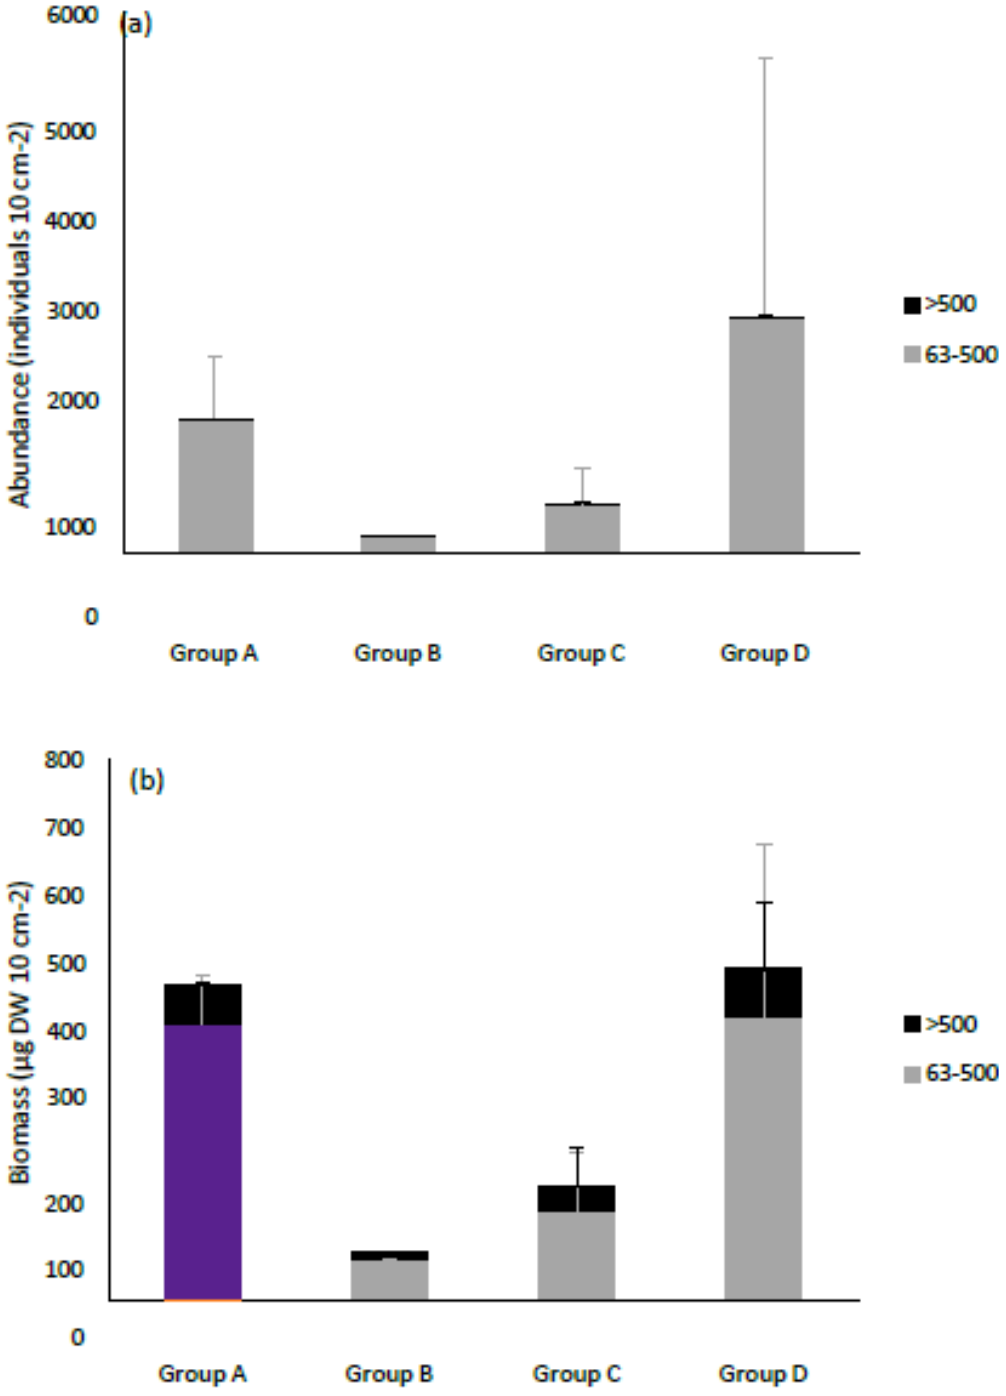

Figure 5: Average meiofaunal-sized and macrofaunal-sized nematode (a) abundance (ind. 10 cm^{-2}) and (b) biomass (µg DW 10 cm^{-2}) in surface sediments (0-1cm) for each group. Groups are based on hierarchical agglomerative clustering and similarity profile test (SIMPROF; Figure 3).

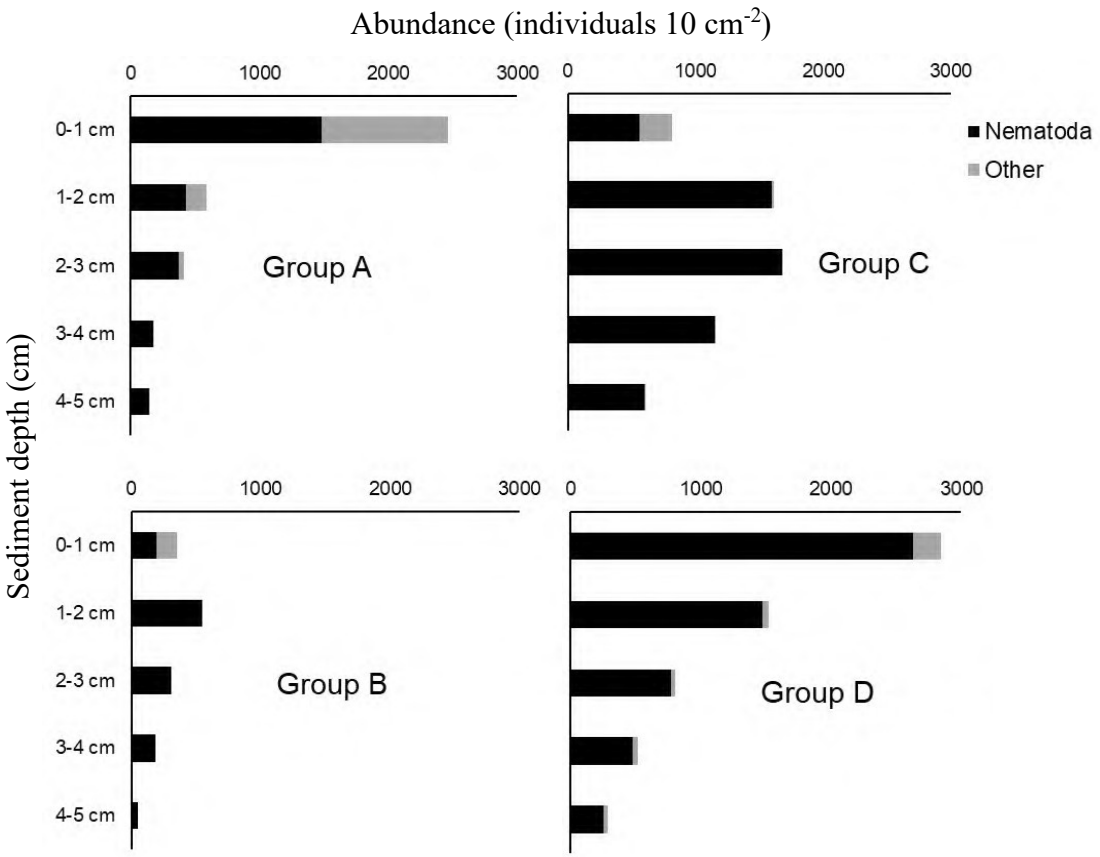

Figure 6: Abundance (individuals $10cm^{-2}$) of nematodes (63-500 µm; black) and other meiofauna (gray) for each sediment depth and group. Groups are based on hierarchical agglomerative clustering and similarity profile test (SIMPROF; Figure 3).

Figure 7: dbRDA displaying the relationship between nematode (63-500 µm) community structure for the upper 1 cm of sediment and environmental correlates. The selected model accounted for 97.2% of total variation.

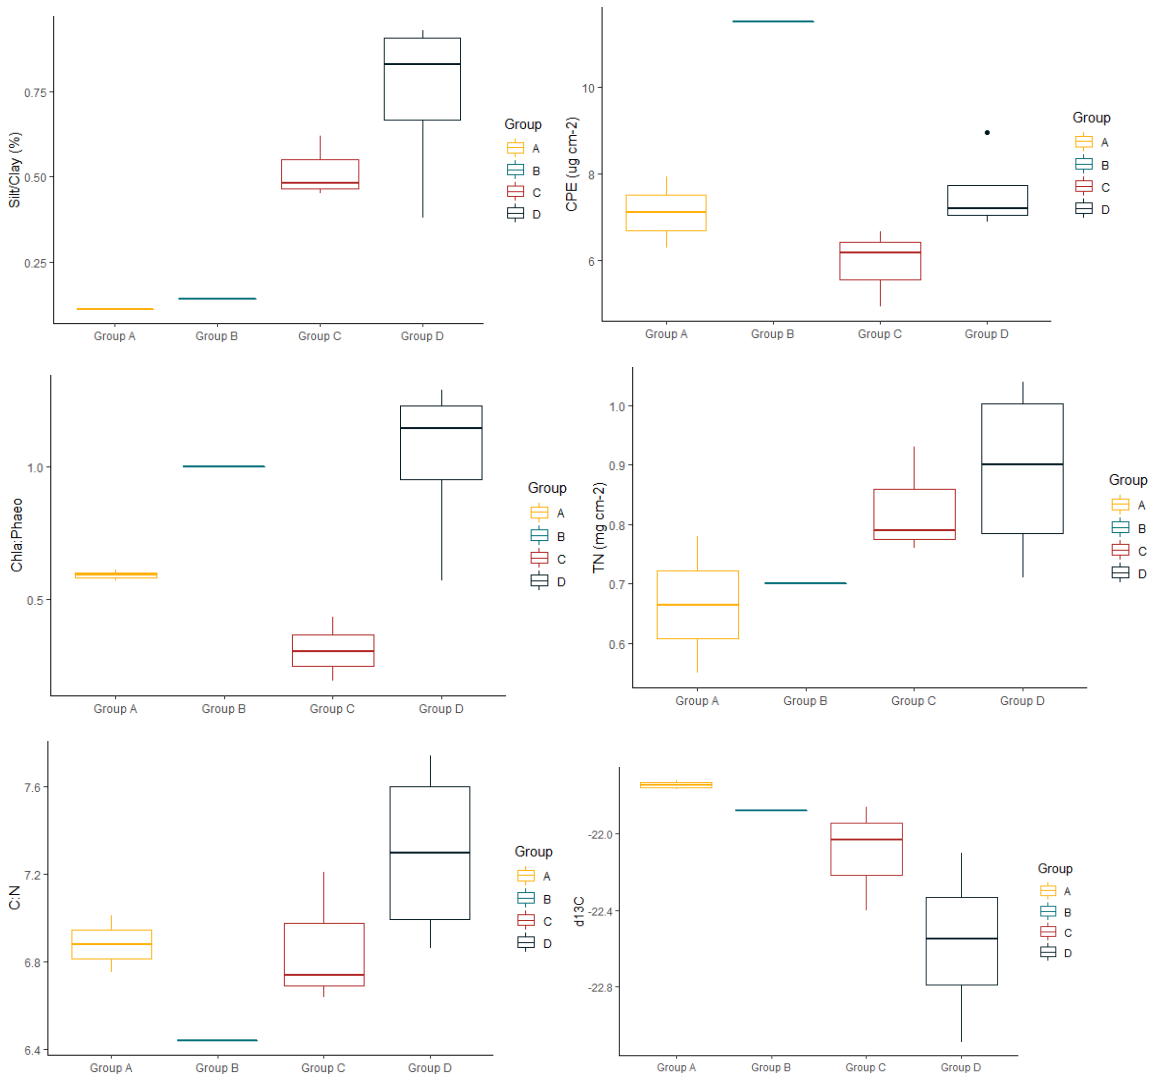

Figure 8: Boxplot of environmental parameters for each group including percent silt/clay (%) and CPE (ug cm^{-2}), chl-a:phaeo, TN (mg cm^{-2}), C:N, and $\delta^{13}C$ for the upper 1 cm of sediment. Groups are based on hierarchical agglomerative clustering and similarity profile test (SIMPROF; Figure 3).

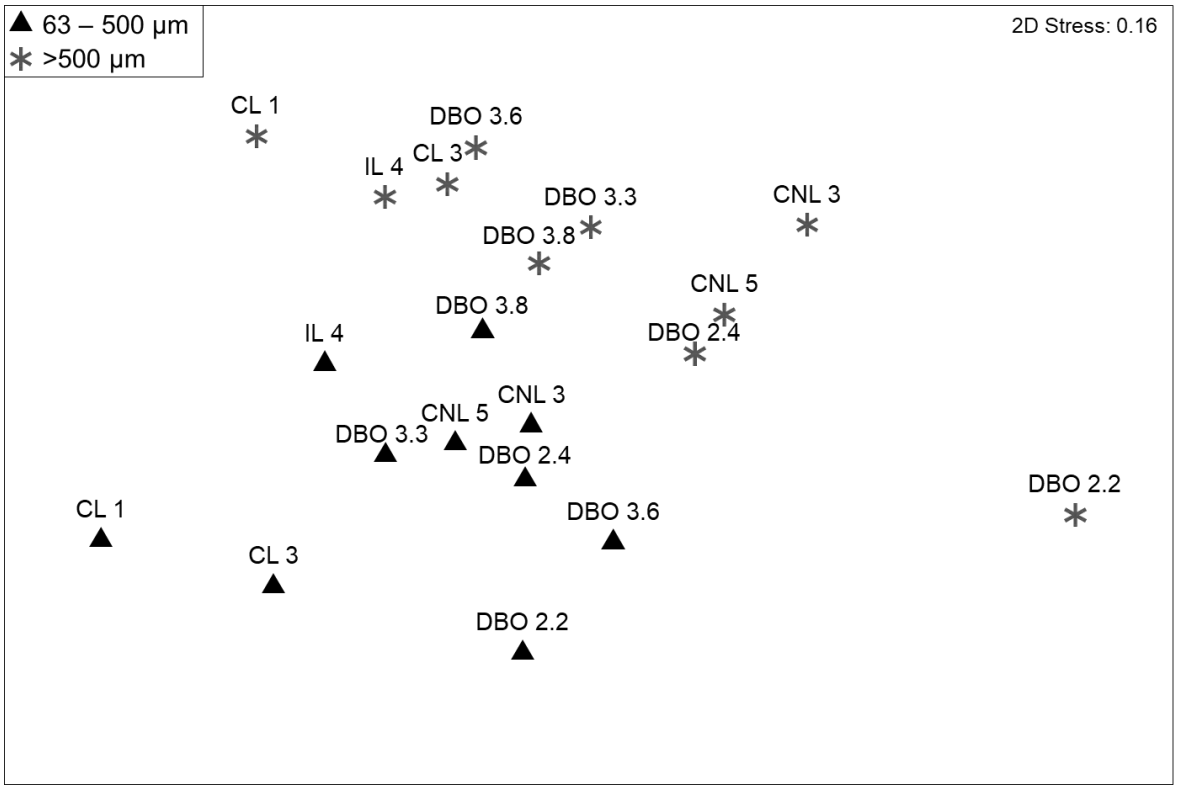

Figure 9: nMDS ordination of meiofaunal- and macrofaunal-sized nematode relative abundance of surface sediment (0-1 cm). Ordination based on hierarchical agglomerative clustering with group-averaged linkage on $\log_{(x + 1)}$ transformed relative abundances and Bray-Curtis similarity. The two size fractions were significantly different (ANOSIM R = 0.356, p = 0.0002). Black triangles are 63-500 µm samples and gray stars are >500 µm sample.

Changes in species composition and biomass of Arctic benthic communities are predicted to occur in response to environmental changes associated with oceanic warming and sea-ice loss. Such changes will likely impact ecosystem function, including flows of energy and organic material through the Arctic marine food web. Oxygen consumption rates can be used to quantify differences in metabolic demand among species and estimate the effects of shifting community structure on benthic carbon consumption. Closed-system respirometry using non-invasive oxygen optodes was conducted onboard the *R/V Sikuliaq* in June 2017 and 2018 on six dominant species of benthic macrofauna from the northern Bering and southern Chukchi Sea shelves, including five bivalve species (*Macoma* sp., *Serripes groenlandicus*, *Astarte* sp., *Hiatella arctica* and *Nuculana pernula*) and one amphipod species (*Ampelisca macrocephala*). Results revealed species-specific respiration rates with high metabolic demand for *S. groenlandicus* and *A. macrocephala* compared to that of the other species. For a hypothetical 0.1-g ash-free dry mass individual, the standard metabolic rate of *S. groenlandicus* would be 4.3 times higher than that of *Astarte* sp. Overall, carbon demand ranged from 8 to 475 µg C individual^{-1} day^{-1} for the species and sizes of individuals measured. The allometric scaling of respiration rate with biomass also varied among species. The scaling coefficient was similar for *H. arctica*, *A. macrocephala* and *Astarte* sp., while it was high for *S. groenlandicus* and low for *Macoma* sp. These results suggest that observed shifts in spatial distribution of the dominant macrofaunal taxa across this region will impact carbon demand of the benthic community. Hence, ecosystem models seeking to incorporate benthic system functionality may need to differentiate between communities that exhibit different oxygen demands.

Key words: Bivalves, macrofauna, metabolism, oxygen consumption, Pacific Arctic, respiration

Introduction

Climate change is impacting Arctic marine ecosystems at a rapid pace. Warming temperatures and declining sea ice (IPCC, 2014; Wang and Overland, 2015; Huntington *et al.*, 2020) are resulting in ecosystem-wide changes in the timing and magnitude of primary production (Arrigo and van Dijken, 2015; Selz *et al.*, 2018), secondary production (Ringuette *et al.*, 2002), the strength of pelagic–benthic coupling (Grebmeier *et al.*, 2006; Moore and Stabeno, 2015)

and benthic community structure and function (Grebmeier *et al.*, 2018). These changes are likely to affect metabolic demand of Arctic marine invertebrates and, in turn, the cycling of organic matter in sediments and subsequent exchanges with the water column.

Oxygen consumption rates (MO_2) provide an estimate of metabolic activity in aerobic organisms and serve as a proxy for organic matter consumption and energy flow through the benthic food web. Metabolic rates vary among individuals due to a variety of factors, including developmental stage (Yagi *et al.*, 2010), age (Sukhotin and Pörtner, 2001; Glazier *et al.*, 2015) and body size (Kleiber, 1932). For instance, MO_2 increases with body size in a relatively predictable manner described by the '3/4-power law', wherein the relationship between MO_2 and body size is quantified by a metabolic scaling coefficient of ~0.75 (Kleiber, 1932); however, many exceptions have been reported (reviewed by Glazier, 2005). In addition to physiological differences among individuals and species, MO_2 also varies with environmental factors, such as temperature (Peck *et al.*, 2002; Clarke and Fraser, 2004; Trigos *et al.*, 2015), pH (Liu and He, 2012; Saavedra *et al.*, 2018) and food availability (Brockington and Clarke, 2001; Sejr *et al.*, 2004). Many of these environmental conditions have already changed or are projected to change under future climate scenarios (IPCC, 2014), potentially resulting in alterations to benthic biomass, taxonomic composition and carbon demand.

Estimates of whole sediment-community oxygen consumption rates are available across the Arctic (reviewed in Bourgeois *et al.*, 2017; Grebmeier *et al.*, 2006). However, MO_2 rates of individual species have rarely been reported for the region (Vahl, 1978; Opalinski and Weslawksi, 1989; Sejr *et al.*, 2004; Goethel *et al.*, 2017), hampering efforts to predict how changes in species composition may impact benthic carbon processing rates and ecosystem function (Grebmeier, 2012). In the Pacific Arctic region, the Bering and Chukchi Seas overlie a shallow inflow shelf influenced by distinct water masses: cold, nutrient-rich Anadyr-Bering Sea Water and warm, more nutrient-poor Alaska Coastal Water (Daniel- son *et al.*, 2017). Flows accelerate through the Bering Strait constriction (Danielson *et al.*, 2014), promoting energetic mixing that locally enhances pelagic primary productivity (Walsh *et al.*, 1989). Downstream of this constriction, the current speeds decline, allowing pelagic production and particle flux to settle to the seafloor (Grebmeier *et al.*, 2015b). Such dynamic oceanographic conditions result in a patchy distribution of benthic organisms, with ecologically important hotspots of high benthic biomass up to 32 g C m^{-2} in the Chirikov Basin and southeast Chukchi Sea (Grebmeier *et al.*, 2015b). These hotspots serve as persistent feeding grounds for marine mammals (Fay, 1982) and birds (Lovvorn *et al.*, 2003). Overall, the benthos accounts for a substantial portion of the total food web production in these regions (Walsh *et al.*, 1989), dominated by infaunal bivalves and amphipods (Feder *et al.*, 1994; Grebmeier *et al.*, 2015b).

We quantified metabolic rates of dominant macrofaunal benthos from the northern Bering and southern Chukchi Sea shelves by measuring oxygen consumption rates in laboratory incubations. Experiments were conducted using five bivalve species (*Macoma* sp., *Serripes groenlandicus*, *Astarte* sp., *Hiatella arctica* and *Nuculana pernula*) and one amphipod species (*Ampelisca macrocephala*). These species exhibit diverse life-history strategies and functional traits. For instance, *Astarte* sp., *H. arctica* and *S. groenlandicus* are all suspension feeders, while *N. pernula* is a deposit feeder and *Macoma* sp. is a facultative feeder, capable of switching between deposit and suspension feeding. *Ampelisca macrocephala* is primarily a suspension feeder but can supplement its diet by deposit feeding or consuming small crustaceans. MO_2 was measured for multiple individuals of each species, spanning a range of body sizes in order to establish metabolic scaling relationships for each taxon. Overall, we found species-specific respiration rates and differences in metabolic scaling, which have implications for benthic carbon demand particularly considering altered environmental conditions and shifting species assemblages.

Methods

Sampling

Macrofauna were collected from the northern Bering and southern Chukchi Seas from 13–24 June 2017 and 9–22 June 2018 from the *R/V Sikuliaq* as part of the Arctic Shelf Growth, Advection, Respiration and Deposition (ASGARD) project (Fig. 1, Table 1). Macrofauna were selected from four sampling stations in 2017 and ten stations in 2018 with an average depth of 50 m (ranging from 39 to 59 m). Near-bottom water temperature at sampling location was 2.8 ± 0.7 °C in 2017 and 1.3 ± 0.8 °C in 2018 (Table 1).

Individuals were selected from plumb-staff beam trawl, multi-core (MC-800, Ocean Instruments, San Diego) and 0.1-m^2 Van Veen grab samples. Experiments conducted in 2017 included the bivalves *Macoma* sp. (mostly *M. calcarea*; four small individuals only identified to genus level) and *S. groenlandicus* (Table 1). In 2018, experiments were conducted for additional *Macoma* sp. (one individual only identified to genus) and *S. groenlandicus,* as well as the bivalves *Astarte* sp. (mostly *A. montagui*; one identified only to genus), *N. pernula*, *H. arctica* and the amphipod *A. macrocephala*.

Respirometry

Closed-system respirometry was performed in a temperature-controlled room onboard the *R/V Sikuliaq*. Non-invasive oxygen optodes (PSt3 oxygen sensor spots; PreSens Precision Sensing GmbH, Germany) were used to measure oxygen concentration inside incubation chambers (Gatti *et al.*, 2002). The sensor spots measure oxygen concentration based on the dynamic fluorescence quenching of a luminophore contained in a polymer matrix and have a detection limit of 0.03% oxygen (15 ppb dissolved oxygen). Factory calibration was

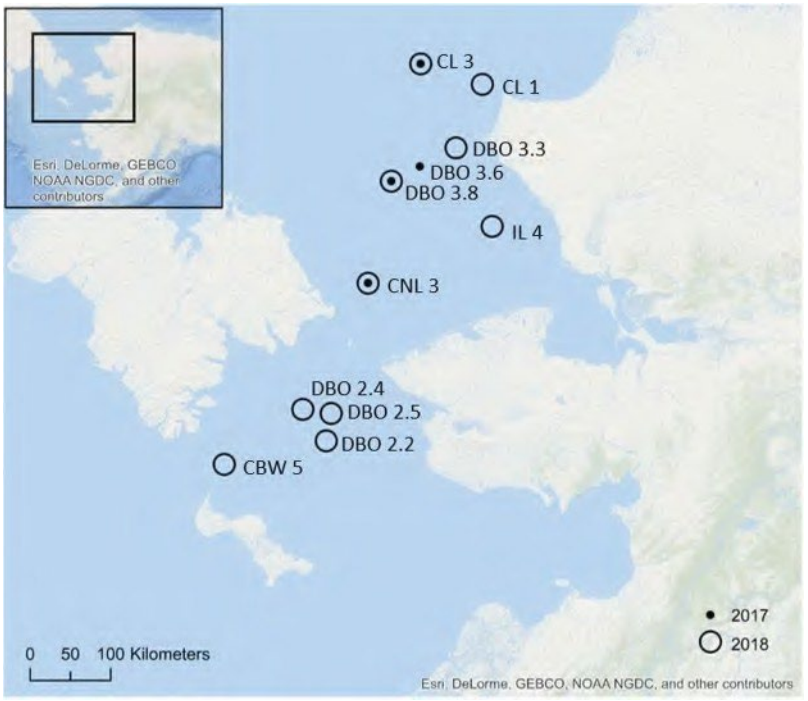

Figure 1: Sampling locations in the northern Bering and southern Chukchi Sea shelves with 2017 in closed circles and 2018 in open circles.

used for new sensor spots purchased in 2017 and 2018. For sensor spots that had been used and stored for a year between field seasons, a two-point calibration was performed per manufacturer's instructions. An aquarium bubbler was used to produce a solution of 100% oxygen air saturation, and a solution of 0% saturation was produced using sodium sulfite and cobalt nitrate (1 g Na_2SO_3 and 50 µL of $Co(NO_3)_2$ dissolved in 100 mL of reverse osmosis water to achieve $\rho(Co) = 1000$ mg L^{-1}; in nitric acid 0.5 mol L^{-1}).

Prior to the start of each experiment, organisms were rinsed with 0.2-µm filtered seawater and bivalve shells were gently scrubbed with a toothbrush to remove microbial films. Each individual was acclimated to experimental conditions by placing it in an incubation chamber submerged in a water bath, which consisted of a plastic tote filled with 0.2-µm filtered seawater aerated with an aquarium bubbler. The temperature-controlled room was set to a target experimental temperature of 0 °C, but recorded temperatures of the seawater baths averaged 0.6 ± 0.3 °C (standard deviation) in 2017 and 0.9 ± 0.2 °C in 2018. Chambers of various sizes (3.7-, 20-, 60-, 120- and 180-ml glass jars) were used to accommodate different sized individuals such that the estimated body volume of each organism did not exceed ~10% of the chamber volume. After organisms were acclimated to experimental conditions for 12 to 24 hours to minimize stress response, each chamber was sealed ensuring no air bubbles were trapped and re-immersed in a water bath to maintain a constant temperature. Organisms were not fed during the acclimation period or incubations to avoid postprandial effects on metabolic rate (Chapelle *et al.*, 1994). Therefore, these measurements of MO_2 estimate the lower bound of carbon consumption for these organisms, given that metabolic rates typically increase following feeding (i.e. a postprandial effect; Brockington and Clarke, 2001; Sejr *et al.*, 2004). In addition, the species inhabit different sediment depths and exhibit different burrowing behaviours *in situ*, which may have influenced species-specific responses to incubation conditions in the absence of sediment for burrowing.

For each incubation, three control chambers (0.2-µm filtered seawater only) of each chamber size were incubated in the water bath alongside the experimental chambers containing organisms. Oxygen concentration of each chamber was measured every 10 to 60 minutes. Average initial oxygen concentration in all incubations was 344.7 µmol O_2 L^{-1} (ranging from 310.9 to 371.8 µmol O_2 L^{-1}). The incubation of each individual chamber was terminated when oxygen concentration declined by ~20% of the initial concentration. For some individuals, the target ratio of body volume:chamber volume was exceeded and oxygen levels declined too rapidly to ensure high-quality data; therefore, data were discarded for incubations lasting less than 1.75 hours. Incubations lasted on average 8.2 hours (ranging from 1.8 to 13.1 hours). In 2017, incubations were repeated three times per individual in order to quantify the variability in respiration rate within an individual. Replicate incubations took place on successive days, and between experiments the organisms were held without

food in open experimental chambers submerged in the aerated water bath. The respiration chambers were sealed with freshly filtered and aerated seawater for each new incubation. In 2018, triplicate incubations were only performed for a subset of individuals from taxa that were not sampled the previous year.

After incubations, bivalve length was measured at the longest part of the shell (Table 2). Length was not measured for amphipods. Organisms were then individually frozen whole at −80 °C. Samples were transported to the laboratory at the University of Alaska Fairbanks and stored at −20 °C for further analysis. Wet mass was measured on thawed, whole organisms. The volume of water in each chamber was determined based on mass measurements. The thawed organism was placed in its original incubation chamber filled with freshwater, and the mass was determined. The mass of water in each chamber was calculated as the mass of the chamber + organism subtracted from the mass of the chamber + organism + water. This water mass was then converted to water volume using a conversion of 1 mL equals 1 g.

Dry mass of each individual was determined by drying at 60 °C until constant mass was achieved. Ash-free dry mass (AFDM) was measured by igniting each individual at 500 °C for 6 hrs. For amphipods, dry mass and AFDM were measured on whole individuals. For bivalves, the soft tissue was removed from the shell and dry mass and AFDM were measured for the soft tissue only.

Data analysis

The linear regression of wet mass versus AFDM was calculated on log-transformed data for all bivalve species taken collectively and for *A. macrocephala* individually, allowing metabolic rates measured here in terms of AFDM to be applied to published estimates of wet biomass from other field studies. Regressions were then expressed as power functions to represent the original data displayed on a log–log scale.

Respiration rates of individuals are typically altered during an initial period of acclimation to the sealed chamber due to handling stress, and the length of this period is variable (Peck and Conway, 2000). The data trend during this acclimation period typically has a different slope than the rest of the incubation. The acclimation period for each individual was thus identified and removed by detecting a breakpoint in the broken-line slope of the linear regression model using a bootstrapped approach, as implemented in the segmented function from the segmented package in R (Muggeo, 2008). Outliers were also identified and removed when standardized residuals were less than −2 or greater than +2. The oxygen consumption rate (MO_2; μmol O_2 L^{-1} min^{-1}) of each individual was then calculated from the linear regression of oxygen concentration versus time. When oxygen concentration significantly changed in the controls, the average rate of the three controls was subtracted from the measured macrofaunal rates of the same incubation to account for background respiration (e.g. by bacteria) or background production. The average rate of change of oxygen concentration in controls was −0.002 μmol O_2 L^{-1} min^{-1} (ranging from −0.015 to +0.013 μmol O_2 L^{-1} min^{-1}).

Rates were converted to μmol O_2 hr^{-1} based on the volume of water contained in each incubation chamber. To model the relationship between MO_2 and AFDM, regressions were calculated on log-transformed data for each taxonomic group:

$$\log MO_2 = b * \log M + \log a,$$

where MO_2 is the respiration rate (standard metabolic rate), b is the slope, M is the AFDM and log a is the y-intercept. The y-intercept (log a) is the metabolic constant and reflects differences in the magnitude of the respiration rate among species. The slope (b) is the metabolic scaling coefficient, relating respiration rate to biomass. Regression equations were then expressed as a power function to represent the original data plotted on a log–log scale:

$$MO_2 = aM^b,$$

where a is the y-intercept at x = 1 on the log–log scale, M is the AFDM and b is the slope. To estimate carbon consumption required to support standard metabolic demand, MO_2 was converted to units of carbon respired (μg C $individual^{-1}$ day^{-1}) based on a respiratory quotient of 0.8 (Witte and Graf, 1996; Ke¸dra *et al.*, 2010).

Mass-specific metabolic rates were calculated by dividing the oxygen uptake rate of each individual by its respective AFDM. Linear regressions on log-transformed data were also calculated for the relationship between mass-specific oxygen uptake rate and AFDM for each taxonomic group and expressed as a power function.

Differences in the intercepts and the slopes of the linear models among species and between years were examined with analysis of covariance (ANCOVA) and Tukey's post hoc test. All analyses were performed in R Studio, and the glht function from the multcomp package was used for Tukey's post hoc (Hothorn *et al.*, 2008). For all comparisons, $\alpha = 0.05$.

Ratios of average measured body length (our study) to maximum length achievable in the field (from the literature) were also calculated to illustrate the potential relationship between metabolic demand and age.

Results

Wet mass and AFDM were strongly related for all bivalve species taken collectively and for *A. macrocephala* individually; therefore, oxygen uptake rates are presented relative to AFDM. The mass conversion relationship was $y = 0.09x^{1.00}$ ($n = 75$, $R^2 = 0.95$, $P < 0.001$) for bivalves (Supplementary Figure 1a) and $y = 0.14x^{0.69}$ ($n = 14$, $R^2 = 0.90$,

Table 2: Power functions of oxygen uptake rate (μmol O_2 h^{-1}) versus ash-free dry mass (g) for taxonomic groups incubated in both years with the R^2, *P*-values and number of individuals (N) associated with each regression; range of maximum length of individuals incubated in each group (mm); average length of incubated individuals (mm ± standard deviation); maximum achievable length (mm) measured in the field taken from the literature; average length to maximum achievable length ratios; average coefficient of variation (CV ± standard deviation) of oxygen uptake rates (MO_2; μmol O_2 h^{-1}) for individuals incubated in triplicate with number of individuals in parentheses; and average mass-specific MO_2 (μmol O_2 hr^{-1} g^{-1} ± standard deviation)

*(Madsen, 1949; Lubinsky, 1980; Hutchings and Haedrich, 1984; Schaefer et al., 1985; Sejr et al., 2002; Kilada et al., 2007; Sejr and Christensen, 2007)

$P < 0.001$) for *A. macrocephala* (Supplementary Figure 1b), where y is AFDM (g) and x is wet mass (g). Replicate incubations conducted with the same individuals showed little variability in MO_2 based on low coefficients of variation (CV; Table 2), with no consistent increasing or decreasing trend in MO_2 over the three days of incubations.

Macoma sp. and *S. groenlandicus* were incubated in both years, with slight differences in the average incubation temperature (0.6 ± 0.3 °C in 2017 and 0.9 ± 0.2 °C in 2018). The slopes ($F_{1,22} = 0.09$, $P = 0.77$) and intercepts ($F_{1,23} = 1.01$, $P = 0.32$) of the regression relationships relating MO_2 and AFDM were not significantly different between years for *S. groenlandicus* (Fig. 2), indicating no interannual variation, even with the small difference in temperature. Therefore, a single regression is reported for *S. groenlandicus* (Table 2). The slopes ($F_{1,22} = 1.33$, $P = 0.26$) for *Macoma* sp. were not significantly different between years; however, the intercepts ($F_{1,23} = 21.30$, $P < 0.001$) were significantly higher in 2018 compared to 2017 and separate regression relationships are reported for each year (Table 2). For *Macoma* sp., we thus present the regression relationships for each year separately, as well as the pooled 2017 and 2018 data which provides an average value for ease of comparison among species.

There were significant differences in the slopes ($F_{5,81} = 4.47$, $P = 0.001$) and intercepts ($F_{5,86} = 43.40$, $P < 0.001$) for the regressions relating MO_2 and AFDM (Fig. 3a) for all six species (pooled among years). The slope of *S. groenlandicus* was significantly higher than that of *Astarte* sp., *Macoma* sp., *H. arctica* and *N. pernula* (Table 3). Although the slope of *A. macrocephala* (0.77) was lower than that of *N. pernula* (0.81) and the same as that of *Astarte* sp., the standard error of the parameter estimate for *A. macrocephala* was high (0.06), likely reducing the discriminatory power of the post hoc test. The difference was greatest between the slopes of *Macoma* sp. and *S. groenlandicus*, both of which deviated from the ¾- power law for metabolic scaling coefficients (Table 2). The post hoc test showed the intercept of *S. groenlandicus* was significantly higher than that of the other 5 species (Table 4). Over the range of sizes of individuals incubated, MO_2 of *S. groenlandicus* was consistently higher than that of *A. macrocephala*, *H. arctica*, *N. pernula* and *Astarte* sp. (Fig. 3). The intercept for *A. macrocephala* was significantly higher than that of *Macoma* sp., *Astarte* sp. and *N. pernula* (Table 4). Additionally, the intercepts of *H. arctica* and *Macoma* sp. were significantly higher than that of *Astarte* sp. (Table 4).

While MO_2 of *S. groenlandicus* did not differ between sampling years, evidence of spatial variation was observed. Lower MO_2 rates were recorded in individuals collected at station CNL3 compared to individuals from the other stations (Fig. 4). The slopes ($F_{1,22} = 6.28$, $P = 0.020$) and intercepts were significantly different ($F_{1,23} = 79.98$, $P < 0.001$).

Mass-specific respiration rates declined rapidly with increasing body size for all species except *S. groenlandicus* (Fig. 3b). The slope for *S. groenlandicus* was not significantly different from zero ($t = -0.82$, $P = 0.42$), while for all other taxa slopes ranged from −0.19 to −0.48. There were statistical differences in average mass-specific respiration rates among the species ($F_{5,87} = 25.75$, $P < 0.001$; Fig. 5). *Serripes groenlandicus* had a significantly higher rate than the other five species, and the rate for *A. macrocephala* was significantly higher than *Macoma* sp., *Astarte* sp. and *N. pernula* (Fig. 5).

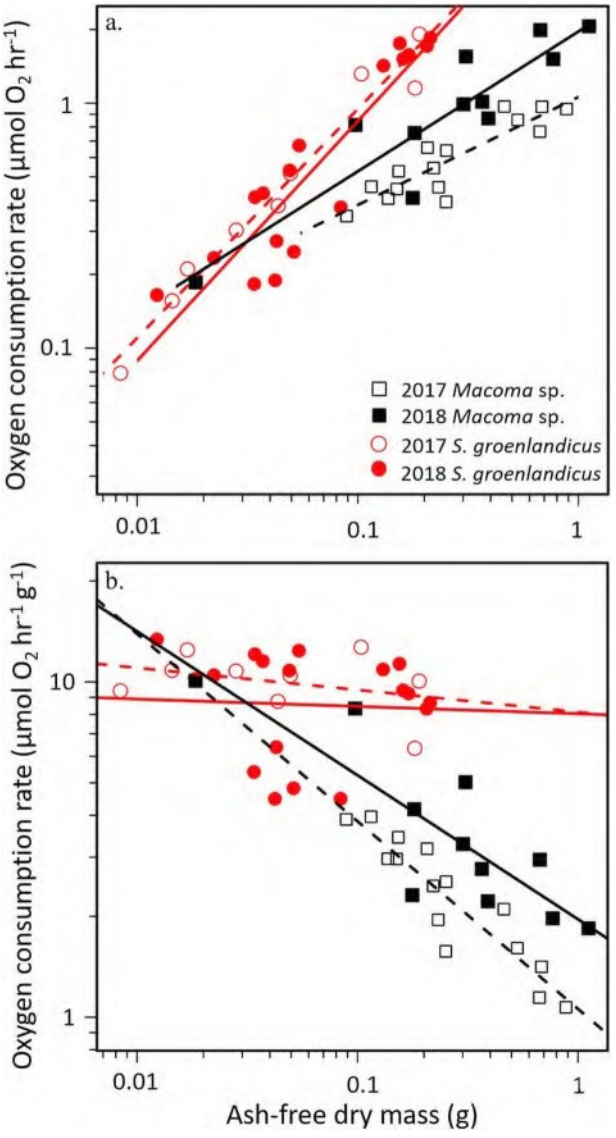

Figure 2: (a) Oxygen uptake rate (µmol O_2 h^{-1}) and (b) mass-specific oxygen uptake rate (µmol O_2 h^{-1} g^{-1}) versus ash-free dry mass (g) for 2017 *Macoma* sp. (black open squares, $n = 15$), 2018 *Macoma* sp. (black closed squares, $n = 11$), 2017 *S. groenlandicus* (red open circles, $n = 9$) and 2018 *S. groenlandicus* (red closed circles, $n = 17$). Discussion

We measured oxygen consumption rates of six dominant macrofauna from the northern Bering and southern Chukchi Sea shelves to determine metabolic demand and organic carbon consumption. Overall, we observed taxonomic variability in metabolic demand with average mass-specific MO_2 rates ranging from 2.1 to 9.5 µmol O_2 hr^{-1} g^{-1}, highlighting the need for species-specific measurements to improve estimates of organic carbon consumption by the benthos. Metabolic scaling coefficients (i.e. slope) also varied among species.

Inter- and intraspecific variation in metabolic rates

We found species-specific standard metabolic rates (MO_2), indicating a wide range in the amount of organic material that benthic species need to consume to maintain baseline metabolic function. For example, the metabolic demand of

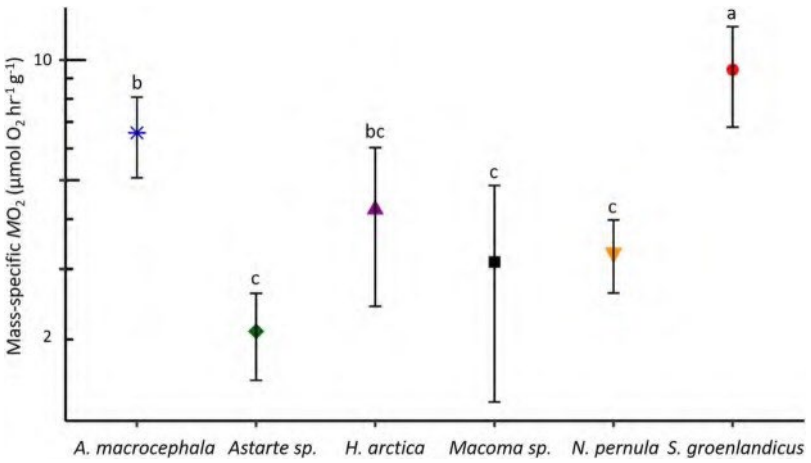

Figure 5: Average mass-specific respiration rates (μmol O_2 hr^{-1} g^{-1}) for each species with standard deviations represented by error bars. *Serripes groenlandicus* had a significantly higher rate than *Macoma* sp. ($t = 9.6$, $P < 0.001$), *Astarte* sp. ($t = 6.8$, $P < 0.001$), *N. pernula* ($t = 7.3$, $P < 0.001$), *H. arctica* ($t = 4.3$, $P < 0.001$) and *A. macrocephala* ($t = 3.1$, $P = 0.028$). The rate for *A. macrocephala* was significantly higher than *Macoma* sp. ($t = 4.7$, $P < 0$ 0.001), *Astarte* sp. ($t = 4.2$, $P < 0.001$) and *N. pernula* ($t = 3.8$, $P = 0.003$).

a hypothetical *S. groenlandicus* with 0.1 g AFDM would be 4.3 times higher than that of a similarly sized individual *Astarte* sp. These rates likely represent conservative estimates of organic carbon consumption. In polar regions, benthic organisms exhibit low metabolic rates when food availability is low, which then increase in response to phytodetrital inputs or elevated food concentrations (Brockington and Clarke, 2001; Sejr *et al.*, 2004).

For the bivalves, these differences in respiration rate among species may be related to the age or life stage of the individuals sampled. The individuals of all species used in our experiments were relatively similar in size (Table 2); however, the maximum achievable length observed in the field varies among species, such that incubated individuals may have been juveniles in some cases. We calculated the ratio of measured body length to maximum achievable length as a proxy to illustrate this relationship (Table 2). In particular, *S. groenlandicus* had the highest average MO_2, but the lowest average measured length to maximum achievable length ratio of only 0.15. Individuals were mostly small, compared to their large maximum achievable size of up to 100 mm in shell length (Lubinsky, 1980; Kilada et al., 2007). In contrast, *Astarte sp*. had the lowest MO_2 and the highest average length to maximum achievable length ratio of 0.64. *Astarte sp*. reach maximum lengths of only 30 mm, but rarely exceed 15 mm (Madsen, 1949; Schaefer et al., 1985), so our individuals were closer to their maximum size compared to *S. groenlandicus*. Overall, individuals selected were likely of different life stages and ages, which can impact respiration rates (Sukhotin and Pörtner, 2001). For instance, all *S. groenlandicus* individuals were smaller than 22 mm in length, which is smaller than the typical size at sexual maturity (Kilada et al., 2007), indicating these individuals were likely all juveniles. A more rapid growth rate that would be expected in these juveniles would thus contribute to the higher MO_2 measured for this species.

In Young Sound, NE Greenland, the respiration rates of 26 individuals of *H. arctica* were measured at −1.3 °C with a constant food supply (Sejr *et al.*, 2004). Adjusting for the differences in temperature using $Q_{10} = 3.64$ (Peck and Conway, 2000) and feeding conditions (using an equation from Sejr *et al.*, 2004), MO_2 for a 0.5 g *H. arctica* was 2 times higher in our study compared to that observed in Sejr *et al.* (2004). Conspecific metabolic rates vary due to numerous factors, such as genotype or environmental conditions during early life stages (Burton *et al.*, 2011). The discrepancies between the rates measured in these studies could also be due to temperature compensation (Rastrick and Whiteley, 2011) or other factors related to differences in experimental design.

The metabolic scaling coefficient, which relates metabolic rate to body mass, is broadly estimated to be 0.75 in a wide variety of taxa (Kleiber, 1932). However, deviations from the '3/4-power law' occur for a variety of reasons in both intra- and interspecific metabolic studies (Glazier, 2005). The metabolic scaling coefficient was close to 0.75 for three of the species measured here, *H. arctica*, *Astarte* sp. and *A. macrocephala* (Table 2), but was much higher for *S. groenlandicus* (b = 0.94) and lower for *Macoma* sp. (b = 0.52). Here again, life stage may be a factor for the high metabolic scaling coefficient of *S. groenlandicus*. Metabolic scaling is often higher in juveniles compared to adults, likely due to greater energetic demands of rapid growth as opposed to somatic tissue maintenance (Glazier, 2005). In 2017, we additionally measured the respiration rates of four large *S. groenlandicus* individuals ranging from 40.6 to 60.0 mm length, which were likely mature adults (Supplementary Figure 2). When MO_2 was calculated for pooled juvenile and adult individuals, the

scaling coefficient declined from b = 0.94 to b = 0.85, suggesting the rate of change of respiration rate with increasing body mass is higher for juveniles than adults (adults-only exponent was b = 0.81; Supplementary Figure 2). Additionally, the slope of the mass-specific oxygen consumption rate for *S. groenlandicus* juveniles was not significantly different from zero, suggesting that the mass-specific respiration rate does not change with increasing biomass. Ontogenetic shifts are known to occur in mass-specific metabolic scaling from near isometry (b = 0) to allometry (b < 0), relating to changes in body shape (Glazier *et al.*, 2015).

Potential environmental effects on metabolic rate

Although we did not sample with the intent to evaluate interannual variability in metabolic rates, we were able to compare data from two years for two species. The small temperature variation in our treatments for each year of about 0.3 ◦C complicates interpretation of this result given the direct effect of temperature on metabolic rate (Peck *et al.*, 2002; Clarke and Fraser, 2004; Trigos *et al.*, 2015). Nonetheless, the respiration rates of *S. groenlandicus* were not significantly different between years, suggesting the temperature difference did not affect our results. Relative thermal independence of metabolic rate has been observed in other benthic species. For instance, the respiration rate of the amphipod *Anonyx nugax* remained constant over the temperature range 1–3 ◦C, suggesting metabolic adaptation to natural variability in environmental conditions (Opalinski and Weslawksi, 1989). In contrast, MO_2 of *Macoma* sp. was significantly higher in 2018. However, if the increased respiration rates were strictly due to temperature, the effect we observed would indicate a Q_{10} of 36 730, which is well beyond typical values (McMahon and Wilson, 1981; Peck and Conway, 2000), suggesting other factors produced this result. Most individuals were collected at different stations in each year, making it difficult to tease apart spatial from temporal differences in the environment as possible influences. Total organic carbon (TOC) concentration was roughly five times higher at station DBO3.8 where most individuals were collected in 2018, compared to station CNL3 where most individuals were collected in 2017, but TOC values were not substantially different between years at either station (Mincks unpublished data). In contrast, chlorophyll-a concentrations in surface sediments were substantially higher in 2017 than in 2018 at both stations due to the timing of ice retreat. Thus, the feeding environment *in situ* may have played a role in producing the interannual differences in MO_2 for *Macoma* sp. Alternatively, this species may simply lack temperature compensation (cf., Rastrick and Whiteley, 2011). Regardless, the experimental temperature difference between the two years is small compared to the seasonal and interannual fluctuations experienced in the region (Danielson *et al.*, 2020).

While the MO_2 of *S. groenlandicus* did not differ between years, evidence of spatial variation was observed, with individuals from one sampling station (CNL3; Fig. 1) exhibiting lower MO_2 compared to individuals from the other stations. This difference may reflect physiological differences related to environmental factors. Intraspecific variation in respiration rate can be related to a variety of factors, such as environmental conditions during early development (Burton et al., 2011). Growth rate of *S. groenlandicus* also varies spatially due to environmental conditions, which likely reflect variations in trophic conditions, and has thus been proposed as an indicator of environmental change (Ambrose et al., 2006; Kilada et al., 2007; Carroll et al., 2009; Gerasimova et al., 2019). While the average depth and other physical variables did not vary substantially at the sampling locations where *S. groenlandicus* was collected (Table 1), sandier sediment and a lower C: N ratio were observed at station CNL3 compared to the other locations (Mincks unpublished data). Both of these variables may reflect feeding conditions, potentially as a function of hydrodynamics at this site where current speeds are high due to the constriction of flow through the Bering Strait (Danielson et al., 2014). The reduced metabolic rate at the sandier CNL3 site seems to contradict evidence of a slower growth rate at stations with high silt fraction reported elsewhere (Gerasimova et al., 2019). However, growth rates and basal metabolic rates do not always align (Sebens, 2002). This spatial difference highlights a need to measure respiration rates from across the region of interest. Individuals with low respiration rates may be buffered against environmental conditions due to their low maintenance costs, which may yield greater fitness in poor trophic conditions (Burton et al., 2011). Not accounting for spatial variability in metabolic rate may bias modelling estimates of regional carbon demand and food web dynamics.

In contrast to *S. groenlandicus*, *Macoma* sp. collected from station CNL3 showed no clear impact of station on respiration rate. However, growth rate of *Macoma* sp. may be less sensitive to environmental conditions than *S. groenlandicus* (Gerasimova *et al.*, 2019) and may be buffered against environmental variability.

Implications for benthic ecosystem functioning

Environmental changes are already resulting in temperature increases, changes in primary production and shifts in benthic species composition, structure and biomass. Species-specific respiration rates suggest these changes will alter organic matter processing and carbon flow pathways in the Pacific Arctic benthos.

Metabolic rate increases with increasing temperature up to an optimal range. Respiration rates were used to estimate the expected increase in metabolic demand of each taxonomic group at a projected future temperature of 5 ◦C (Mora *et al.*, 2013) assuming Q_{10} values between 2.56 and 3.64 (Peck and Conway, 2000) following the equation:

$$R_2 = R_1 Q_{10}^{\frac{T_2 - T_1}{10}}$$

where R_1 is the measured respiration rate at the initial temperature (T_1 = 0.9 °C) and R_2 is the calculated respiration rate at the projected temperature (T_2 = 5 °C). These calculated rates provide an estimate of the increase in carbon demand under projected future warming scenarios. Indeed, bottom-water temperatures of 4 °C are already occurring in the Bering Strait region (Huntington *et al.*, 2020). At a projected future temperature of 5 °C, average mass-specific MO_2 would increase by 48–70% to a value of 14.0–16.1 μmol O_2 hr^{-1} g^{-1} for *S. groenlandicus*, 9.7–11.2 for *A. macrocephala*, 6.2–7.2 for *H. arctica*, 4.8–5.6 for *N. pernula*, 4.6.-5.3 for *Macoma* sp. and 3.1–3.6 for *Astarte* sp., again assuming Q_{10} values between 2.56 to 3.64 (Peck and Conway, 2000) and that an upper critical temperature limit has not been exceeded (Peck *et al.*, 2002). However, Q_{10} likely varies among the species and over different temperature ranges.

With this increase in standard metabolic demand and a potential decline in phytodetrital input to the seafloor (Lee *et al.*, 2013; Moore and Stabeno, 2015; Lovvorn *et al.*, 2016), carbon reserves in the sediment may become depleted, although there are some projections of increased primary production and input to the seafloor in this region (Grebmeier *et al.*, 2015a). Temperature-induced increases in metabolic demand coupled with low food availability can result in reproductive failure, death and a subsequent decline in benthic production and biomass (Hummel *et al.*, 2000). If input of organic carbon to the benthos declines and carbon resources in the sediments are depleted, biomass of bivalves and amphipods in persistent macrobenthic hotspots may then decline, with deleterious impacts on upper trophic levels, such as benthic-feeding marine mammals and birds that depend on these prey items. For instance, in the northern Bering Sea shelf, decline of the spectacled eider population has been associated with a reduction in the biomass of bivalve populations that serve as critical prey for these birds (Lovvorn *et al.*, 2009).

However, species with low metabolic demand may be more adapted to this low-food future scenario. Nuculanidae (which includes *N. pernula*) currently dominate in the northern region of our study area (Grebmeier *et al.*, 2015a). The relatively low respiration rate, and thus low metabolic demand, of *N. pernula* may leave it preadapted to the lower-productivity waters of this area, which is influenced by the Alaska Coastal Current. This low metabolic demand may confer a physiological competitive advantage over other taxonomic groups with higher carbon requirements (Burton *et al.*, 2011; McClain *et al.*, 2020). Therefore, we hypothesize that species with low metabolic rates, such as *Astarte* sp. and *N. pernula*, may dominate under a low-food scenario given their reduced organic carbon requirements necessary to maintain metabolic function. In contrast, species with high metabolic rates, such as *S. groenlandicus* and *A. macrocephala*, may be hindered by higher carbon demands and become food limited. In response to ocean warming, spatial shifts in the frequency and abundance of species associated with differing physiological tolerances has already been identified in many other regions (Sunday *et al.*, 2012).

In the Arctic, emerging evidence indicates environmental change has influenced the distribution of macrofaunal biomass, with declining biomass in some areas and increasing biomass in others (Moore *et al.*, 2018; Goethel *et al.*, 2019). In addition to changes in overall biomass, shifts in community structure and composition are occurring (Grebmeier, 2012; Waga *et al.*, 2020). Shifts in dominant species could impact community metabolic demand even if total biomass remained constant. For instance, if *S. groenlandicus* were outcompeted and replaced by *N. pernula*, carbon demand would decline given the lower MO_2 of *N. pernula*.

In conclusion, the average mass-specific MO_2 of sampled species ranged from 2.1 to 9.5 μmol O_2 hr^{-1} g^{-1}, with species-specific differences up to 4.3 times for a 0.1 g AFDM individual. These differences in MO_2 have implications for the overall carbon demand of the benthic infaunal community as assemblages are likely to continue to change under future climate scenarios.

Supplementary material is available at *Conservation Physiology* online.

Funding

This research was part of the Arctic Integrated Ecosystem Research Program (IERP; http://www.nprb.org/arctic-program/). This manuscript is Publication ArcticIERP-17. Funding for the program was provided by the North Pacific Research Board, US Bureau of Ocean and Energy Management, Collaborative Alaskan Arctic Studies Program and US Office of Naval Research. Generous in-kind support for the program was contributed by the US National Oceanic Atmospheric Administration Alaska Fisheries Science Center and Pacific Marine Environmental Laboratory, University of Alaska Fairbanks, US Fish and Wildlife Service and US National Science Foundation. Support for this research was also provided by the Robert and Kathleen Byrd Award. This publication was, in part, made possible by the University of Alaska Fairbanks Office of the Vice Chancellor for Research Publication Award.

Acknowledgments

We would like to thank the Captain and crew of the *R/V Sikuliaq* for making sampling possible; and Opik Ahkinga, Lorena Edenfeld, Caitlin Forster, Silvana Gonzalez, Katrin Iken, Jessica Pretty, Sarah Seabrook, Andrew Thurber and Ann Zinkmann for helping collect organisms. We would also like to thank Arny Blanchard for help with experimental design; Max Hoberg for macrofaunal identification; and Seth

Danielson, Jeroen Ingels, Andrew Thurber and Leah Zacher for guidance and comments on this manuscript.

Spatial patterns and effects of temperature on rates of organic matter processing in sediments across the northern Bering and southern Chukchi Sea shelf (Manuscript in preparation)

Sarah L. Mincks, Brittany Jones Charrier, Sarah Seabrook, Andrew Thurber

Abstract: Labile organic matter deposited at the seafloor is respired by benthic organisms, and respiration rates are highly temperature dependent in both microbes and metazoan in sediments. In light of changing temperature and productivity regimes across the Pacific-Arctic domain, we measured respiration rates of sediment communities at in situ and elevated temperatures at ten locations across the N Bering and S Chukchi Seas. Intact sediment cores were incubated at 0ºC (ambient) and 5ºC (projected warming). On average, sediment community oxygen demand, a proxy for organic carbon consumption, was ~30% higher in warmer treatments. Substrate type, productivity, and particulate flux rates varied across the study area, resulting in spatial differences in microbial and metazoan biomass. In the southeast Chukchi Sea (DBO 3 region), high biomass of large infaunal species, particularly bivalves, generated somewhat elevated oxygen demand. However, oxygen consumption rates were more consistent across the rest of the study area, with rates increasing more rapidly as a function of microbial biomass than of macrofaunal biomass. Fluxes of dissolved inorganic carbon (DIC) were also measured in incubation experiments as an additional means of quantifying oxygen consumption due specifically to respiration of infauna. DIC fluxes were decoupled from oxygen fluxes at some locations. In some cases, DIC was taken up by sediment communities, suggesting autotrophic production which could have been producing oxygen during experiments, resulting in underestimation of respiration rates by oxygen flux measurement.

Introduction

The processing of organic material by sediment communities has significant consequences for ecosystem functioning and productivity—particularly in the shallow inflow shelf seas of the Pacific-Arctic region, which are characterized by tight benthic-pelagic coupling, high benthic biomass, and high rates of organic matter remineralization in sediments (e.g., Walsh et al. 1989; Whitehouse et al. 2014; Grebmeier et al. 2015; Bourgeois et al. 2017). Organic matter processed by the benthic food web is either respired or assimilated into biomass of benthic organisms; thus, these key processes must be measured in order to characterize the flow of carbon under current conditions, and to project how rates and pathways may change with warming and sea-ice loss (Wassmann and Reigstad 2011).

Organic carbon consumption by Arctic shelf benthos has been estimated as sediment community oxygen consumption (SCOC) (reviewed by Grebmeier et al. 2006; Bourgeois et al. 2017), providing bulk measurement of energy demand for all sediment organisms. Although published data are limited in the Pacific-Arctic region, the majority of the oxygen consumption

(and thus carbon demand) has typically been attributed to macrofaunal organisms (Devol et al. 1997; Clough et al. 2005). For example, in the northern Bering and southern Chukchi seas, amphipods and bivalves were estimated to account for 61% of SCOC (Grebmeier and McRoy 1989). However, bacterial biomass and respiration, which constitute a large portion of SCOC in other regions (Hubas et al. 2007; Franco et al. 2010; Braeckman et al. 2018; Mäkelä et al. 2018), have not been directly measured in sediments on the Pacific-Arctic shelves,.

Bacteria may become increasingly important in organic matter processing on Arctic shelves under future scenarios of increasing temperature and changes in particulate flux to the seafloor. As temperatures increase, heterotrophic bacteria become more efficient, because the activity of extracellular enzymes used by bacteria to hydrolyze high molecular-weight organic matter also increases (Arnosti and Jorgensen 2003; Arnosti 2011). Experimental results are limited for Arctic sediments, but Kritzberg et al. (2010) showed that a 6°C temperature increase resulted in a six-fold increase in pelagic bacterial carbon demand. This and other studies also show strong interactions between the effects of temperature and substrate availability on microbial activity (Pomeroy and Deibel 1986; Wiebe et al. 1992; Canion et al. 2014), which suggests that bacteria may be able to process a larger portion of the sedimentary organic carbon pool at warmer temperatures, potentially affecting food availability for detritivores (cf., Mincks et al. 2005).

We conducted sediment-core incubation experiments in the Northern Bering and Chukchi Seas to measure oxygen consumption of the sediment community at two different temperatures, and estimate rate of organic matter consumption. Microbial and macrofaunal biomass were estimated at the same sites, and patterns in oxygen consumption are considered in light of these biomass patterns as well as other features of the benthic environment.

Methods

To quantify the effect of changing temperatures on the carbon demand of the benthic community, we conducted sediment-core incubation experiments at 13 stations in the Northern Bering and Southern Chukchi Seas in June 2017 and June 2018, during the Arctic Shelf Growth, Advection, Respiration, and Deposition Rates (ASGARD) field program on board *R/V Sikuliaq* (Figure 1). Eight stations were sampled in both years. Station depths ranged from 32 – 58 m (Table 1). Two sampled areas correspond to the Distributed Biological Observatory (DBO) areas 2 and 3, also known as the Chirkov and SECS hotspots, respectively (Grebmeier et al. 2006; Grebmeier 2012). The study area is seasonally ice covered and highly productive, characterized by northward flow of cold, nutrient-rich Anadyr-Bering Sea Water in the west and warmer, more nutrient-poor Alaska Coastal Water in the east (Danielson et al. 2017). Downstream of the Bering Strait constriction, water masses fan out over the shallow Chukchi Sea shelf, resulting in declining current speeds and deposition of suspended particles to the seafloor. Grain-size characteristics generally reflect these patterns, with sandy substrate in the Chirikov Basin south of Bering Strait, and muddier sediments further north in the Chukchi Sea. In turn, composition of macrofauna communities is influenced by grain size and spatial patterns in organic matter

deposition (Grebmeier et al. 2015; Charrier & Mincks, in prep.). The Chirikov Basin is dominated by suspension-feeding amphipods as well as bivalves, whereas large bivalves dominate the infaunal biomass in the central Chukchi with smaller-bodied organisms, mainly polychaetes, dominating in the nearshore areas influenced by Alaska Coastal Water (Charrier & Mincks, in prep.).

Samples were collected using an MC-800 multi-corer with 12 x 10-cm diameter polycarbonate tubes (Ocean Instruments, San Diego, CA). Multi-core samples were retrieved from replicate deployments at each station to obtain true sample replicates. In 2017, the number of cores incubated at each station ranged from one to three per treatment, whereas three cores per treatment were incubated at all stations in 2018 (Table 1). Additional cores were taken from the same multi-core deployments for measurement of environmental variables, including grain size, total organic carbon (TOC), total nitrogen (TN), chloropigment concentration, and stable carbon isotope ($\delta^{13}C$) values. These data and associated methods have been described in detail by Charrier & Mincks (in prep.; see also Study 16, this report).

Sediment community oxygen consumption experiments

High-quality cores with clear top water and undisturbed sediment-water interface were selected for incubation experiments. Most of the top water was siphoned off of each core through a 45-µm screen into a clean bucket, and chilled to experimental temperatures for use during incubations. Each core was then extruded into a shorter 25-cm long x 10-cm diameter acrylic tube to obtain an intact sub-core approximately 15 cm deep. Sediment-community oxygen consumption (SCOC) was measured in each of two different temperature treatments. We targeted 0° and 5°C, simulating ambient and predicted future bottom-water temperatures in the study area (Mora et al. 2013), but actual temperatures fluctuated between 0 – 1°C and 4 – 5°C. Sub-cores were partially submerged in seawater in plastic crates, placed in either a chest freezer (5° C) or in a walk-in environmental chamber (0° C) on board the ship, and allowed to reach the desired temperature. Cores were topped off with the reserved filtered water removed from multi-core tubes upon collection, such that all experimental cores were topped with the same water. In 2018, samples of this water were taken at the start of each experiment for analysis of dissolved inorganic carbon (DIC) concentrations, and in both years were taken for nutrient analysis. Nutrient samples were removed using a syringe filter, and frozen at -20° C, and DIC samples were poisoned with saturated $HgCl_2$. Cores were then capped with rubber stoppers from which a rare-earth magnet was suspended. Small motors were used to rotate a magnetic bar which agitated the magnets inside each core tube, gently stirring overlying water to prevent boundary layer formation. Cores were kept shielded from ambient light during acclimation and incubation periods, except during periodic oxygen measurements.

Oxygen concentration in the incubated cores was measured using non-invasive optodes (PSt3 oxygen sensor spots; PreSens Precision Sensing GmbH, Germany; detection limit = 0.03% oxygen) which were glued to the inside of each core tube. The sensor spots measure changes in oxygen concentration based on the dynamic fluorescence quenching of a luminophore contained

in a polymer matrix. An initial oxygen concentration reading was recorded as soon as tubes were capped, and additional measurements were recorded at consistent intervals throughout each experiment. A temperature probe was placed in the water bath containing submerged core tubes during oxygen readings, and all oxygen concentrations were corrected for temperature by the PreSens meter. Incubations were terminated when oxygen had declined by ~20% of initial concentration (typically 10 - 18 hours after cores were capped). The oxygen consumption rate was then calculated from the linear regression of oxygen concentration versus time. SCOC measurements were converted to estimates of benthic carbon demand using a respiratory quotient of 0.8 (Smith 1978). At the end of the experiment, cores were harvested and either sectioned into discrete depth layers and frozen (2017) or sieved for macrofaunal biomass (2018).

DIC concentrations were analyzed using an Apollo DIC Analyzer AS-C6 following best-practices protocols (Dickson et al. 2007). Nutrient samples were sent to the nutrient analysis lab at Oregon State University for analysis.

Biomass estimation

Bacterial biomass was measured in background cores collected from all stations that were sampled in both years using phospholipid fatty-acid analysis (PLFA). PLFAs were extracted from freeze-dried sediment via a one-step extraction-transesterification method using a transesterification reaction mix of 10:1:1 methanol: chloroform: hydrochloric acid. The resulting fatty-acid methyl esters (FAMEs) were then extracted using 4:1 hexane:chloroform (Lewis et al. 2000). Samples were analyzed using a Thermo-TRACE 1310 gas chromatogram with flame ionization detector (GC-FID). A C19:0 internal standard (Methyl nonadecanoate, CAS 1731-94-8) was added to each sample prior to analysis for FAME quantification, and peaks were identified through comparison to two external standards (Supelco 37 FAME mix CRM47885, and BAME mix 47080-U, Millipore Sigma). Biomass was calculated from the peak areas for known bacteria-specific markers iso15:0, iso16:0, and anteiso15:0 (Boschker and Middelburg 2002; Moodley et al. 2005).

Macrofaunal biomass was measured in background cores (2017) or in the incubated cores (2018). Samples were sieved live on board the vessel over 500 µm mesh using filtered seawater, preserved in 10% buffered formalin, and returned to the lab for sorting and taxonomic identification. Taxa were generally identified to phylum or class, and polychaetes were identified to family. In 2018, a subset of cores (those from the 5°C treatment) received a more detailed analysis with genus- or species-level identification of polychaetes and amphipods.

Results and Discussion:

Stations with replicated sampling in both years were included in a nested ANOVA for temperature treatment, station, and year, which showed no evidence of differences in sediment community oxygen consumption (SCOC) between years ($F = 0.251$, $p = 0.622$). Higher rates were measured in 2018 at station CNL 3, and at DBO 3.8 in the 5°C treatment only; however, only one replicate core was incubated at each temperature at CNL 3 in 20017 so it is difficult to

determine whether the difference is meaningful. Given the lack of detectable difference at most sites between years, samples were pooled among years were for further comparisons, which indicated significant effects of temperature and station on SCOC rate (Table 2). The 5°C temperature difference between treatments resulted in increased SCOC rates at nearly all stations in both years, with increases ranging from 4 to 107% (2017 mean = 38%; 2018 mean = 31%). At DBO 3.8 in 2017, and at DBO 3.3 in 2018, decreases in SCOC of ~10% were observed at the warmer temperature, although these differences may result from high variability among replicates.

Results of Charrier & Mincks (in prep.) indicated four different regions with distinct habitat characteristics and benthic communities, and those station groupings are used here for comparison of SCOC rates (Figure 2). SCOC rates were roughly comparable at most sites (~10 – 20 mmol O_2 m^{-2} d^{-1}), with the exception of sites in the southeast Chukchi Sea benthic 'hot spot' in the DBO 3 area where values ranged from ~20 – 80 mmol O_2 m^{-2} d^{-1} (Table 2, Figure 2). The two stations immediately north of Bering Strait, while situated in close proximity, displayed markedly different results with CNL 3 showing some of the highest rates overall, compared to nearby CPL 8 which was more comparable to other coastal sites. Charrier & Mincks (in prep.) identified similar infaunal communities at these two sites, which suggests macrofauna are not driving this difference. The high SCOC at CNL 3 was mainly observed in 2018, with a rate of 56.5 mmol m^{-2} d^{-1}, compared to 38.7 mmol m^{-2} d^{-1} in 2017. While macrofaunal biomass estimates were similar between years, microbial biomass was 4x higher in 2018. Further, while SCOC rates were roughly similar at coastal and Chirikov Basin sites, macrofaunal biomass varied by as much as two orders of magnitude, again suggesting that macrofauna are not solely responsible for driving spatial variation in SCOC. Organic matter input has been identified as a key driver of SCOC rates in other regions (e.g., Kiesel et al. 2020); we will continue to explore relationships to habitat features and macrofaunal community structure in future analysis.

SCOC rates show strong relationships to both microbial and macrofaunal biomass, although for macrofauna there appear to be two clouds of points representing the southeast Chukchi Sea 'hot spot' sites and the rest of the stations (Figure 3). Our data are more limited for bacterial biomass, but do suggest a steeper relationship between SCOC and biomass which may indicate that smaller changes in microbial biomass may have relatively greater impacts on rate of organic matter consumption.

Change in DIC concentration over the course of the experiment provides an additional estimate of sediment community respiration, and changes in nutrient concentrations provide insights into microbially mediated remineralization pathways occurring in sediments (e.g., Henriksen et al. 1993; Horak et al. 2013). We measured DIC flux across the sediment-water interface in 2018 only, and results show a decoupling between DIC and O_2 fluxes (Figure 4). At the stations with higher macrofaunal biomass, relationships are tighter, whereas coastal sites which may be more heavily influenced by microbial processes show low DIC flux relative to O_2, and even show DIC consumption at station CL 3. This pattern may indicate chemical uptake of O_2 by products of anaerobic microbial respiration (e.g., H_2S). At CL 3, uptake of DIC may

suggest viable photosynthetic cells such as newly settled phytoplankton or benthic microalgae, or other microbial processes. In any case, SCOC measurements alone would likely overestimate true community respiration at these sites. Analysis of microbial community structure in this area does indicate shallow anoxia in sediments, as well as presence of iron reducing and oil degrading species (Walker et al., in prep.).

Table 1. Sampling location information, environmental data, sediment community oxygen consumption (SCOC, averaged across temperature treatments, ± std. dev.), and average biomass for all stations. Stations are grouped into "sampling areas" with similar habitat types, based on differences in benthic community structure and environmental factors as identified by Charrier & Mincks (in prep.; see Study 16, this report). N = number of cores incubated at each experimental temperature at each station. Average macrofaunal biomass (wet weight) ±std. dev is based on analysis of background samples (2017), or experimental cores (2018). Microbial biomass is based on bacterial phospholipid fatty-acid analysis as described in the Methods (n.d. = no data). Inventories of chlorophyll a (Chl-a) in the upper 10 cm of sediment, and total organic carbon and nitrogen (TOC, TN) in the upper 1 cm of sediment provide indicators of organic matter content in sediments.

Abstract

The Chukchi Sea continental shelf is a highly productive inflow shelf of the Arctic Ocean that is experiencing climate warming events and declines in seasonal sea ice cover at one of the fastest rates compared to other Arctic shelves. Climate-induced changes in phytoplankton and ice-algal primary production, inflow of terrestrial matter through riverine discharge and coastal erosion, and increases in bacterial production have previously been predicted to cause shifts in the composition and distribution of organic matter supply and energy flow in this system. The goal of this study was to examine potential shifts in the Chukchi Sea ecosystem energy flow under various future climate scenarios. To address these goals, an existing mass balance Chukchi Sea ecosystem model by was updated by incorporating terrestrial matter as an energy source, especially for benthic consumers. Incorporation of the terrestrial matter component allowed us to adjust current model phytoplankton biomass to better match recent empirical measurements and to update the system-wide mass-balance. We also modeled potential impacts of future climate-driven alterations in the composition and flow of organic matter supply on major ecosystem groups for the 2015 – 2050 period. Iterations showed that climate-driven increased retention of phytoplankton biomass in the pelagic realm would depress biomass of most benthic-feeding organisms across several larger ecosystem groups (invertebrates, fishes, mammals). However, simulated increases in both terrestrial matter inflow and bacterial biomass have the potential to compensate for some of the reductions in the energy supply from phytoplankton to the benthic food web, as well as to diversify the supply of organic matter to the seafloor. This diversification could make the Chukchi Sea ecosystem more stable to future climate-driven changes.

Keywords: Ecosystem modelling, Ecopath with Ecosim, benthic food webs, terrestrial matter, bacterial production, future Arctic

Introduction

The Chukchi Sea continental shelf is one of the most productive Arctic shelves (Codispoti et al., 2013); however, patterns in primary productivity and subsequent flow of energy through the Arctic food web are being altered by the rapid atmospheric warming and decline in seasonal sea ice cover (Steele et al., 2008; Serreze et al., 2009; Kumar et al. 2020). Under past conditions of extended seasonal ice cover, up to 70 % of ice-associated and pelagic primary production was exported to the benthos through tight pelagic-benthic coupling, supporting high benthic invertebrate biomass (Grebmeier et al., 1988; Walsh et al., 1989). This high standing stock of benthic invertebrates in the Chukchi Sea supports many benthic-feeding higher trophic levels, e.g., spectacled eiders (*Somateria fischeri*), walruses (*Odobenus rosmarus*), and gray whales (*Eschrichtius robustus*) (Grebmeier et al., 1988; Lovvorn et al., 2003; Dehn et al., 2006; Moore and Huntington, 2008). Changes in atmospheric forcing and sea ice cover can have major impacts at the base of the Arctic food web, including levels of ice algal and phytoplankton production, the strength of pelagic-benthic coupling, and the importance of additional food sources, such as terrestrial matter inflow and bacteria (Bopp et al., 2001; Lavoie et al., 2010; Holmes et al., 2016; Taylor et al., 2018; Zinkann et al. a, in review). Such changes may have repercussions for the energy flow to and between higher trophic levels. Ecosystem models are useful tools to evaluate the potential impacts of changing conditions on the energy flow through a system (e.g., Aydin and Mueter, 2007; Gaichas et al., 2011; Doney et al., 2012; Harvey et al., 2012). Current ecosystem models describe the Chukchi Sea ecosystem as a benthos-dominated system, where much of the primary production is routed through the benthos to higher trophic levels (Christensen and Walters, 2004; Aydin et al., 2007; Whitehouse et al., 2014; Whitehouse and Aydin, 2016); here, we offer perspectives on how changes in primary producer carbon supply and energy flow through the food web may impact the structure and functioning of the Chukchi Sea ecosystem.

In Arctic shelf systems, such as the Chukchi Sea, the benthos represents a cornerstone of the food web (Grebmeier et al., 1988; Aydin et al., 2007; Whitehouse et al., 2014). As organic matter sinks to the seafloor, benthic organisms utilize this material directly as food, while indirectly affecting the detrital distribution and mineralization into nutrients via respiration and bioturbation activities (Heip et al., 1995). The standing stock of the benthic community largely depends on the amount and quality of the detrital material fulfilling the energetic needs of the community (Gooday et al., 1990; Ruhl and Smith, 2004). The reliance of benthic organisms on different organic matter sources (such as from bacteria, phytoplankton, and terrestrial matter) is variable (Zinkann et al. b, in review), and changes in the composition of organic matter to the seafloor can have implications to the benthic community composition.

Ice-algal and phytoplankton production is typically considered the main food source for the Arctic benthos (Grebmeier and Barry, 1991). In regions with abundant seasonal sea ice, the seasonal increase of light and ice melt in late spring results in early-season ice-edge blooms, often dominated by relatively large centric diatoms that sink rapidly and largely ungrazed to the benthos (Grebmeier and McRoy, 1989; Lovvorn et al., 2005). With a reduction of sea ice in warmer years, the ice-algal production in the marginal ice edge may be reduced while phytoplankton blooms are postulated to occur later, once a thermally stratified water column develops (Wassmann and Reigstad, 2011). Increased light availability and a longer growing season in ice-free conditions could allow for an overall increase in Arctic primary production (Brown and Arrigo, 2013). However, a shift towards smaller-celled phytoplankton communities (Li et al., 2009; Morán et al., 2010) and an increase in grazing pressure by zooplankton (Neeley et al., 2018) could result in higher proportions of the primary production being retained in the water column. Such a shift would lead to a weakening of pelagic-benthic coupling in the system with ramifications for the benthos-dependent food web (Lalande et al., 2007; Arrigo et al., 2008; Wassmann and Reigstad, 2011).

Organic matter sources, other than ice algae or phytoplankton, that support the benthic food web on the Chukchi shelf, include terrestrial matter and bacterial production. Arctic river discharge that carries terrestrial matter has increased by 2.6 % per decade since the 1970s (Bopp et al., 2001; McClelland et al., 2006; Lantuit et al., 2012) due to increases in coastal erosion and permafrost thaw (Guo et al., 2004; Semiletov et al., 2011). The presence of terrestrial matter in Chukchi Sea marine sediments and invertebrate diets is high, illustrating the importance of this material to the benthic food web in this region (Yunker et al., 2005; Morris et al., 2015; Rowe et al. 2019; Zinkann et al. b, in review). Although the input of terrestrial matter via rivers and coastal erosion is typically still smaller than the input from marine primary producers, in a warming climate, an increases of terrestrial material to the benthos could affect the direction and efficiency of energy flow through the food web (Dunton et al., 2006). Additionally, sediment bacteria contribute nutritional value to the detrital food supply to and also play an important role in the breakdown and recycling of organic matter (e.g., Newell, 1965; Heip et al., 1995). While Arctic bacterial production and metabolic processes are well adapted to the ambient low temperatures, the predicted increases in bottom water temperature on the Chukchi shelf (Wang et al., 2012) are likely to result in higher bacterial metabolic processes and thus bacterial production (Pomeroy and Deibel, 1986; Kirchman et al., 2009; Zinkann et al. a, in review). This could lead to changes in the carbon cycling of the system, and a potential increase in the importance of bacteria as a benthic food source (Kirchman et al., 2009; McMeans et al., 2013; Bell et al., 2016). Therefore, both terrestrial and bacterial sources should be considered in predictive ecosystem models of the Chukchi Sea.

The goal for this study was to enhance our understanding of trophic pelagic-benthic couplings in the Chukchi Sea ecosystem, and to examine potential ecosystem shifts under future climate scenarios. To address these goals, a recent Chukchi Sea ecosystem mass-balance model (Whitehouse and Aydin, 2016) was updated to include terrestrial matter as a potentially important food source. We determined the necessary terrestrial biomass to balance the ecosystem model with the expected loss in phytoplankton derived organic matter. We accordingly re-defined the routing of phytoplankton, terrestrial, and bacterial matter through the benthic and pelagic food webs. This updated model was then used to determine potential impacts of climate-driven variability in organic matter supply to the food web over time. We hypothesize that weakening of pelagic-benthic coupling would negatively impact benthic biomass and benthos-dependent trophic pathways, but that an increase in terrestrial material and bacterial production would compensate for some of the loss of phytoplankton-derived carbon to the benthos-driven food web.

Materials and Methods

Study area

The Chukchi Sea is a shallow (~ 50 m max), marginal, highly productive shelf of the Arctic Ocean bounded by the Alaskan and Siberian coasts (Fig. 1). Three major water masses (Bering Shelf Water, Anadyr Water, and Alaska Coastal Water) flow through the Bering Strait northward and spread across the shelf (Coachman et al., 1975). Bering Shelf and Anadyr waters mix on the shelf into the salty (30.0 - 33.5), cold (0 – 7 °C), and nutrient-rich Bering Shelf Anadyr Water that flows northwards through the central channel of the Chukchi Sea. Alaska Coastal Water is a nutrient-poor and freshwater-influenced (salinity 20 – 32, 7 - 12°C) water mass that flows along the eastern coast of the Chukchi Sea that carries terrestrial matter from the Yukon River. The Yukon River discharges about 2×10^{11} m^3 freshwater and 2.02×10^{12} g total organic carbon annually into the Bering Sea (Guo and Macdonald, 2006), much of which is advected northward onto the Chukchi shelf (Coachman, 1986; Jorgenson and Brown, 2004; Guo and Macdonald, 2006; Pisareva et al., 2015). In present climate conditions, the Chukchi shelf is sea ice covered for up to 7 months a year (November – May), resulting in short seasonal pulses of ice edge-associated primary production (Walsh et al., 1989). Variations in physical properties and biological dynamics, such as timing and location of phytoplankton blooms, grazing pressure of zooplankton, and organic matter degradation through bacteria, have strong influences on the amount of pelagic-benthic coupling and organic matter pathways in the Chukchi Sea (Walsh et al., 1989; Grebmeier and Barry, 1991).

Modeling Approach

1. *Ecopath modelling framework*

Ecopath (http://ecopath.org/) is a publicly available ecosystem modeling software package that

allows the user to create a mass-balanced snapshot of a system of interest. Configuration of the model requires categorization of the organisms, or groups of organisms, that will be represented and information about how these groups are related though energy flow. The model summarizes and optimizes information on biomass, diet composition, rate of production and consumption, biomass removals from fishery and natural mortality, and information about detrital fate (Christensen and Pauly, 1991; Christensen et al., 2000). Ecopath is based on the assumption of steady state mass-balance over an arbitrary period of time, in this study, a year. The program uses two governing equations to describe both the production and energy balance of each functional group by quantifying the material (biomass) moving in and out of functional groups in a given food web. A functional group can consist of a single species, a set of species, or represent a detrital pool. Following are the master equations in Ecopath that are being applied for each functional group (*i*):

$$P_i = Y_i + B_i * M2_i + E_i + BA_i + P_i\,(1 - EE_i) \quad (1)$$

Production = fisheries catch + predation mortality + biomass accumulation + net migration + other mortality

$$(Q/B)_i * B_i = \left(\frac{P}{B}\right)_i + B_i + R_i + UN_i \quad (2)$$

Consumption = production + respiration + unassimilated food

Definitions of the parameters in the two equations are given in Table 1.

Model parameters can be specified based on observational data, experimental results, or estimated by the model by solving the set of equations. While most parameters are mandatory inputs, optional inputs are the parameters biomass (B), consumption to biomass ratio (Q/B), production to biomass ratio (P/B), and ecotrophic efficiency (EE), as they can be computed by Ecopath given all other parameters. Ecopath links the production of each functional group with the consumption of all other groups and uses the linkages among groups to estimate any missing parameters, using one equation for each functional group. Ecopath works with energy-related currencies and energy output and input must be balanced, so that production of any group is routed to other functional groups within the system, or

out of the system. If not balanced, the EE of a group is >1, indicating that less material is entering the group or box than is consumed. In this study, all production terms represent annual integrations.

2. Update of existing mass-balance model

The most recent version of Ecopath model for the eastern Chukchi Sea shelf was acquired (Whitehouse and Aydin, 2016) (Table 3) and used as baseline model. In the present study, phytoplankton biomass was reduced relative to the baseline to reflect recent estimates of annual production on the Chukchi Sea shelf (Arrigo and van Dijken, 2015). Terrestrial production was added to account for external organic matter input and balance the reduction in phytoplankton biomass. Detrital fates were adjusted to account for the export of material (e.g., waste products) to both terrestrial and phytoplankton detritus pools, and diets of benthic invertebrates were adjusted to reflect our recent findings of organic matter consumption (Zinkann et al. b, in review) (Table 3, Fig. 2).

i. Phytoplankton

In the development of the original Chukchi Sea ecosystem model (Whitehouse et al., 2014), a top-down balance approach was used to estimate phytoplankton production in the system resulting in an annual phytoplankton production of ~170 g C m^{-2} y^{-1}. Subsequent model iterations (Whitehouse and Aydin, 2016) put annual phytoplankton production closer to empirical values, at 141 g C m^{-2} y^{-1}, by reducing the phytoplankton biomass from 27.8 t km^{-2} to 15.0 t km^{-2}, assuming a P/B ratio of 75 and 150 days of growing season for phytoplankton. Whitehouse and Aydin (2016) acknowledged that these annual production and biomass values were still high but were needed to balance an insufficient supply of phytoplankton biomass to the benthic detritus box of the model. Annual primary production estimates for the Chukchi shelf are highly variable, ranging from 20 g C m^{-2} to >400 g C m^{-2} y^{-1} (Sakshaug, 2004), but an average annual primary production of ~141 g C m^{-2} y^{-1} for the entire shelf is likely an overestimate. Annual primary production estimates for the shelf in recent years were closer to ~96 g C m^{-2} y^{-1} (Arrigo and van Dijken, 2011), about 30 % lower than the Whitehouse and Aydin (2016) model requires. To reflect these findings, phytoplankton biomass was reduced by 30 % to 15.0 t km^{-2} in our updated model while keeping P/B values at 75, assuming an average growth rate for Arctic diatoms to be ~0.5 d^{-1} (Connell et al., 2018) and a growing season of ~150 days (Walsh et al., 1989).

ii. Detrital components

Terrestrial organic matter was not included as a food source in any of the previous mass balance Chukchi Sea ecosystem models (Aydin et al., 2007; Whitehouse, 2013; Whitehouse et al., 2014;

Whitehouse and Aydin, 2016). For our updated model, a novel terrestrial production box was added to reflect the terrestrial organic matter that is imported onto the shelf as detritus, where it serves as a food source for the benthic food web. The P/B value for terrestrial production was set to 75, assuming a similar growth rate and 150-day growing period as marine primary producers. The value of 'terrestrial production' biomass was then estimated in an iterative process, starting at 10 t km^{-2}, until the model was balanced (see: Model balancing).

Chukchi Sea benthic invertebrates were permitted to use terrestrial matter and bacteria in our updated model in addition to phytoplankton based on our recent findings (Zinkann et al. b, in review). In the original model (Whitehouse and Aydin, 2016), benthic invertebrates largely fed on benthic detritus, a functional component fueled by inputs from primary pelagic production and secondary production including molts and fecal pellets. For a finer delineation of detrital sources in our updated model, the phytoplankton production component was separated into one that was retained in the pelagic system (phytoplankton retained detritus) and one where phytoplankton was exported to the benthos (phytoplankton export detritus). The phytoplankton export detritus component replaced the 'benthic detritus' box of the original Whitehouse and Aydin (2016) model.

iii. Detrital fate

In our updated model, the phytoplankton export detritus component received ~70 % of total phytoplankton production, while the remaining 30 % were routed into the phytoplankton retained detritus component to reflect the tight pelagic-benthic coupling of the Chukchi Sea shelf (Grebmeier and Barry, 1991). All non-assimilated organic matter by consumers, e.g., due to excretion, was routed in equal amounts to the phytoplankton retained detritus component and the terrestrial detritus component. These proportions are consistent with those used in the Whitehouse and Aydin (2016) model, although in that model all detrital material from non-assimilated food and waste products was routed into the benthic detritus box (Fig. 2). As in the original Whitehouse and Aydin (2016) model, we also assumed that benthic invertebrates directly used benthic bacterial biomass, and parameters for this benthic bacterial box remained unchanged. Finally, detrital flux from fishery discards (in the Chukchi Sea this is related to subsistence or research activity harvests) was routed equally into phytoplankton export and terrestrial detritus components.

iv. Consumer diets

Diets of all functional groups within the original Whitehouse and Aydin (2016) model were set at a fixed diet proportion from prey components or one detrital source. In our updated model, diets of all benthic invertebrates were adjusted based on recent findings that determined the proportions of bacterial, phytoplankton, and terrestrial detrital matter in Chukchi Sea benthic invertebrate diets (Zinkann et al. b, in review). Specifically, the diets of the following benthic invertebrate groups were updated based on the following species: snow crab (*Chionoecetes opilio)*, shrimp (average of *Argis* and *Eualus*), benthic amphipod (*Anonyx*), Bivalvia (average of *Serripes*, *Macoma*, and *Nuculana*), Gastropoda (*Buccinum*), Polychaeta (Maldanidae), and worms etc. (containing bryozoans) (*Alcyonidium*). A mean of all decapod diets (*C. opilio*, *Argis*, *Eualus*) was used for the box "other crabs" (see Table 3). Other benthic invertebrate boxes in the model were updated using a mean of the proportional diet contributions of the three organic matter sources across all benthic taxa from Zinkann et al. b (in review), spanning a multitude of taxonomic groups and feeding characteristics. Diets of pelagic invertebrates, such as Cephalopoda and jellyfish were not updated from the previous model (Whitehouse and Aydin, 2016). In the original Whitehouse and Aydin (2016) model, benthic bacteria were assumed to obtain 100 % of their diet from 'benthic detritus'. Because 'benthic detritus' in our updated model was split into terrestrial detritus and phytoplankton export detritus, benthic bacteria were assumed to consume equal amounts of these two pools. The diets of all higher trophic levels (fish, birds, marine mammals) were kept the same as in Whitehouse and Aydin (2016).

v. Model balancing

Once updated, we re-balanced the model to be based on the reduced phytoplankton production and the added terrestrial production. Because phytoplankton production was set, balancing was achieved by adjusting terrestrial production in a stepwise fashion, increasing production values in 0.1 t km^{-2} increments until the model was in balance (following procedures in Whitehouse and Aydin, 2016).

3. Ecosim framework

Once the updated mass-balanced Ecopath model for the Chukchi Sea was balanced, we used Ecosim simulations (Walters et al., 1997; Christensen et al., 2000; Walters et al., 2000) to run a series of dynamic simulations. Ecosim allows for the manipulation of parameters and analysis of potential impacts of a changing environment on the food web. Ecosim is expressed through a master equation derived from the Ecopath equations (eq. 1 and 2) as follows:

$$dB_i/dt = g_i \sum_j Q_{ji} - \sum_j Q_{ji} + I_i - (MO_i + F_i + e_i) B_i \quad (3)$$

Definitions of the parameters in the equation are given in Table 1.

Ecosim provides the ability to adjust model parameters over time, including the biomass of food web components such as phytoplankton or detrital sources. Ecosim only describes movement of biomass through feeding interactions, so changes in model parameters will affect biomass of the respective functional groups. For the purpose of this study, our updated Ecopath model was assumed to define present steady state conditions. Then, anticipated changes over the 2015-2050 period were cumulatively applied to phytoplankton production, strength of pelagic-benthic coupling, terrestrial matter inflow, and bacterial production (simulations 1-4 below), meaning each subsequent simulation also included the changes of all previous simulations.

4. Model simulations to explore impacts of environmental change

i. Detrital biomass

The biomass of detrital pools reflects the sum of non-assimilated food and organic matter flows from other mortality divided by the P/B ratio of the detritus pool in question:

$$\text{Detritus biomass} = \frac{\left(\frac{B * Q}{B * UN}\right) + \left(\frac{B * P}{B\,[1-EE]}\right)}{P\frac{P}{B_{detritus}}} \quad (4)$$

The P/B ratio in this case is expressed as 1/turnover and reflects the turnover time of detritus. In systems with slow turnover, such as the Arctic, the P/B ratio is usually assumed to be low. Ecosim simulations require detrital biomass to be entered directly. Here, we assumed a P/B ratio of 0.5 as a value that is fast enough to show some detrital dynamics, but slow enough to be stable and reflect detrital burial (Christensen and Pauly, 1993; A. Whitehouse. pers. comm). The sum of flows to each detrital pool was calculated and entered into the basic input in Ecopath.

ii. Simulation 1: Increased phytoplankton biomass

The continued reduction in sea ice cover on Arctic shelves may lead to an increase in phytoplankton production by 10 % between 2015 and 2050 (Arrigo and van Dijken, 2015). To represent a ~10 % increase in phytoplankton production for this simulation, we assumed a linear annual 0.28 % increase in phytoplankton biomass over the targeted time frame (2015-2050), from an initial phytoplankton biomass of 15.0 t km^{-2} in 2015 to 16.5 t km^{-2} by 2050.

iii. Simulation 2: Weakening of pelagic-benthic coupling

Phytoplankton communities are expected to shift to smaller phytoplankton species and an increase in zooplankton grazing on pelagic production is predicted to result in a decrease in the flux of pelagic production to the seafloor (Lalande et al., 2007; Arrigo et al., 2008; Wassmann and Reigstad, 2011). To reflect this change, we assumed in this simulation, in addition to increased phytoplankton biomass (simulation 1), that 30 % rather than 70 % of primary production as in the steady state model is routed to the seafloor; conversely, 70 % of phytoplankton biomass rather than 30 %, as in the steady state model, remains in the pelagic realm.

iv. Simulation 3: Increase in terrestrial matter inflow

Increased river discharge and coastal erosion are expected to increase the influx of terrestrial matter onto the Chukchi Sea shelf (Semiletov et al., 2011). In this simulation, in addition to the increase in phytoplankton production and a weakening in pelagic-benthic coupling (simulations 1 and 2), we assumed that terrestrial matter loading will increase in proportion to the predicted increase of river discharge of 2.6 % per decade (Bopp et al., 2001; McClelland et al., 2006). Accordingly, terrestrial biomass was increased at a linear rate (0.26 % y^{-1}) over 35 years (2015-2050) from an initial biomass value of 15.6 t km^{-2} (see results) to a final value of 29.7 t km^{-2}.

v. Simulation 4: Increase in bacterial production

Bacterial production in Chukchi Sea sediments is known to be temperature dependent, increasing by 182 % within 12 h when the temperature was raised from an ambient 0 °C to 5 °C under replete substrate conditions (Zinkann et al. a, in review). To reflect this response to warming temperatures, in this simulation, we assumed a linear increase of 182 % in benthic bacterial biomass to represent an increase in bacterial production between 2015 and 2050, so that bacterial biomass increased from an initial value of 26.4 t km^{-2} to 74.4 t km^{-2}. Previous model adjustments, i.e., the increase in phytoplankton production, a weakening in pelagic-benthic coupling, and an increase in terrestrial matter inflow (simulations 1-3) were also applied.

Results

Changes in detrital sources at the base of the food web

Following the reduction of phytoplankton biomass, the updated model was initially out of balance due to a higher demand for detritus than the model provided (EE>1 for phytoplankton export detritus).

After the addition of a terrestrial detritus component and updates to diets of benthic invertebrates, the phytoplankton export detritus component was balanced, but the overall model was still out of balance due to insufficient supply of terrestrial detritus (EE>1 for terrestrial detritus). Therefore, terrestrial detritus was increased in 0.1 t km^{-2} increments until the model was in balance at 15.6 t km^{-2} (EE<1 terrestrial detritus).

The throughput representing the size of the entire system in terms of matter flow was calculated by Ecopath directly as 9277.5 t km^{-2} yr^{-1} in our updated model, compared to 8453.1 t km^{-2} yr^{-1} in Whitehouse and Aydin's (2016) model. Most updated model components (mammals, birds, fish, pelagic invertebrates) exhibited similar biomass to that of the Whitehouse and Aydin (2016) model. Adjustments to phytoplankton production values, and the addition of terrestrial detritus, resulted in decreases of overall production of phytoplankton (from 2085 to 1125 t km^{-2} yr^{-1}) and slight increases in bacterial production (from 625 to 730 t km^{-2} yr^{-1}, Fig. 4). While these changes did not lead to strong changes in biomass of the consumer components of the model, energy flow in our updated model was more diversified with the addition of more detrital groups.

Temporal / multi-decadal simulations

Outputs from model simulations are presented as relative biomass. Relative biomass refers to the percentage change in biomass of an ecosystem group relative to its biomass at the beginning of the simulation period. Results show change in relative biomass at the end of the model simulation period (2050) for major ecosystem groups (Fig. 5a-d). An increase in annual phytoplankton production (simulation 1, Fig. 5a) resulted in a slight increase of relative biomass across all ecosystem groups, ranging from 1 to 18 %. The largest increase in relative biomass was observed in pelagic invertebrates (12-18 %; Fig. 6a). Smaller increases in relative biomass occurred in birds and fishes, while benthic invertebrates and marine mammals remained practically unchanged in average relative biomass (Fig. 5). Within these ecosystem groups, larger biomass increases were typically observed in pelagic-feeding functional groups, such as pelagic-feeding birds versus piscivorous birds (see Fig. 6).

When the system was forced into a state of weakened pelagic-benthic coupling in addition to increased phytoplankton biomass (simulation 2, Fig. 5b), average relative biomass increased in pelagic invertebrates and birds, but decreased in benthic invertebrates, fishes, and marine mammals. Relative biomass of pelagic invertebrates increased most (average 26 %) with the enhanced retention of primary production in the pelagic realm. The strongest declines in biomass were observed in benthic invertebrate

groups (9-68 %, average 27 %) with especially large declines for groups that fed on a variety of organic matter sources (Fig. 6b). Fishes showed the largest range in responses with increases in biomass by up to 36 % in some of the pelagic-feeding groups, especially Arctic cod (*Boreogadus saida*), salmon (Salmonidae), and pollock (*Gadus chalcogrammus*), and decreases in relative biomass in mostly benthic-feeding groups, such as small-mouth flatfish (*Etropus microstomus*), sculpins (Cottoidea), and skates (Rajidae) (between 17-47 % decrease) (Fig. 6c). A variable response also was observed in birds, where relative biomass of planktivorous birds (e.g., scolopacids) increased (between 24-32 %), while most piscivorous birds remained stable or decreased in biomass by up to 6 % (e.g., larids, cormorants) (Fig. 6d). Benthic-feeding mammals, including gray whales (*Eschrichtius robustus*), Pacific walrus (*Odobenus rosmarus*), and bearded seals (*Erignathus barbatus*) experienced decreases in biomass ranging from 18 to 26 % (Fig. 6e).

An increase in terrestrial organic matter inflow onto the shelf, in addition to increased phytoplankton production and weakened pelagic-benthic coupling (simulation 3, Fig. 5c), resulted in small increases in relative biomass of most groups, compensating for several of the biomass declines observed in simulation 2. Relative biomass changes of pelagic invertebrates were similar to those in previous simulations, indicating that this ecosystem group was mostly unaffected by the terrestrial matter influx (Fig. 5c, Fig. 6a). Equally, average bird biomass in simulation 3 was similar to levels in simulation 2 but with no functional group experiencing a decrease. Benthic invertebrates, on average, showed a small increase in relative biomass compared to the steady state level and to simulation 2 responses (Fig. 5c), albeit with a large range of biomass changes among functional groups (Fig. 6b). Benthic invertebrate functional groups that showed the largest increases in biomass were snails, benthic urochordates, and sponges (increases by 60 %, 44 %, and 43 %, respectively), while decreases in relative biomass were observed in, e.g., snow crab (*Chionoecetes opilio*) (-17 %) (Fig. 6b). Fishes showed a similar trend to benthic invertebrates with minor increases compared with the steady state level and higher average biomass compared with the previous simulation. The largest biomass increases in fishes (up to 33 %) occurred in mostly pelagic-feeding species, while some benthic-feeding fishes experienced declines in biomass (up to -10 %). Overall, marine mammal biomass remained mostly unchanged compared to steady state conditions with largest increases in biomass observed in pelagic-feeding mammals (+18 %).

Lastly, with the exception of pelagic invertebrates, an increase in annual bacterial production resulted in large average biomass increases in all ecosystem groups, but to varying degrees within each functional group (simulation 4, Fig. 5d). Pelagic invertebrates remained mostly unaffected by the increase

in bacterial production compared with previous simulations. Benthic invertebrates experienced the strongest increases in relative biomass, between 46 – 182 % for different functional groups (Fig. 6b). The second largest increase in biomass occurred in fishes, with strongest responses in benthic-feeding fish groups (up to 170 %, Fig. 6c). The simulated increase in bacterial production also resulted in higher relative biomass of up to 87 % in piscivorous birds, while it only increased in planktivorous birds by up to 32 % (Fig. 6d). With biomass increases of up to 90 % in some benthic-feeding species, marine mammals responded with stronger biomass increases to increased bacterial production than to any prior model adjustment (Fig. 5d).

Discussion

Unprecedented changes occurring on Arctic shelves, such as the Chukchi Sea, have the potential to influence the flow of energy through the ecosystem and alter the supply of organic matter sources in this benthos-dominated system. In an effort to predict potential food web responses of these changes we performed a series of model simulations with an updated Chukchi Sea ecosystem model. We found that the addition of terrestrial matter as a benthic food source diversified the energy flow at lower benthic trophic levels, but overall energy flow through the ecosystem components and biomass of the components remained largely the same as in the previous model version (Whitehouse and Aydin, 2016). Further, cumulative model simulations of climate-driven changes in phytoplankton production, strength of pelagic-benthic coupling, terrestrial matter inflow, and bacterial production were used to assess potential changes in major ecosystem groups of the Chukchi Sea. The biomass of most ecosystem groups increased slightly in response to elevated phytoplankton production, while feeding habits (pelagic-feeding versus benthic-feeding) strongly determined the changes in biomass in subsequent simulations. In several groups, high terrestrial inflow and increases in benthic bacterial production had the potential to compensate for the loss in phytoplankton export to the benthos in a weakened pelagic-benthic coupling scenario.

Annual phytoplankton production in the original Chukchi Sea ecosystem model was estimated at ~141 g C m^{-2}, so that balanced energy flow through the functional groups could be established; however, the authors considered the production value an overestimation (Whitehouse and Aydin, 2016). This suggests that there are food sources in the system that were not included in the original model. One of these food sources could be terrestrial matter. Terrestrial matter has traditionally been assumed a negligible food source in Arctic marine food webs (Schell, 1983), but has recently been identified as a major contributor to at least benthic invertebrate diets in the Arctic (Dunton et al., 2006; Bell et al., 2016;

Harris et al., 2018; Rowe et al., 2019; Zinkann et al. b, in review). For example, ~40 % on average and at some locations up to 80 % of the organic matter in Chukchi Sea sediments can originate from terrestrial matter (Zinkann et al. a, in review). Some consumers like the benthic snail *Buccinum* derived, on average, 81 % of their diet from terrestrial sources on the shelf (Zinkann et al. b, in review). In our model, 15.6 t km^{-2} of terrestrial organic matter were needed to sustain the high benthic biomass and achieve model balance. This may be a high estimate of terrestrial carbon for the Chukchi Sea. One study identified regional benthic carbon concentrations on the Chukchi shelf and reported 5.6 – 7.5 g m^{-2} of organic carbon concentrations (Naidu et al., 1993). Based on our recent work, we estimated 40 % of this to be terrestrial matter (Zinkann et al. a, in review), which would, at maximum, amount to only about a fifth of the terrestrial carbon concentrations that we calculated to balance the model. More in-depth analyses of terrestrial matter concentrations in sediments would improve our ability to model energy flux from the different organic matter sources. However, our updated model provides a new portfolio framework of the Chukchi Sea ecosystem, where a more diversified food base may present a more stable system than previously realized (Huxel et al., 2002).

Arctic benthic invertebrates, especially detritivores, use a variety of organic matter sources deposited to the benthic environment. The use of terrestrial matter by benthic invertebrates has recently been confirmed across various regions of the Alaskan Arctic shelves (Bell et al., 2016; Harris et al., 2018; Rowe et al., 2019; Zinkann et al. b, in review), emphasizing the need to include terrestrial matter into ecosystem models for this region. Information about the proportional contribution of bacteria, phytoplankton, and terrestrial matter to the diets of ten common benthic invertebrate species on the Chukchi shelf, ranging across feeding types and taxonomic groups (Zinkann et al. b, in review), allowed for better resolution of detrital source use in our updated model. What is less well known at this point is the efficiency with which terrestrial matter can be assimilated by these invertebrates. In other Arctic areas, such as the Beaufort Sea, the use of terrestrial matter in benthic food webs increased the trophic steps in the system by reducing the trophic efficiency and the flow of energy to higher trophic levels (Dunton et al., 2006; Bell et al., 2016). Bacterial processes may break down terrestrial matter to facilitate incorporation into marine food webs (Garneau et al., 2009), which increases bacterial production in regions of high terrestrial influx (Figueroa et al., 2016). Energetically, however, the added trophic level of bacterial processing can reduce overall energy transfer efficiency to higher trophic level consumers (Sommer et al., 2002; Berglung et al., 2007). For example, in boreal lake systems, terrestrial organic matter subsidies are abundantly used, but are less effective in supporting consumer population biomass than other food sources (Karlsson et al., 2015). Therefore, trophic transfer efficiency of terrestrial matter in the

Chukchi Sea food web will need to be further investigated to understand the importance of terrestrial matter addition and to appropriately model its incorporation into the energy pathways in the updated model.

Ecosystem model simulations are a valuable tool to discern potential responses of various ecosystem components to anticipated changes in the energy supply and flow of a system. The large changes that Arctic shelf ecosystems are experiencing because of climate change (Steele et al., 2008; Alabia et al. 2020; Huntington et al. 2020) make this a particularly valuable and tractable system for model simulations. Here, we implemented four simulations in a stepwise cumulative fashion, meaning that each subsequent simulation also contained the previous changes. In the natural system, complex ecosystem changes at the base of the marine food web and energy flow are unlikely to happen consecutively, but occur simultaneously and likely not linearly (Doney et al., 2012). However, to discern stepwise responses across the ecosystem, we applied an order where an increase in phytoplankton production (Arrigo and van Dijken, 2015) was followed by weakening of pelagic-benthic coupling (Lalande et al., 2007; Wassmann and Reigstad, 2011), because of greater retention of smaller phytoplankton cells in the water column (Li et al., 2009) and greater grazing pressure in the plankton (Neeley et al., 2018). This enhancement of the pelagic food web may then be countered by an increase in other food subsidies to the benthic system, namely terrestrial matter and subsequent increase of bacterial production (Bopp et al., 2001; Kirchman et al., 2009).

Reductions in sea ice cover allow for a longer growing season and pelagic production has been estimated to increase by 10 % over the next 35 years (Simulation 1, Arrigo and van Dijken, 2015). Enhanced pelagic production resulted in slight increases in relative biomasses of all major ecosystem groups across all trophic levels, reflecting the larger carrying capacity of a more productive system (Christensen and Paul, 1998). Our simulations are only based on feeding interactions and do not take into account other aspects that add complexity to the simulation responses. For example, changes in the physical environment (e.g., warming, Grebmeier et al., 2006; Wang et al., 2012) may cause shifts in community composition that could alter the simulated response to enhanced primary production, which assumes constant community composition. Zooplankton community composition has shifted over the past decades due to larger proportions of Pacific zooplankton species entering the Chukchi shelf in the summer (Matsuno et al., 2011; Ershova et al., 2015; Kim et al., 2020) and trends towards smaller microzooplankton species during warm conditions (Dolan et al., 2014). Similar climate-driven changes have been found in the Atlantic Arctic, with increasing proportions of smaller copepod species due to changes in the

462 phytoplankton community, temperature, and inflow of boreal species (Leu et al., 2011). Such changes in
463 the zooplankton community could influence the efficiency with which the enhanced primary production
464 is channeled through the food web though altered feeding rates, assimilation efficiencies, and lipid
465 storage (Baier and Napp, 2003; Matsuno et al., 2011; Ershova et al., 2015). The increased retention of
466 phytoplankton detritus in the pelagic food web, and subsequent higher zooplankton biomass, may supply
467 larger quantities of prey items to pelagic-feeding mid-trophic level species such as Arctic cod. This, in turn,
468 could lead to increased biomass that supports higher trophic level predators including seals, whales, and
469 birds (Welch et al., 1992; Hop and Gjøsæter, 2013; Marsh et al., 2017). Although increased pelagic food
470 availability could lead to increases in biomass in lower trophic levels, observed trends in zooplankton
471 community composition suggest a shift towards smaller, less lipid-rich copepod species (Matsuno et al.,
472 2011; Ershova et al., 2015), which suggests that subsequent energy transfer through the pelagic food web
473 may eventually be reduced. In addition to possible shifts in energy flow, ice-dependent species, such as
474 Arctic cod may be affected by habitat loss from climate-related changes independent of phytoplankton-
475 driven energy flow. Sea ice is an important habitat for Arctic cod juveniles for feeding as well as protection
476 from predators (Geoffroy et al., 2011). Although Arctic cod biomass responded positively to our simulated
477 ecosystem changes, their likely northward contraction and reduction in juvenile survival rate in response
478 to increased temperature could impact the abundance of this key species in the Arctic food web with
479 implications for higher trophic levels (Darnis et al., 2012). In addition, increased water temperatures are
480 likely going to result in elevated metabolic demands by organisms (Lischka and Rieesell 2017).

481 The Chukchi Sea is known for its tight pelagic-benthic coupling exporting the majority of pelagic
482 production to the benthos and supporting a rich benthic community. These communities serve as an
483 important feeding ground for many higher trophic levels, including fish, birds, and mammals (Moore and
484 Huntington, 2008). It is unsurprising that a weakening in pelagic-benthic coupling (simulation 2) resulted
485 in a strong decline of benthic invertebrate biomass due to the reduced amount of primary production
486 reaching the seafloor in this scenario. In response to this reduction in benthic biomass, benthic-feeding
487 marine mammals and fish showed noticeable declines in biomass (Gray et al., 2017; Jay et al., 2012; Moore
488 and Gulland, 2014). For example, gray whales feed on a broad range of benthic invertebrates, but tend to
489 primarily feed on ampeliscid amphipods (Yablokov and Bogoslovskaya 1984, Nerini 1984). The abundance
490 and biomass of ampeliscids have declined in the Bering Sea, presumably due to changes in the primary
491 production regime, although these changes could have resulted from top-down predation control (Coyle
492 et al., 2007). An ampeliscid decline based on bottom-up factors would be in line with the simulated

493 weakening in pelagic-benthic coupling and a subsequent decline in gray whale biomass and shifts of the
494 foraging area of this top predator (Moore et al., 2003).

495 Increases in terrestrial organic matter source availability (simulation 3) could compensate for
496 some of the biomass loss that several benthic groups experienced under the previous simulation scenario
497 (simulation 2), depending on the composition of organic matter diet composition of benthic functional
498 groups. The addition of this terrestrial material to the model represents a diversification of food sources,
499 which supports notions established for Arctic coastal systems that higher diversity of basal food sources
500 stabilizes the overall food web (McMeans et al., 2013). Benthic functional groups that use high
501 proportions of terrestrial matter (e.g., bivalves and sponges, Harris et al., 2018; Zinkann et al. b, in review)
502 increased the most in relative biomass in the simulation of terrestrial matter addition, while benthic
503 functional groups depending on high proportions of bacteria and phytoplankton in their diet decreased in
504 relative biomass (e.g., snow crab, other crabs and benthic amphipods). Thus, the incorporation of detailed
505 diet compositions in the updated model allowed us to identify some of the more vulnerable functional
506 groups to changes in the organic matter supply to the benthos rather than assuming mostly unified
507 responses across all benthic invertebrates. These results provide new context for potential distribution
508 changes in benthic invertebrate species that are expected to occur in a warmer Arctic, which would
509 consequently influence foraging quality for higher trophic levels (Grebmeier and Dunton, 2000).

510 In addition to the incorporation of terrestrial matter as a food source, the increase in benthic
511 bacterial production further offset some of the expected benthic biomass declines in response to a
512 weakening in pelagic-benthic coupling (simulation 4). A change in organic matter availability may change
513 the habitat suitability for benthic invertebrates. Particularly vulnerable to a decrease in phytoplankton
514 export are benthic-feeding organisms that rely heavily on phytoplankton organic matter sources, e.g.,
515 some crabs; in contrast, taxa relying on bacterial matter would potentially thrive under increased bacterial
516 organic matter availability (e.g., polychaetes, benthic amphipods). Food source availability could,
517 therefore, influence the distribution of ecologically influential species, consequently changing prey quality
518 and foraging areas for important top predators (Alabia et al., 2018). Although biomass of most functional
519 groups increased in this simulation, additional parameters can influence the strength of these effects.
520 These can include temperature effects on growth rates and energy requirements, which will impact
521 energy demands and flow through the system (Ambrose et al., 2006; Bluhm et al., 2009; Węsławski et al.,
522 2011). Higher temperatures could increase metabolic demands of all functional groups, giving rise to a
523 higher demand for food supply, thus reducing the effects seen in our model simulations.

In conclusion, we have provided an updated model of the Chukchi Sea ecosystem and have presented new findings with respect to organic matter supply and use in the Chukchi Sea marine ecosystem. Changes in energy flow and diversification at the base of the Chukchi Sea food web provided a foundation to evaluate the response of major ecosystem components to the changes in energy routing through the pelagic or the benthic food web pathways. The loss in phytoplankton routing to the benthos in a weak pelagic-benthic coupling system may at least partially be offset by an increased inflow of terrestrial matter and in bacterial production. The effects of changes in pelagic or benthic energy flow were detectable throughout all trophic levels and taxonomic groups. However, other ecosystem changes, such as changes in competitive interactions from invading species, energetic composition of key prey items, or changes in trophic transfer efficiency of different organic matter sources, are likely to have effects across trophic levels, but were not reflected in the current model simulations. In future iterations, the model could be used to simulate other climate-driven changes as well as potential external activities, including fishing and oil and gas extraction on the Chukchi shelf. The shelf is home to a variety of fish species and marine mammals that are an important subsistence resource for indigenous residents (Hovelsrud et al., 2008; Zeller et al., 2011). The model presented here is a useful tool to simulate potential changes in the system and manipulate parameters based on those activities (e.g., Harvey et al., 2012). This allows for the assessment of risks to targeted functional groups, guidance to stakeholders, and identification of knowledge gaps (Samhouri et al., 2009).

Acknowledgements

This work was funded in particular through a National Ocean Partnership Program (NOPP grant NA14NOS0120158 to KI) by the National Oceanographic and Atmospheric Administration (NOAA), the Bureau of Ocean Management (BOEM) and Shell Exploration & Production under management of the Integrated Ocean Observing System (IOOS). This publication was also sponsored in part by the Cooperative Institute for Alaska Research with funds from the National Oceanic and Atmospheric Administration under cooperative agreement NA13OAR4320056 with the University of Alaska. SLD acknowledges support from the North Pacific Research Board's Arctic Integrated Ecosystem Program grants A91-99a and A91-00a to the Arctic Shelf Growth, Respiration, Advection and Deposition (ASGARD) rate experiments project. Thanks to Andy Whitehouse (NOAA, NMFS) for his continuous support in the development of this model. Additional thanks to Villy Christensen at the University of British Columbia for providing ACZ with the opportunity to attend the Ecopath class in Vancouver in 2017. We thank Matthew Wooller and Mary Beth Leigh (UAF) for valuable comments on this manuscript.

Figures and tables

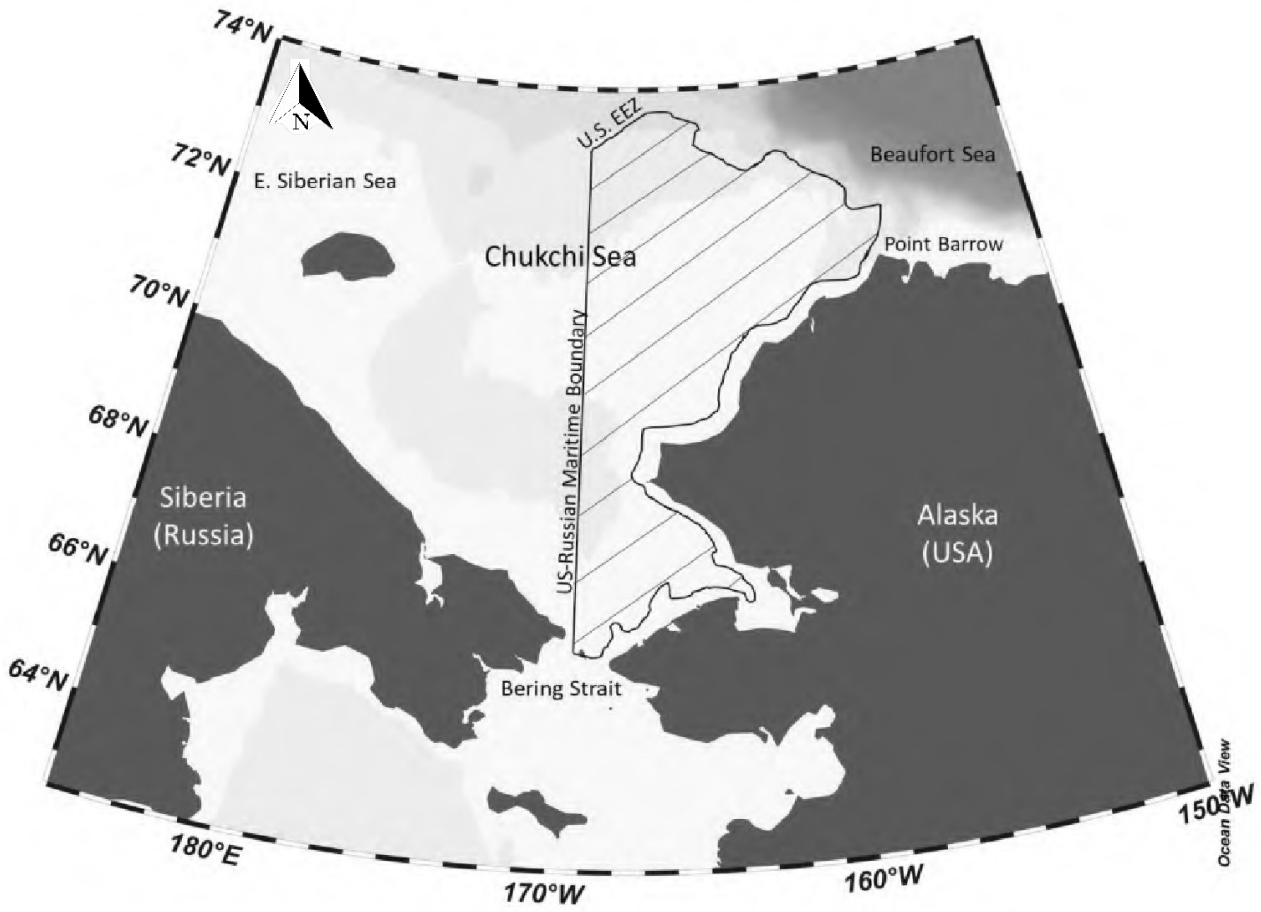

Figure 1. Map of the model area on the eastern Chukchi Sea shelf (hatched area). The model is bounded by the US-Russia maritime border to the west, Bering Strait to the south, Point Barrow to the east, and the US exclusive economic zones along the shelf break to the north.

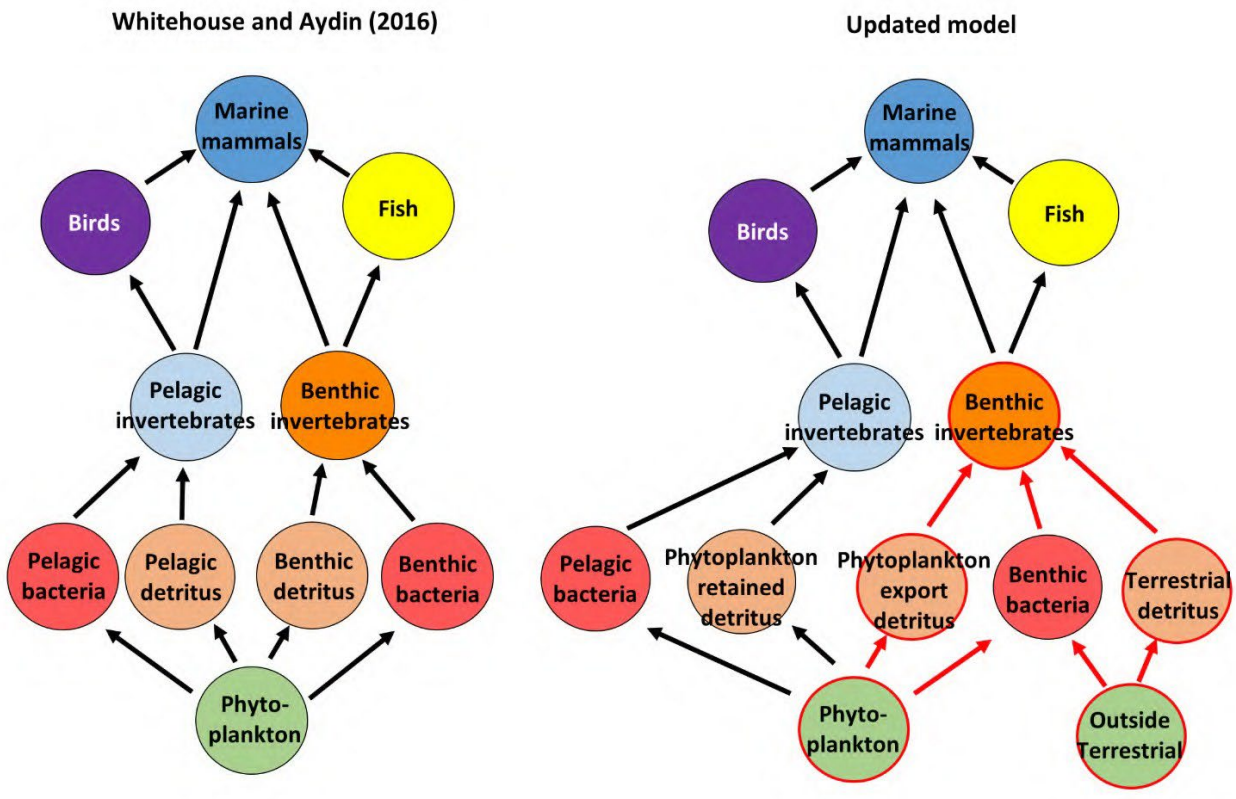

856

857 Figure 2. Comparative schematic of the original Whitehouse and Aydin (2016) and our updated
858 mass-balanced Chukchi Sea ecosystem model. Arrows indicate feeding connections and
859 flow of energy between larger functional groups. Color of circles indicates: brown =
860 detrital pools, green = primary producers, red = bacteria, orange = benthic invertebrates,
861 light blue = pelagic invertebrates, yellow = fish, purple = birds, dark blue = marine
862 mammals. Red outlines and arrows indicate parameters and functional groups that reflect
863 changes in the updated model.

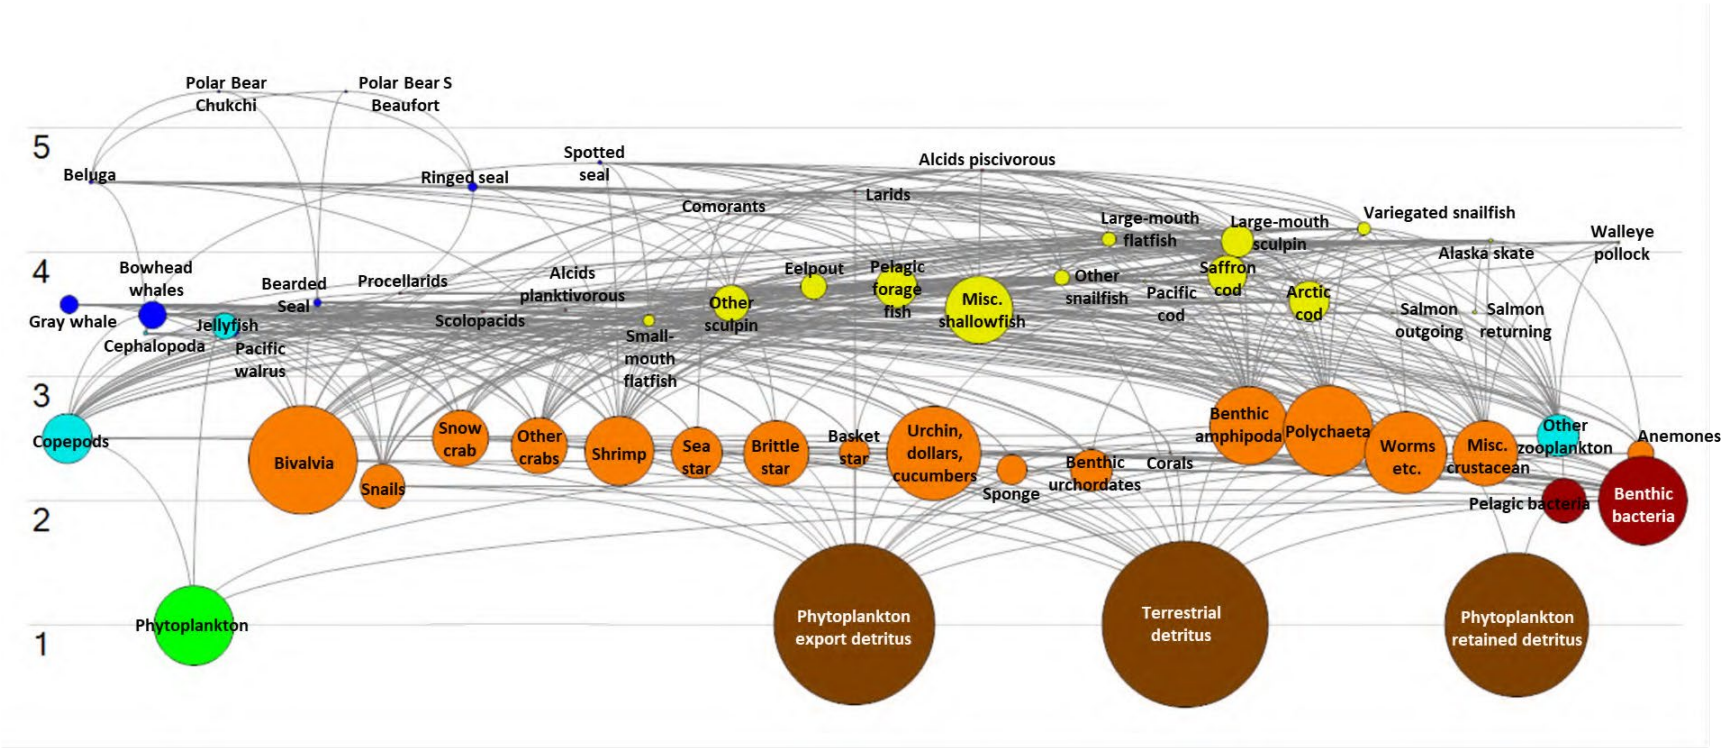

Figure 3. Flow chart for the updated mass-balanced Chukchi Sea ecosystem model. Numbers on the left indicate trophic level, size of nodule indicates biomass of respective functional group, gray lines indicate unidirectional feeding connections and energy flow between functional groups, and colors are indicative of larger functional groupings: brown = detrital pools, green = primary producers, red = bacteria, orange = benthic invertebrates, light blue = pelagic invertebrates, yellow = fish, purple = birds, dark blue = marine mammals.

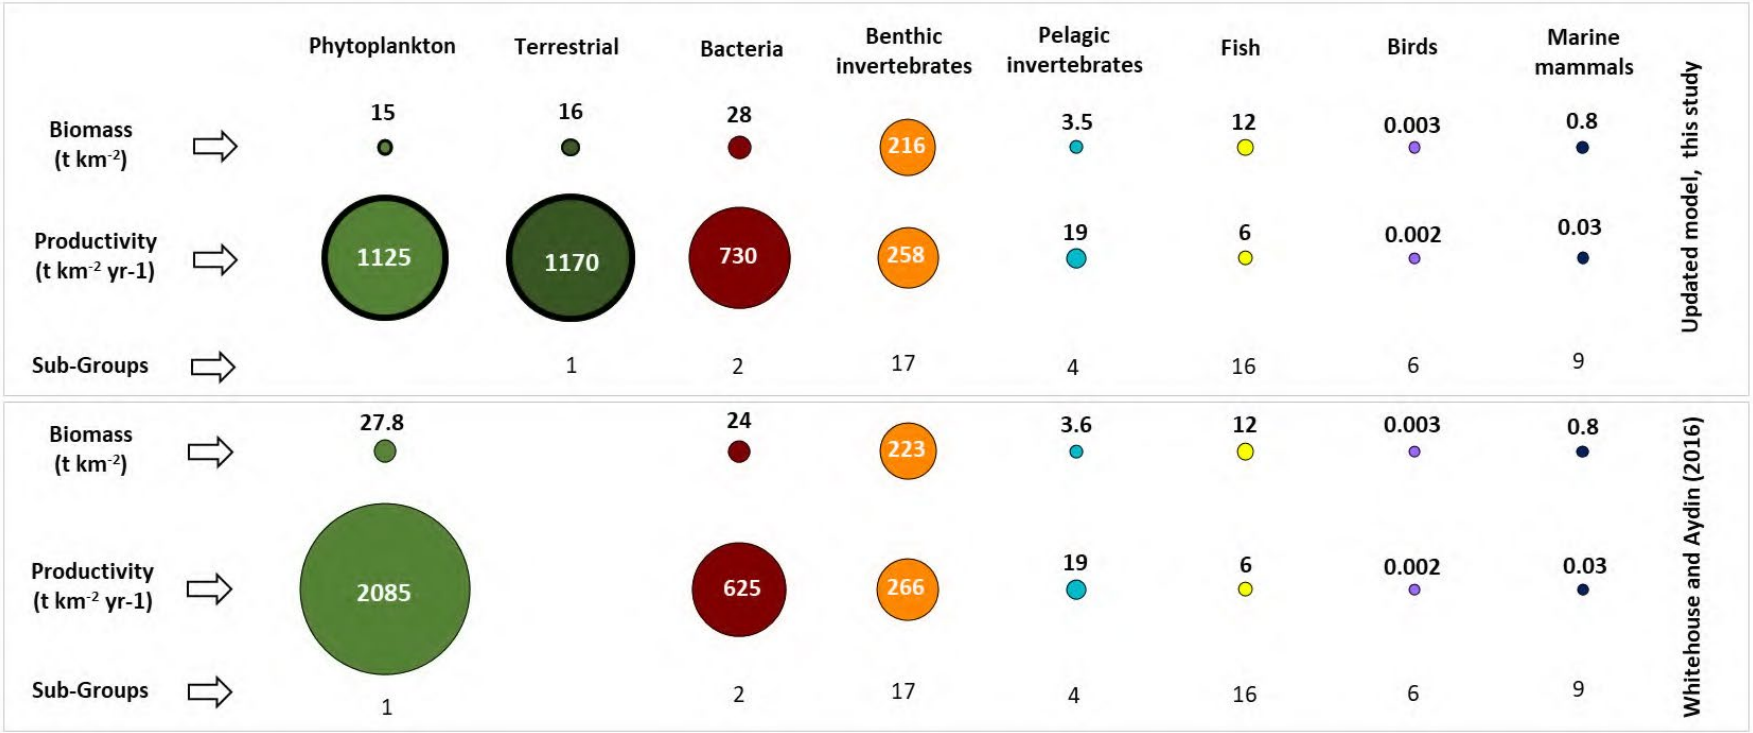

Figure 4. Biomass, productivity of larger functional groups in our updated Chukchi Sea ecosystem model (top panel) and the Whitehouse and Aydin 2016 (bottom panel) model. The figure shows cumulative biomass (t km^{-2}), productivity (t km^{-2} yr^{-1}), and number of subgroups included in each group. Size of circles indicates the representative biomass and production value. Thick black outline indicates the groupings that were updated in the current model: green = primary producers, red = bacteria, orange = benthic invertebrates, light blue = pelagic invertebrates, yellow = fish, purple = birds, and dark blue = marine mammals.

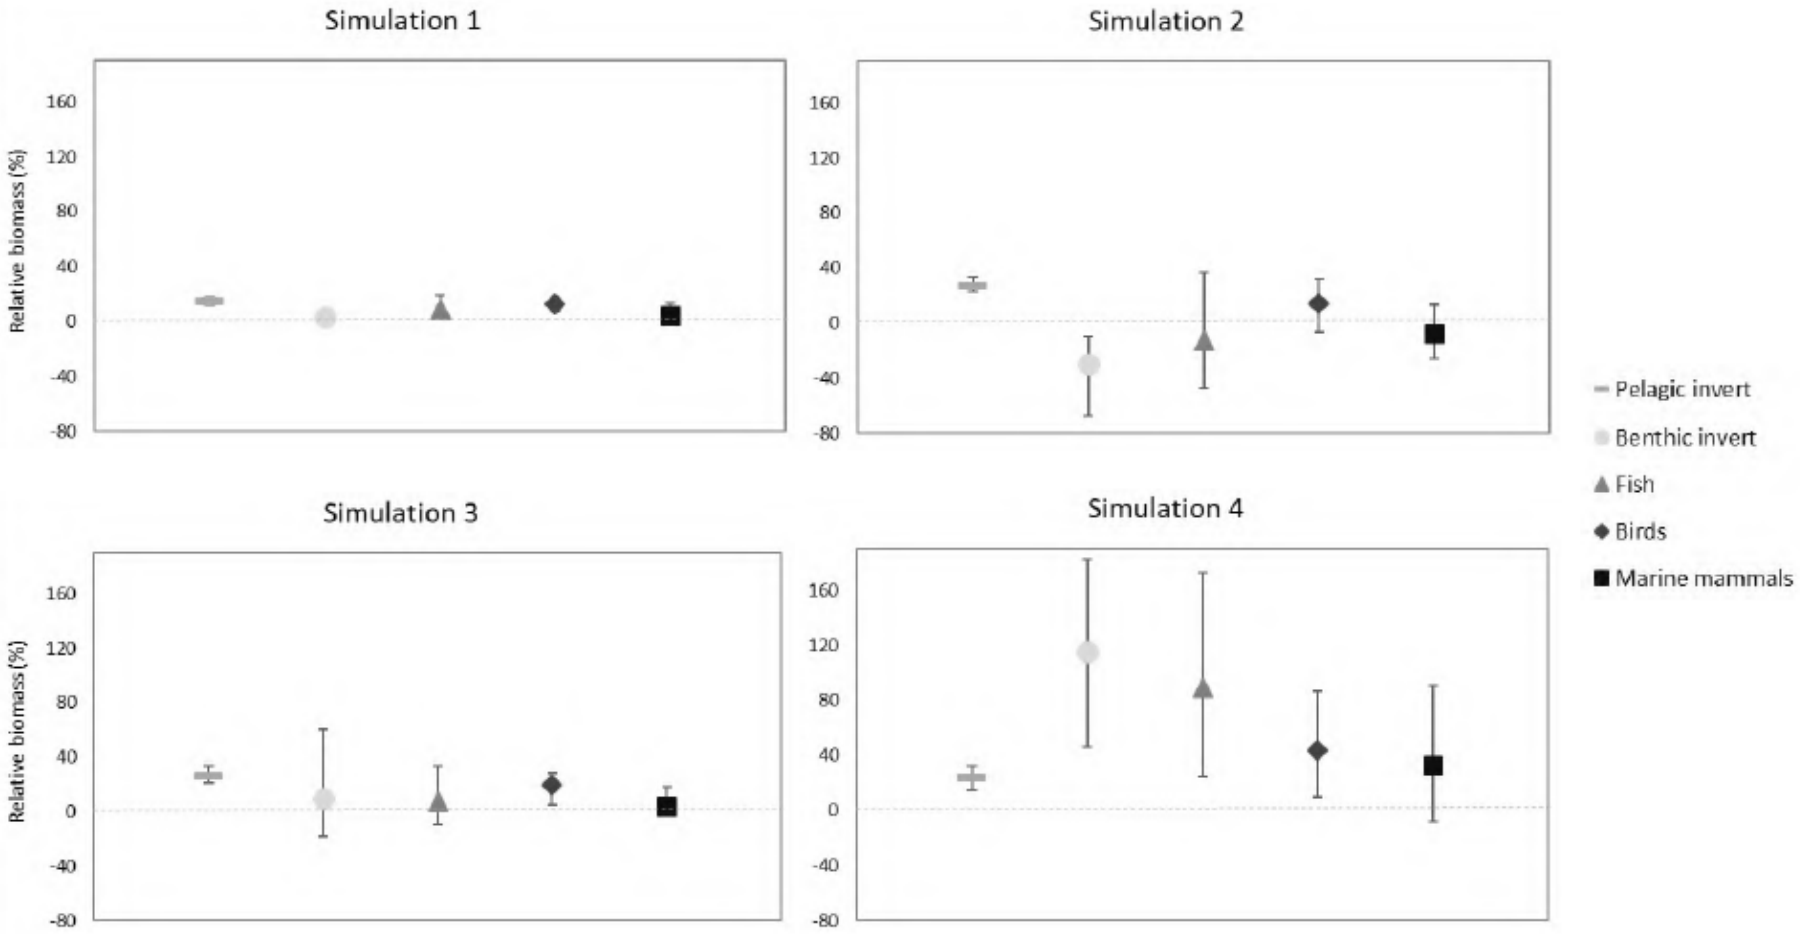

Figure 5. Average relative change in biomass (averaged across functional groups) compared to initial relative biomass (2015) at end of simulation period (2050) based on cumulative Ecosim simulations of the updated mass-balanced ecosystem model of the Chukchi Sea shelf. Error bars for each ecosystem group indicate the minimum and maximum relative biomass values from the functional groups within each ecosystem group (see Fig. 3). Simulation 1 refers to an increase in phytoplankton biomass, simulation 2 refers to an additional weakening in pelagic-benthic coupling, simulation 3 refers to an additional increase in terrestrial matter biomass, and simulation 4 refers to an additional increase in microbial production. The gray line indicates steady state situation with no changes in relative biomass from the initial start year (2015).

Figure 6. Trends in relative biomass (change from initial biomass) for each major ecosystem group (a-e) across the simulation period (2015-2050) based on Ecosim modeling of an updated mass-balanced ecosystem model of the Chukchi Sea shelf. Simulation 1 refers to an increase in phytoplankton biomass, simulation 2 to a weakening in pelagic-benthic coupling, simulation 3 to an increase in terrestrial matter biomass, and simulation 4 to an increase in microbial production. Each simulation also included the changes of all previous simulations. Different shades within some of the larger taxon group indicate functional groupings based on feeding preferences (see legend). Abbreviations in figures refer to specific ecosystem groups: Benthic invertebrates – S (Snails), BU (Benthic urchordates), Sp (Sponges), SC (Snow crab), Birds – S (Scolopacids), L (Larids), C (Cormorants), Fish – AC (Arctic Cod), S (Salmon), P (Pollock), SMF (Small-mouth flatfish), Sc (Sculpin), Sk (Skates), Mammals – G (Gray whales), W (Pacific walrus), S (Bearded seals).

Table 1. Term, descriptions, and units of parameters required for mass-balanced ecosystem model master equations in Ecopath and Ecosim.

Term	Description	Unit
P	Total production rate	t km^{-2} yr^{-1}
Y	Total fishery catch rate (here subsistence harvest)	t km^{-2} yr^{-1}
B	Biomass	t km^{-2}
M2	Instantaneous predation rate	yr^{-1}
E	Net migration rate (emigration-immigration)	t km^{-2} yr^{-1}
BA	Biomass accumulation rate	t km^{-2} yr^{-1}
1-EE	Other mortality	proportion (unitless)
EE	Ecotrophic efficiency	proportion (unitless)
Q/B	Consumption/biomass ratio	yr^{-1}
P/B	Production/biomass ratio	yr^{-1}
R	Respiration of group	t km^{-2} yr^{-1}
UN	Unassimilated food	proportion (unitless)
g	Gross food conversion efficiency (estimated as P/Q ratio)	unitless
Q	Total consumption rate	t km^{-2} yr^{-1}
I	Immigration rate	t km^{-2} yr^{-1}
MO	Instantaneous 'other mortality' rate	yr^{-1}
F	Instantaneous fishing mortality rate	yr^{-1}
e	Emigration rate per unit biomass	t km^{-2} yr^{-1}

Table 2. (Next page). Basic model parameters for the updated Ecopath model for the Chukchi Sea. Parameter inputs into the model were taken from Whitehouse and Aydin (2016). Parameters in bold were computed by the updated model. New functional groups and changed input parameters are highlighted by gray background. TL is trophic level, B is biomass (t km^{-2}), P/B is production to biomass ratio (y^{-1}), Q/B is consumption to biomass ratio (y^{-1}), EE is ecotrophic efficiency, GE is growth efficiency (y^{-1}), UN is unassimilated food, PED is phytoplankton export detritus, TD is terrestrial detritus, and PRD is phytoplankton retained detritus.

Abstract

The highly productive northern Bering and Chukchi marine shelf ecosystem has long been dominated by strong seasonality in sea ice and water temperatures. Extremely warm conditions from 2017into 2019 - including loss of ice cover across portions of the region in all three winters - were a marked change even from other recent warm years. Biological indicators suggest this state change could alter ecosystem structure and function. Here we report observations of key physical drivers, biological responses, and consequences for humans, including subsistence hunting, commercial fishing, and industrial shipping. We consider whether observed state changes are indicative of future norms, whether an ecosystem transformation is already underway, and if so, whether shifts are synchronously functional and system-wide, or reveal a slower cascade of changes from the physical environment through the food web to human society. Understanding of this observed process of ecosystem reorganization may shed light on transformations occurring elsewhere.

The Pacific Arctic, composed of the Chukchi and northern Bering seas (Figure 1), is one of the world's most productive ocean ecosystems (1), characterized by high benthic biomass resulting from persistent, nutrient rich flow through the Bering Strait (2) that fuels high primary production (3). In summer and fall, the region is home to millions of nesting and migratory seabirds, with hotspots of foraging activity shared with marine mammals (4), supporting coastal Indigenous communities. The delivery of nutrients together with the extent and timing of sea ice (5) are dominant environmental factors structuring this ecosystem. Freeze-up in fall and winter eliminates large expanses of open water, causing whales, Pacific walrus (*Odobenus rosmarus divergens*), many seals, and seabirds to migrate southwards into the Bering Sea and beyond (6).

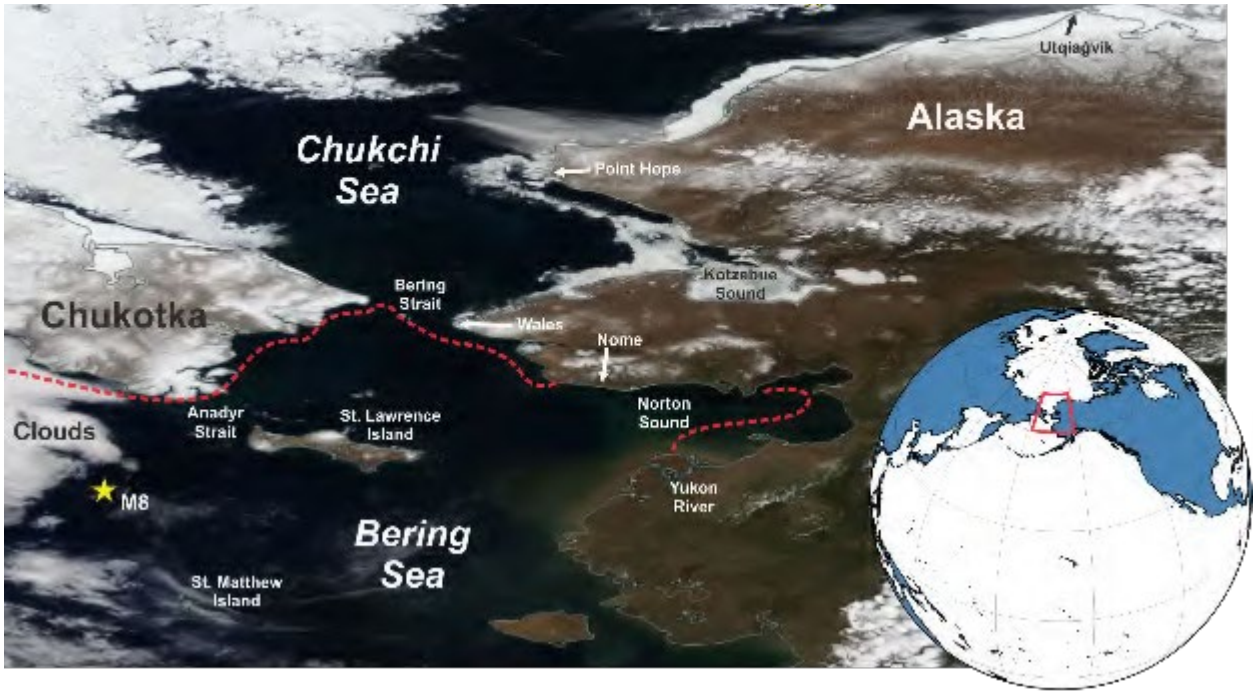

Figure 1. Sea ice changes in recent years. True-color MODIS satellite image showing northern Bering and Chukchi sea ice conditions on 2 June 2017. Red dotted lines denote the 1980-2010 ice edge climatology for June 2nd. Yellow stars denote locations of oceanographic moorings M8 and CEO. Inset locates the study region. Image from NASA Worldview.

In spring, the return of sunlight heralds snow melt, growth of sea ice algae, and a phytoplankton bloom that typically exceeds the consumption capabilities of pelagic consumers, resulting in carbon falling to the seabed, fueling rich benthic communities (7,8). Solar radiation and melting sea ice help stratify the upper water column, impeding the ability of winds to mix surface and subsurface waters. In summer, low-salinity surface waters near the pack ice remain cool relative to the shelf waters warmed by insolation. The Bering Sea cold pool, near-bottom shelf waters cooler than 2°C south of Bering Strait, has long served as a thermal barrier to northward migration of subarctic groundfish (9), which are major stocks for the southeastern Bering Sea's $2 billion fishery and account for about half the seafood landings in the United States (10,11).

Recent Changes in the Pacific Arctic Marine Ecosystem

Declining sea ice in this century has reduced surface albedo in spring and summer, accelerating oceanic heat uptake and causing earlier and more rapid sea ice melt (12). The pack ice and marginal ice zone has retreated north beyond the Chukchi shelf in recent summers, while warmer shelf waters delay sea ice formation in fall. Simultaneously, the northward flow of water through Bering Strait has increased, as has its temperature (2), so that it now delivers more heat, freshwater, nutrients, and biota northwards into the Arctic (13). Near-bottom water temperatures exceed 0°C for a larger portion of the year (Figure 2).

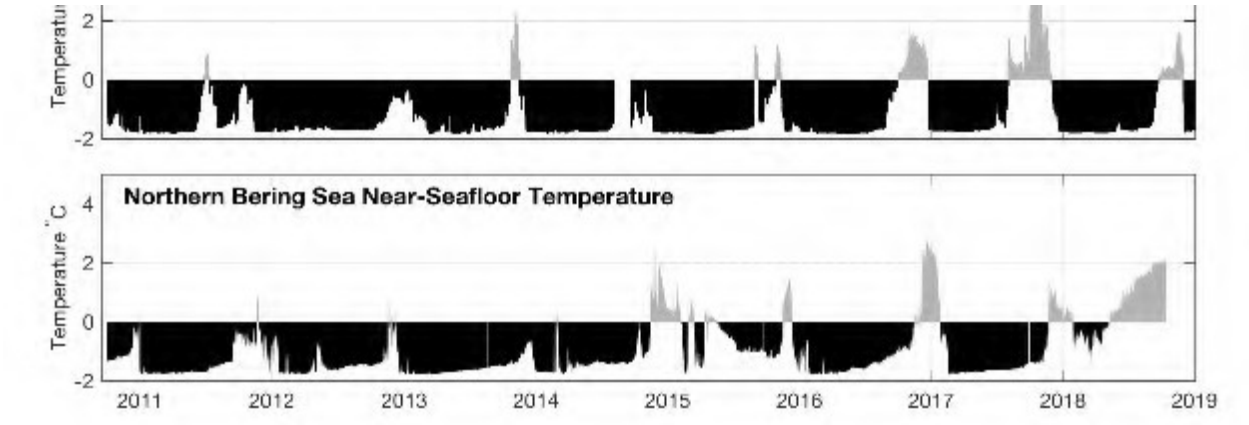

Figure 2. Near-bottom water temperatures. Previously, temperatures in important seafloor habitats remained below 0 ℃ for most of the year. In recent years, an increasing number of months exhibited temperatures well above 0 ℃. Mooring locations are indicated on Figure 1.

Ramifications of these physical changes have included more salmon in the Chukchi and Beaufort seas (14,15), walrus hauling out on shore in northwestern Alaska in late summer instead of on sea ice (16), an increase in the frequency and seasonal duration of killer whale (*Orcinus orca*) presence in the Chukchi Sea (17), an increase in planktivorous seabirds in the Chukchi Sea (18), and a northward shift in the distribution of other seabird species (19,20). For the Indigenous peoples of the region, spring marine mammal hunting opportunities dependent on the presence of sea ice have decreased and shifted in time (21), although the lack of sea ice has allowed additional whaling to occur in fall and early winter in the northern Bering Sea (22).

And Then Came 2017

In 2017, physical conditions in the Pacific Arctic marine shelf ecosystem of the Chukchi and northern Bering seas described above showed signs of a sudden and dramatic shift relative to historical means and even to other recent unusually warm years. In turn, these physical changes seemingly precipitated several significant ecological shifts, with consequences for the region's residents. Based on published and unpublished data from the authors, many changes persisted in 2018 and even into 2019, suggesting that 2017 was not a passing oddity of brief consequence to social-ecological systems, but a sign of what is to come.

In early January 2017, the sea ice edge had barely progressed south of Bering Strait and for the entire winter its extent remained at least $2x10^5$ km^2 below the long-term average. In June, ship-based observations found near-bottom ocean temperatures in Bering Strait of nearly 4 °C, over 3°C and four standard deviations warmer than the 1991-2016 June mean (2). Indeed, by June, the eastern Chukchi shelf was already mostly sea ice-free (Figure 1). In early December 2017, the ice edge was over 1000 km north of its climatological mean position near St. Lawrence Island. There was no sea ice in the Bering Strait in February 2018 and southerly winds forced a large ice retreat again in February 2019 (23). Waters in Norton Sound exceeded 10°C before the end of June 2018 and the cold pool was again minimal by late summer.

Reduced ice cover and warmer seas likely impacted primary production by influencing thermal, light, and stratification conditions. In spring of 2018, in the southern Bering Sea, the bloom was delayed due to a lack of freshwater input from melting sea ice, and chlorophyll concentrations were an order of magnitude lower than usual; however in the northern Bering Sea the ice-associated bloom was early and extensive (24). In addition, the detection of domoic acid in shipboard water samples (Figure 3) and saxitoxin in a few stranded and harvested walruses from Bering Strait villages led to concern about harmful algal blooms and food safety from Indigenous residents, though analytical challenges make the impact difficult to determine (25).

Changes in species distributions had already been observed this century, but not to the extent observed in 2017. The copepods *Calanus glacialis/marshallae* in 2017 were found to be remarkably low in abundance relative to 2012-2015 (Figure 4). Multispecies epibenthic biomass in the southern Chukchi Sea also exhibited a pronounced decline relative to comparable collections in 2004, 2009, 2012, and 2015 (Figure 4). In contrast, acoustic-trawl surveys indicate that age-0 Arctic cod abundance was dramatically higher in the Chukchi Sea in 2017 compared with previous surveys: backscatter in the northern Chukchi Sea (67 N to 71.5 N) was 5.6 times greater than in 2013, and 16.3 times greater than in 2012 (Figure 5), but the fish had low energy content. Juvenile pink salmon (*Oncorhyncus gorbuscha*) catch per unit effort in surface trawl surveys in the northern Bering Sea was two times greater during 2017 than previous years (Figure 4). Juvenile pink salmon return as adults the following year, and the adult pink salmon return to Norton Sound was much stronger than expected during 2018 (27). Adult walleye pollock (*Gadus chalcogramma*), Pacific cod (*Gadus macrocephalus*), and northern rock sole (*Lepidopsetta polyxystra*) biomass in bottom trawl surveys increased in the northeastern Bering Sea during 2017, likely due to northward movement of these fishes in the absence of the Bering Sea cold pool (28).

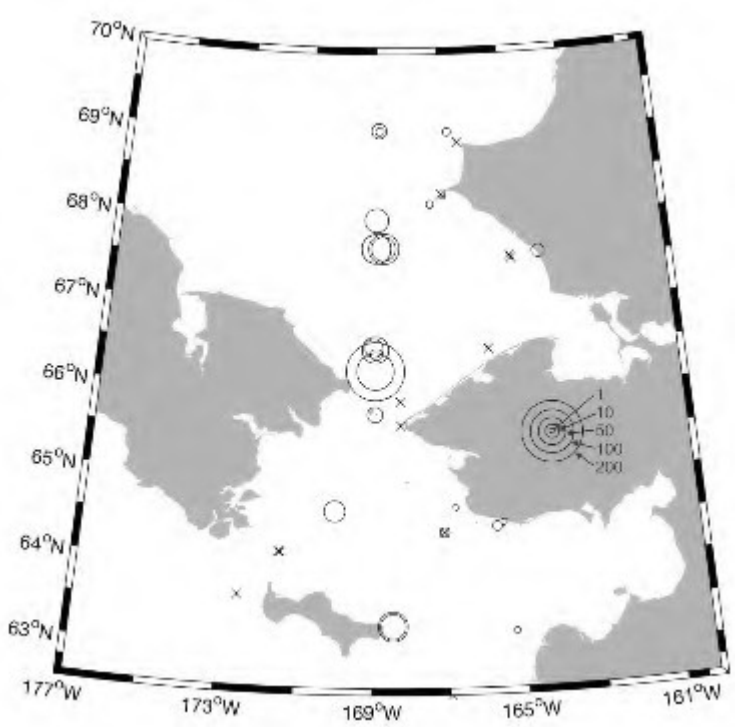

Figure 3. Seawater concentrations of domoic acid, June 2017. NTD = no toxin detected.

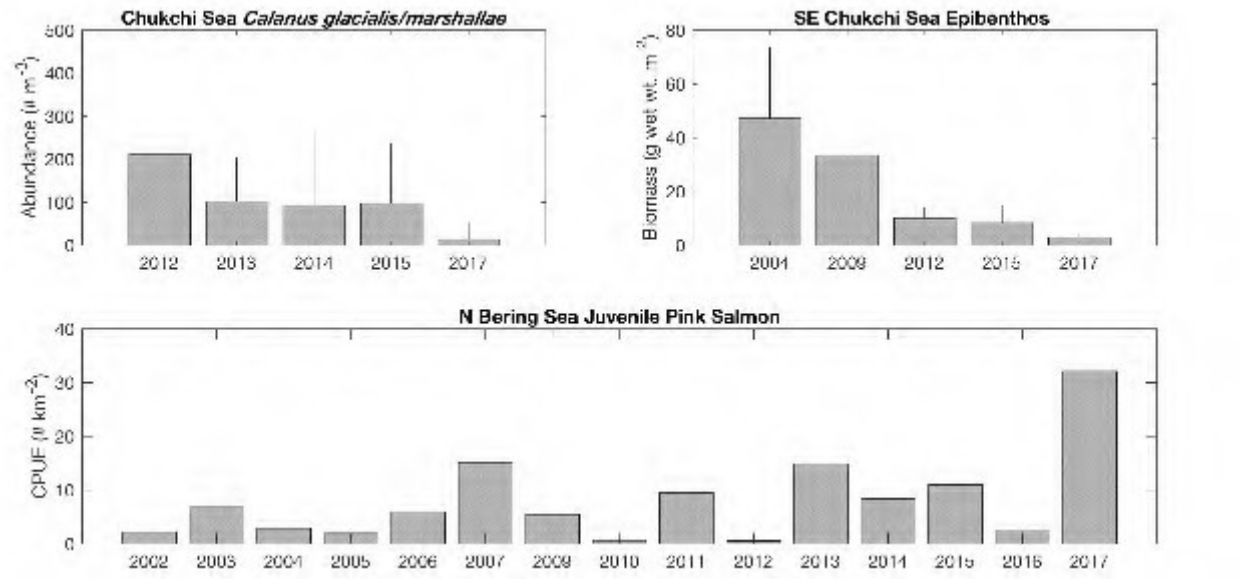

Figure 4. Biological changes in recent years. Observations show declines of Calanus glacialis/marshallae abundance (upper left) and epibenthic biomass (upper right) in 2017

relative to prior years, and an increase in juvenile pink salmon catch per unit effort (CPUE) (bottom). The graphs in upper left and upper right show simple means and standard deviation error bars.

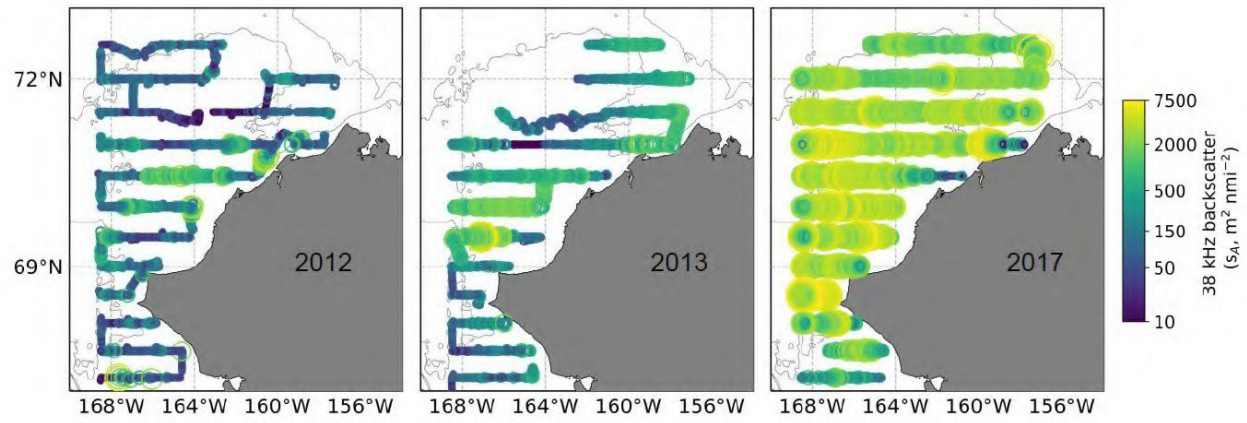

Figure 5. Arctic cod abundance change. Acoustic surveys indicate that the abundance of age-0 Arctic cod increased substantially in 2017 relative to 2012 and 2013. Trawl sampling indicated that Arctic cod dominated acoustic backscatter in this area in 2012 and 2013 (26). This was also the case in 2017: Arctic cod accounted for 95.4% of fish captured in 33 midwater trawl hauls.

In offshore waters, total seabirds declined from 2012-2017 in the southern and northern Bering Sea, but densities were above the long term mean in the Chukchi Sea during most of that period. The increase in the Chukchi Sea in 2015-2017 was primarily due to short-tailed shearwaters (*Ardenna tenuirostris*), which feed primarily on euphausiids, and less pronounced increases in piscivorous black-legged kittiwakes (*Rissa tridactyla*) and murres (*Uria* spp). In contrast, planktivorous auklets (*Aethia* sp.) had low densities in the Chukchi Sea in 2017 and 2018 but increased in the northern Bering Sea those years (24). Reproductive success was low for seabirds in the Bering Sea in 2017-2018, and there were mixed-species die offs there and in the Chukchi Sea (24,29;), with dead birds emaciated. Notably, numbers of murres and kittiwakes attending the large Chukchi Sea colony continued to increase (30) at a rate suggesting immigration of piscivorous nesting birds.

In the spring of 2017, bowhead whales, including females with calves, were seen near Utqiaġvik, Alaska, a month earlier than usual and the Utqiaġvik whale hunt recorded the earliest

known landing, on 13 April. Four bowhead whales equipped with satellite transmitters all wintered (2017/18) in the Chukchi instead of their usual wintering area south of Anadyr Strait in the Bering Sea (31) and a bowhead was recorded singing near Utqiaġvik on 11 January 2018, something never recorded before at that time of year. In 2018/19, the bowheads were again north of Anadyr Strait in winter. Spotted seal (*Phoca largha*) pups in the spring of 2018 were found in poorer condition (less fat and lower mass/length) than in recent years, and almost no ribbon seals (*Histriophoca fasciata*) were seen during those same surveys, raising the specter of a failure in the 2018 year class. In the spring and summer of 2018 and 2019, more than 280 bearded (*Erignathus barbatus*), ringed (*Pusa hispida*), spotted, and unidentified seal carcasses, primarily young and many emaciated, were reported from beaches mostly of the northern Bering and southern Chukchi seas, nearly five times the annual average from 2014-2017, prompting the National Oceanic and Atmospheric Administration to declare an "unusual mortality event" (32).

Anomaly or Transformation?

Changes in sea ice extent, water temperature, currents, zooplankton abundance, animal distribution and health, hunting success, and other aspects of the ecosystem are noteworthy in themselves, but such large-scale changes could conceivably occur without altering basic relationships among ecosystem components. The investigation of specific mechanisms underlying these changes were not part of the cited studies, however it is known from other areas, including the southern Bering Sea, that the spring sea-ice break-up spurs a productive phytoplankton bloom, and its timing together with ocean temperatures determines phytoplankton species composition, carbon export to the benthos, and food quality for zooplankton (24). Changes towards lower-lipid zooplankton reduces over-winter survival of fishes such as salmon and Arctic cod (33), even if they increase numerically in summer due to favorable thermal and oceanographic conditions. Lower zooplankton food quality and increased competition from predatory fish moving north from the Bering Sea might explain seabird and seal mortality.

The ecosystem-wide changes seen in 2017-2019 have the potential to fundamentally reconfigure the Pacific Arctic marine food web. An altered physical environment characterized by warmer waters and a longer open-water season is allowing subarctic species to establish themselves in the Chukchi Sea; seasonally for now, but possibly year-round in the future. Subarctic invaders such as walleye pollock and Pacific cod could fundamentally transform

interactions among pelagic species, benthic invertebrates, groundfish, seabirds, and marine mammals by exerting strong predation pressure on forage fishes and benthic crab, worm, and shrimp communities (10). Predation pressure from these fishes adds top-down stresses to the bottom-up changes associated with altered temperature and primary and secondary productivity. Indigenous hunters may begin to find familiar species of fishes and marine mammals at unusual times of year or unfamiliar species during customary hunting and fishing periods (21).

An interdisciplinary look at the Pacific Arctic marine ecosystem as it changes may provide a rare opportunity to track ecosystem transformation in detail as it unfolds, rather than reconstructing details after the fact. The transformation of an ecosystem may reflect a cascade of sequential changes that take place over multiple years rather than a single shift or tipping point (e.g., 34), though changes to individual ecosystem components may be sudden and dramatic. For example, because of positive feedbacks in the climate system (e.g., 12) it is possible that 2017 marked the crossing of a threshold that precludes return to the system state common just a decade ago. We find that a closely coupled synergy between bottom-up and top-down factors (e.g., 35) appear to best characterize this system's transition, and the interactions among these multiple stressors have important implications for understanding any subsequent reorganization.

The result would be the transformation of an Arctic marine ecosystem into one characterized by subarctic conditions, subarctic species, and subarctic interactions (Figure 6). The Chukchi Sea may soon resemble the east-central Bering Sea shelf in condition, structure, and function, with annual sea ice, warmer bottom water temperatures, and ecosystem productivity derived from forage fishes and pelagic zooplankton rather than the benthos. Changes in the historically strong benthic-pelagic coupling have already been observed in the southeastern Chukchi Sea, where overall epibenthic biomass declined by an order of magnitude from 2004 to 2017; the fact that the most abundant taxa were consistent over time may hint at overall changes in ecosystem productivity or pathways rather than specific habitat changes (36,37). Yet this transformation is more complex than an ecosystem migrating north. For example, the Chukchi Sea would likely retain some characteristics distinguishing it from the Bering Sea shelf, due to higher latitude and downstream location relative to the Bering Strait nutrient supply. How these competing features will combine to create a new state of the Pacific Arctic ecosystem remains to be seen.

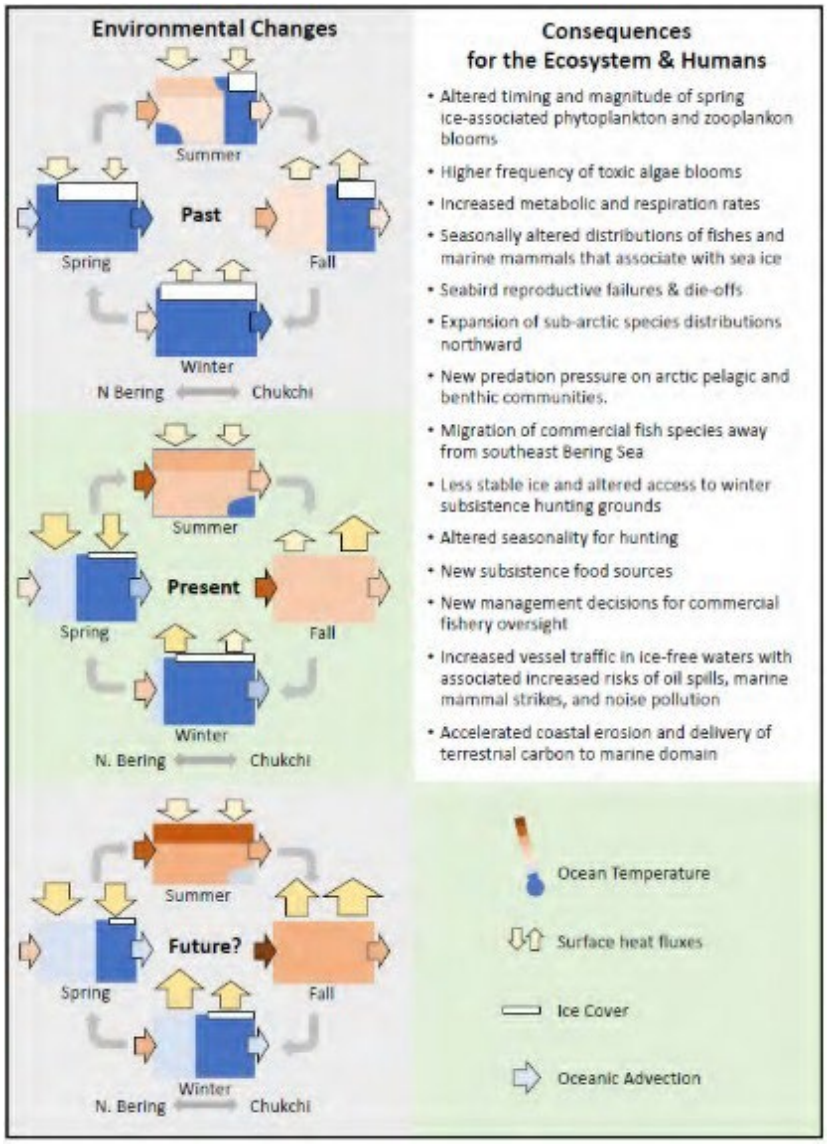

Figure 6. Environmental changes and related consequences. Observed and potential future changes in the physical environment (left panels) in the Northern Bering and Chukchi shelf systems (i.e., bottom-up forcing), along with observed and anticipated consequences for the biological and human components of the ecosystem (right panel).

In addition to its regional significance, the pattern of change underway in the Pacific Arctic may eventually shed light on the progression of ecosystem transformation more generally (38), which manifests as large-scale alterations in the connections and interactions among species and among physical and biological processes. Overpeck et al. (39) suggested the

possibility of such a transformation resulting from the removal of perennial ice in the Arctic, though they focused on "before" and "after" states of the system without describing the transformation in between. The pioneering work of Gunderson and Holling (40) recognized that transformation and reorganization are less predictable and less well understood than a simple shift from stability to instability.

What To Expect Next?

The expectation is for the sea ice season to further shorten and sea ice coverage to diminish (41). Waters will become warmer and stay warm longer into fall and winter. How quickly these changes propagate through and persist in the system, and what additional sudden shifts may occur, are hard to predict. It is likely, however, that there will be differences in the temporal and spatial scales over which physics and biology change (42). Physical conditions that were once anomalous may become normal. The biological response will follow but may not carry over across years until species and behaviors that thrive in the new conditions are able to persist. Hunters and fishers will adjust to some degree but may find it necessary to switch the timing or targets of their efforts (43).

Specific trajectories of these changes and their implications for the Pacific Arctic ecosystem, including Indigenous coastal communities, are still unclear. To stay with or ahead of these system transformations rather than reacting to a new state some years from now, some critical unknowns, especially regarding ecosystem relationships, require further attention and continued monitoring at multiple scales. As sea ice retreats earlier, will some species cling to existing fixed habitats (e.g., depositional zones) and remain largely in place, while others follow shifting habitats (such as the ice edge)? Will subarctic species be able to flourish and persist in the Chukchi Sea year-round, transforming the ecosystem into a locus of groundfish or pelagic predator abundance? Will increased industrial activity such as shipping combine with climate-driven ecosystem changes in ways that amplify the consequences of either alone (44)? How can coastal communities adjust and adapt quickly enough to retain cultural and nutritional security (45)?

Even in this age of information overload, it is how remarkable how scarce (and thus how valuable) the available data are for making statistically robust comparisons of today's conditions versus yesterday's. For example, quantifying changes in primary and secondary productivity

cannot immediately follow the spring retreat of sea ice because previously the ice itself precluded ship-based measurements at locations and times now ice-free. Across the study region, even 15 years of annually collected data is an unusually long time series, and for biological parameters most of these data are confined to summer months. Hence, it is important to learn to distinguish surprises from completely new observations.

A cascade of effects through an ecosystem may include tipping points governed by positive feedbacks for individual components, making recovery to the previous structure and function ever less likely (e.g., 34,46). Top-down changes such as increased predation may result from bottom-up changes such as the removal of thermal barriers to range expansion of predators. The experience to date in the Pacific Arctic by itself will not resolve these questions, but it does suggest that, with regard to cascades versus tipping points or top-down versus bottom-up controls (e.g., 47), ecosystem transformation may be a complex matter of "both and" rather than a simple dichotomy of "either/or."

These questions are more than a curiosity (48). The well-being of coastal communities and the management of human activities in the region, including potential commercial fisheries, depend on reliable information and insight into what is likely to happen next. In Alaska waters, industrial and research activities are planned in ways to reduce interference with Alaska Native subsistence harvests, and conscientious vessel operators communicate with communities and adjust their plans to avoid areas where hunters are active (e.g., 49). Growing uncertainty about the timing of animal migrations and optimal harvest conditions increases the likelihood of conflict and concerns about food security. Coastal communities are likely to face difficult choices between capitalizing on increased economic opportunity and limiting industrial interference with subsistence activities.

The profound shift in ecosystem state and conditions suggest a new framework is needed to replace the paradigm that served well in recent decades. The Pacific Arctic marine ecosystem transformation is not an isolated case. Social-ecological systems worldwide are facing similar pressures from changing physical conditions, with implications that are increasingly uncertain as transformation propagates through the food web and to human outcomes (50). Long-term and multi-scale data are necessary to detect, examine, and respond to such changes. A better understanding of the nature of system transformation will help humans detect transformations

earlier, perhaps in time for more effective response or adaptation, even if prevention may no longer be possible.

Data Availability

All data collected as a part of the North Pacific Research Board's Arctic Integrated Ecosystem Research Program (Arctic IERP) are being curated and preserved. Because the research is actively ongoing, the data are under program embargo through July 2021. At that time, all Arctic IERP data will be publicly released with a CC-0 license from the Research Workspace DataONE Member Node, and this paper will be cited in the DOI for those data, to create a formal link. In the interim, please contact the authors for access to Arctic IERP data.

In Figure 1, we acknowledge the use of imagery from the NASA Worldview application (https://worldview.earthdata.nasa.gov/), part of the NASA Earth Observing System Data and Information System (EOSDIS). Ice-edge marking is from Maslanik, J. and J. Stroeve. 1999. Near-Real-Time DMSP SSMIS Daily Polar Gridded Sea Ice Concentrations, Version 1, F17. Boulder, Colorado USA. NASA National Snow and Ice Data Center Distributed Active Archive Center. doi: https://doi.org/10.5067/U8C09DWVX9LM. Accessed 12-December-2018.

2015 epifauna data are available at https://doi.org/10.25921/b2g4-bs86.

Other data are available on request, pending curation and archiving as part of ongoing studies.

Acknowledgments

- Much of the research reported here and preparation of the manuscript was conducted under the Arctic Integrated Ecosystem Research Program (Arctic IERP; http://www.nprb.org/arctic-program/). This manuscript is Publication Arctic IERP-014. Funding for the program was provided by North Pacific Research Board, the U.S. Bureau of

Ocean Energy Management, the Collaborative Alaskan Arctic Studies Program (formerly the North Slope Borough/Shell Baseline Studies Program), and the U.S. Office of Naval Research Marine Mammals and Biology Program. Generous in-kind support was provided by the U.S. National Oceanic and Atmospheric Administration (NOAA; Alaska Fisheries Science Center and Pacific Marine Environmental Laboratory), University of Alaska Fairbanks, U.S. Fish & Wildlife Service, and the U.S. National Science Foundation. The findings and conclusions of this paper are those of the authors and not necessarily those of the agencies and organizations with which the authors are affiliated or which provided support.

- This manuscript is a contribution to the U.S. Marine Biodiversity Observation Network (MBON), the U.S. Integrated Ocean Observing System, and the Group on Earth Observations Biodiversity Observation Network (GEO BON). The work and publication were partially funded under the U.S. National Oceanographic Partnership Program (NOPP) through NOAA award # UAF NA14NOS0120158 Arctic Marine Biodiversity Observing Network (AMBON), with contributions from NOAA, the U.S. Bureau of Ocean Management (BOEM), Shell Exploration & Production under management of the Integrated Ocean Observing System (IOOS), as well as contributions of U.S. National Science Foundation (NSF) grant #1204082.
- We are grateful for the contributions of many colleagues to the research and writing of this paper, including Gay Sheffield.
- This paper is PMEL contribution # 4917.
- Collections of fish specimens were made under the auspices and terms of Scientific Research Permit numbers 2012-11, 2013-8, 2017-2 and 2019-7 issued by the NOAA's Alaska Regional Office and permit numbers CF-12-005, CF-13-016, CF-17-023, and CF-19-018 from Alaska's Department of Fish and Game.

Author Contribution Statement

HPH, SLD, FKW, EF, CL, and KS developed the idea and contributed to writing and editing the paper. MB, PB, JJC, ADR, DD, JCG, KI, DGK, KK, RL, LQ, PS, DS, and CW wrote sections of the paper and contributed to editing of the manuscript. All authors provided data and reviewed the final manuscript and approved it for submission and publication.

Competing Interests

The authors declare no competing interests.

Synopsis

Synopsis: ASGARD project

Seth Danielson, Russ Hopcroft, Andrew McDonnell, Sarah Mincks, Brenda Norcross, Dean Stockwell

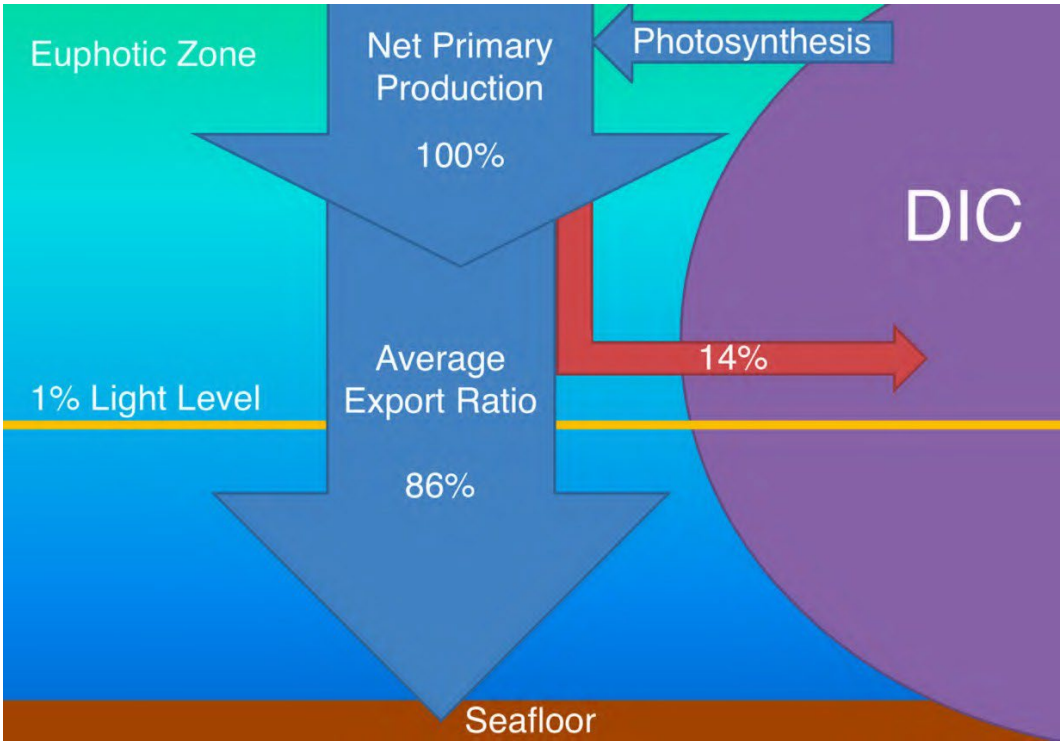
Why we did it
Sea ice is one of the defining characteristics of the Arctic Ocean, and while its timing and extent has already undergone significant human-induced changes, it is projected to further decline in the coming years. The ASGARD project was designed to better refine our knowledge of carbon and nutrient dynamics on the northern Bering and Chukchi sea continental shelves in the face of changing sea ice.

The fundamental science question we addressed is: ***What regulates variations in carbon transfer pathways and how will the changing ice environment alter these pathways and ecosystem structure in the Pacific Arctic and beyond?***

What we did
The ASGARD study consisted of ship-based and mooring-based studies that collected observations of: heat, salt, nutrients and plankton carried by ocean currents; phytoplankton primary productivity; zooplankton growth/reproduction, respiration and fecal pellet production rates; particle deposition rates from the water column to the seafloor; quality of organic matter deposited to the seafloor; benthic respiration and organic matter decomposition rates; abundance and biomass of benthic microbial and metazoan fauna; distribution of fishes at different life history stages; and underwater sound and seasonal distributions of marine mammals.

We sailed to the northern Bering and southern Chukchi shelf in 2017 and 2018 on *R/V Sikuliaq,* occupying "process" stations at which experimental work was carried out, and "survey" stations at which we collected a reduced set of observations. Moorings were deployed in the water from June 2017 to August 2019.

What we learned:
Ample supplies of nutrients delivered to the Southern Chukchi Sea through Bering Strait fuel a high level of Chukchi shelf primary productivity during months in which water column light levels are sufficient to maintain phytoplankton blooms. Portions of the region likely exist in a near-perpetual state of patchy phytoplankton blooms from the spring ice retreat all the into the fall. Export fluxes to the benthos are large because large-celled diatoms sink rapidly to the shallow seafloor and because mesozooplankton often are unable to constrain the phytoplankton bloom by grazing. The benthic community carbon consumption and oxygen turnover rates are sensitive to the bottom water temperature, and are species-specific. Together, these findings suggest that the future Pacific Arctic ecosystem will adjust in species composition and species abundance in a bottom-up response to environmental change. Species that can maintain low basal metabolic rates in the face of larger annual swings in bottom temperature may find a competitive advantage. At the same time, range expansions of sub-Arctic predators into the Chukchi Sea will exert new top-down pressure on both the benthic and pelagic communities. Previously unobserved competition between Arctic and sub-Arctic species will also likely play a role in determining the eventual character of the Chukchi Sea ecosystem.



The Chukchi Sea exhibits a highly efficient delivery of carbon from the surface to the seafloor biological community.

Synopsis: Bering-Chukchi Heat Budgets

Seth Danielson

Why we did it
To understand how the Pacific Arctic may change in the future, we first must understand the present and the past. Sea ice extent is highly sensitive to oceanic heat content and ocean-atmosphere exchanges of heat. We were interested in how the ocean currents and surface heat fluxes of today's Pacific Arctic shelves differ from the past.

What we did
We assembled an archive of all known conductivity-temperature-depth (CTD) data from the Bering and Chukchi sea continental shelves. Data were found in the Chukchi Sea beginning in 1922 and in the Bering Sea in 1966. We averaged the data on a monthly basis into a spatial "grid", and then analyzed these compiled data for changes through time. Using an atmospheric reanalysis model, we formed heat content budgets and heat flux estimates for the two shelves, constraining the results with the oceanic water column profile observations.

What we learned
Summer and fall ocean temperatures in the Chukchi Sea increased by 1.4 °C over 1922-2018; the rate of warming sharply increased to 0.43 °C per decade after 1990. The average ocean water column temperature of July-October in some recent years was nearly 3 °C higher than in the same months in the 1970s. The Chukchi Sea is an important contributor to the Arctic amplification of atmospheric temperature increases. In recent autumns, the Chukchi shelf has transmitted enough heat to the atmosphere to raise the temperature of the entire Arctic lower atmosphere by 1 °C. We also found that oceanic heat delivered to sea ice melt or the deep basin of the Arctic Ocean has increased significantly relative to years past.

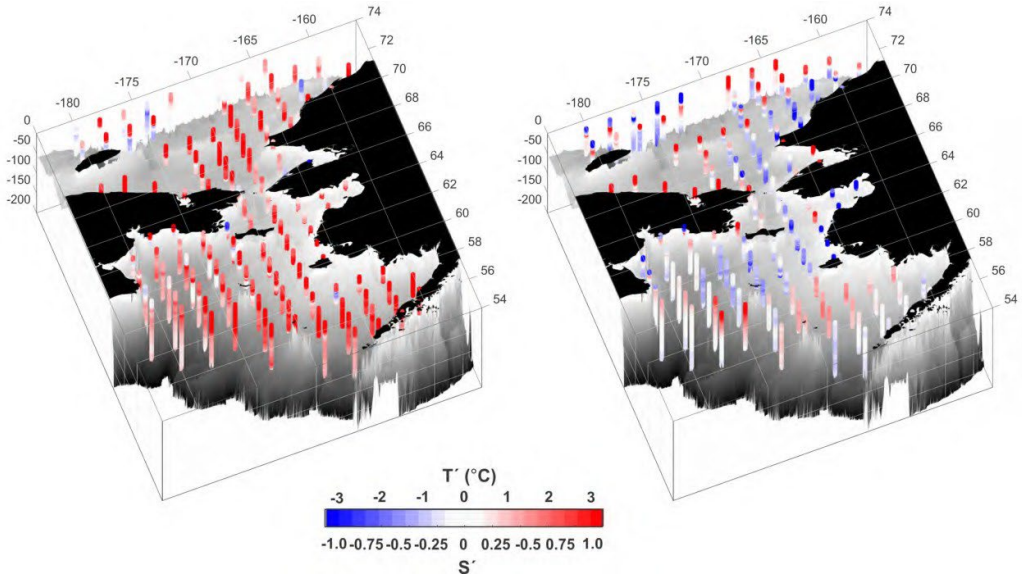

Figure: Perspective view showing water column profiles of summer season temperature anomalies (T'; left) and salinity anomalies (S', right) for 2014-2018 relative to all hydrographic data collected prior to 2014. Seafloor topography (gray shading) is shown only for depths shallower than 200 m.

Synopsis: Biological carbon pump

Andrew McDonnell and Stephanie O'Daly

Why we did it

How will the biological carbon pump change in reaction to the extreme warming and decrease in sea ice in the Pacific Arctic shelf? Warming ocean temperature and decreasing sea ice prevalence on the Pacific Arctic Shelf has been hypothesized to result in changes in the biological carbon pump in a couple of ways such as shifts in predominantly ice algae to ocean phytoplankton production and increased consumption of production in the water by zooplankton grazing and bacterial consumption. If these changes occur, less organic carbon will be deposited on the sea floor of the Pacific Arctic Shelf, which would impact food security in the region and decrease the carbon sink that has historically occurred in this region. We sought to measure the strength and efficiency of the biological carbon pump of the Pacific Arctic Shelf during an unprecedentedly warm and low ice period of time.

What we did

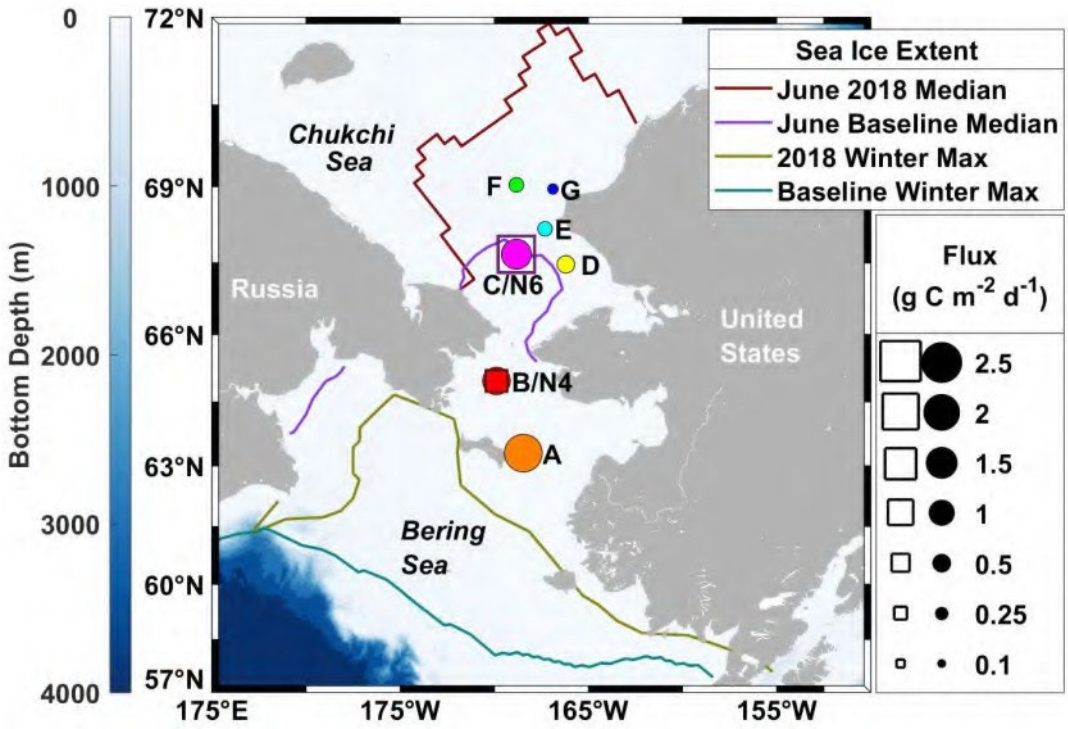
We used sediment traps to measure the amount of carbon that was sinking through the ocean, now called carbon flux. We had two sediment traps tethered to the sea floor that collected sinking particles throughout the year resulting in a time series of organic carbon flux from these two locations. During June of 2018 we also deployed short term drifting sediment traps to collect sinking particles at 7 locations throughout the study area. We also measured rates of organic carbon production using primary productivity experiments in June of 2017 and 2018.

During June of 2018 we also incubated the sinking particles we collected using drifting sediment traps to measure the rate of bacterial respiration associated with the sinking material. We measured the change in oxygen over time and converted that to units of carbon. This is used to estimate how much of the sinking organic carbon will be consumed by bacteria in the ocean before the material lands on the sea floor.

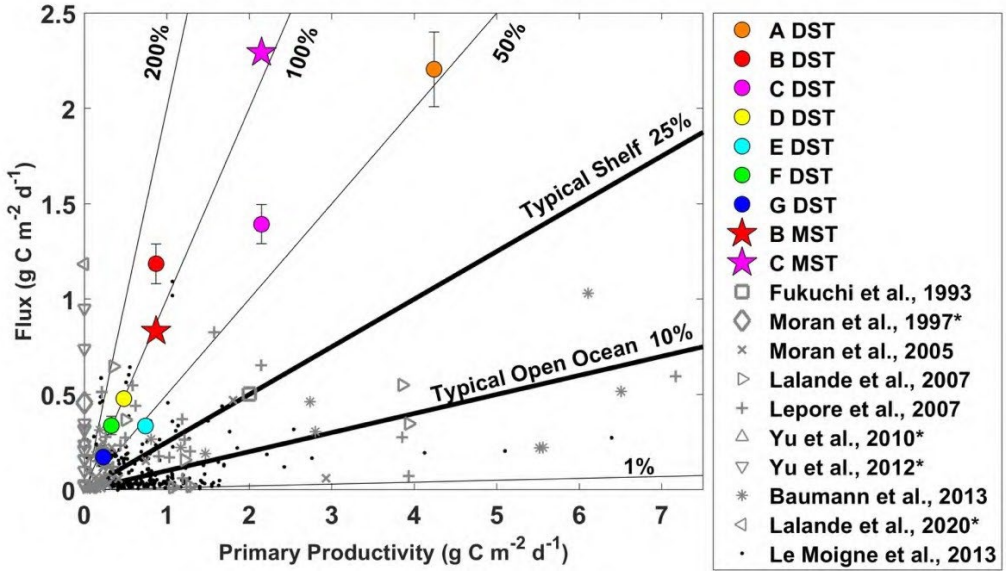
What we learned

We measured a strong and efficient biological carbon pump during June of 2018 in the Pacific Arctic Shelf, despite strong environmental shifts. We measured the highest rates of carbon flux occurring around May or June from the moored sediment traps. We measured relatively normal rates of primary productivity for the region, predominately consisting of pelagic diatoms. We measured an average of 82% of organic carbon production sinking through the ocean, meaning the biological carbon pump is very efficient. Our most notable findings were measuring amongst the highest carbon flux rates ever measured during June of 2018. We measured near zero rates of bacterial degradation of the sinking material. These findings indicate a very strong biological carbon pump.

We are entering the synthesis phase of this project. We will be collaborating more with other groups, specifically the zooplankton and benthic groups, to try to see if we can measure a balanced carbon budget for the region in June. We are also collaborating on an inverse modeling study, which can inform us of holes in our understanding or potentially important features of the system. Additionally we will investigate more about the types of particles collected with the moored sediment trap and how they change over time over the course of the two year study.



Spatial patterns of sinking particulate organic carbon fluxes on the Pacific Arctic shelf in June 2018. Drifting sediment trap measurements are depicted relative to the diameters of the circles, while moored sediment traps fluxes are shown as the length of the squares. Colored lines represent sea ice extent (Fetterer et al., 2017).



Sinking particulate organic carbon fluxes and primary productivity rates with contours of the export ratio between these two parameters measured during June 2018 on the Pacific Arctic shelf. The circles represent flux measurements from the drifting sediment trap. The stars represent the final flux measurement from the moored sediment traps (values plotted against the same primary productivity rates). Gray markers provide regional and black markers global context.

Synopsis: Benthic carbon cycling

Sarah Mincks and Brittany Charrier

Why we did it

Out on the continental shelf, much of the seafloor is covered with soft sediment which is home to microbial communities as well as many burrowing invertebrates. The energy demands of the sediment community are fueled by phytoplankton and zooplankton that grow in the water column and sink to the seafloor as detritus (waste products, dead and decaying cells or tissue). In the Arctic, much of this detritus falls to the seafloor during the spring and summer productive period. Seafloor organisms, including microbes, play an important role as the decomposers of the marine environment, breaking down this material and releasing nutrients back to the water column. In addition, they serve as food for larger organisms, forming an important component of the food web.

All organisms that eat food must consume oxygen in order to respire, or burn that food to produce the energy that fuels the body's activities. Oxygen's critical role in respiration makes it very useful for measuring metabolism—the rate at which food is burned. Some of that food is also assimilated by the body to make new biomass, so organisms can grow or reproduce. Metabolic rates vary among different types of organisms and among species, due in part to their biology and how they make their living. However, temperature also directly affects metabolic rate. As temperatures increase, the slow metabolic rates of cold-water organisms will increase, and they may need to consume more fuel to compensate. Our goal was to measure the metabolic rate of the sediment community—microbes and small invertebrates—at different temperatures to determine how warming may affect the rate of organic matter consumption.

What we did

We collected sediment cores from multiple sites throughout our study area using a multi-core, and conducted shipboard experiments on board *Sikuliaq* to measure respiration rates of the whole sediment community at two different temperatures (~0° and 5°C). Cores were kept intact to preserve the natural structure of the sediment community, including microbes and microscopic as well as macroscopic invertebrates such as small worms, clams, and crustaceans. We used fiber-optic oxygen sensors to record oxygen consumption during the experiments, as a measure of community metabolism. We also measured the production of nutrients produced via respiration of organic matter. In addition, we collected individuals of larger organisms (clams, amphipods) from bottom trawls to measure the respiration rates of some of the larger sediment-dwelling species that are important prey species and likely responsible for a relatively large fraction of detritus consumption. Multiple individuals of each species were sealed in separate glass chambers, and incubated in a similar manner as whole sediment cores to measure oxygen consumption of each individual organism. These experiments allowed us to compare metabolic rates among different species to determine if shifts in community composition may impact the breakdown of organic matter at the seafloor.

What we learned/Why it matters

A temperature increase of 5°C resulted in an average increase in oxygen consumption rate of about 30%, suggesting this degree of warming will lead to increased consumption of food by seafloor microbes and small invertebrates. Most of the food that supports these organisms all year is produced during the short spring bloom season, so considering that there is only so much food in the fridge which needs to last all winter, increased consumption may lead to a decrease in the amount of organic material stored in sediments to sustain the productive benthic component of the food web.

Results of our experiments with individual benthic organisms showed that the metabolic rate is quite different even among species of clams which one might expect to have similar life habits and

biology. These differences in metabolism result in carbon demand (i.e., amount of food required) that

varies over two orders of magnitude among taxa. With changes in the dominant species of clams already occurring in some areas, these differences in metabolic rate point to consequences of these shifts for the food web. Declines in the amount of organic material available in sediments may favor smaller-bodied species with lower metabolic rates; however, these smaller species may constitute lower quality prey for larger predatory species that feed at the seafloor.

Synopsis: Oceanic Nutrient Fluxes

Tyler Hennon, Seth Danielson, Brita Irving, Dean Stockwell, Rebecca Woodgate, and Calvin Mordy

What did we do?
We estimated the transport of nutrients (nitrate, phosphate, and silicate) going through Bering Strait into the Arctic every month from 1998-2018. We used data from two moorings to form our estimates. Mooring N2 was deployed for just one year (2017-2018) and was located in the middle of the Anadyr Current that flows into Chirikov Basin as it passes between St Lawrence Island and the Russian mainland. The Anadyr Current is the major oceanic artery that supplies nutrients to the Arctic from the Pacific Ocean. Mooring A3 is located in the middle of Bering Strait, and now has over 20 years of temperature, salinity, and current data.

By combining the N2 nitrate and salinity data then the A3 salinity data, we developed a method that allows us to estimate the Arctic-bound concentrations nitrate, phosphate, and silicate. Using the estimated nutrient concentration along with the current measurements, we were able to calculate the nutrient transport through Bering Strait for every month between 1998 and 2018.

Why did we do it?
The Arctic environment is undergoing rapid transformation due to climate change. Sea ice is breaking up sooner, and the timing and magnitude of phytoplankton and ice algae blooms depend on light and nutrient availability. To understand phytoplankton growth, phytoplankton species prevalence, and their future trajectories, we must first have a good handle on how much nutrients are available for their growth. Establishing the abundance of phytoplankton and algae is important to understanding the food available to higher trophic levels and the general ecological health of the Arctic.

What did we learn?
We found that nutrient flux through Bering Strait may be up to ~50% higher than previously estimated. We also found a lot of year-to-year (interannual) variability in transport, where some years have high nutrient transport and others are low. There are also large seasonal differences, where April usually has the highest nutrient transport and December has the lowest. Perhaps most importantly, we found that phosphate and silicate nutrient transports increased over the last 20 years, while nitrate had no trend. These results have implications for the distribution, quantity and character of future phytoplankton and ice algae growth.

Synopsis: Phytoplankton Productivity

Dean Stockwell

Why we did it

Phytoplankton form the biological foundation of the food web, converting light and nutrients into biomass. Phytoplankton productivity provides food to the prey consumed by arctic cod, bowhead whales, seals and walrus. This study was designed to improve our understanding of how and where phytoplankton most efficiently grow in the northern Bering Sea and southern Chukchi Sea.

What we did

We conducted phytoplankton growth incubations. Plankton were collected from six light levels from the surface (100% illumination) down to near darkness (1% light level). Productivity was assessed using a ^{13}C-^{15}N dual-isotope tracer technique, measuring carbon and nitrogen uptake rates. The plankton samples were placed into screened polycarbonate incubation bottles and incubated in on-deck incubators that were cooled with running surface seawater. Following an incubation period, samples were filtered and frozen for mass spectrometric analysis at the Alaska Stable Isotope Facility housed at UAF.

What we learned

Phytoplankton productivity is extremely patchy, exhibiting rates as low as 0.1 gC m^2 day^{-1} and as high as 14 gC m^2 day^{-1}. The average productivity measured across all stations and both years was about 2 gC m^2 day^{-1}. These results are consistent with prior studies placing the Bering Strait region as one of the most biologically productive marine systems in the world. Despite a wide range of productivity, a few regions stand out as exhibiting particularly persistent elevated productivity rates. These include locations immediately downstream (north) of Anadyr Strait, the eastern edge of St. Lawrence Island, and Bering Strait. These same regions were also associated with relatively high levels of nitrate (high f-ratio) as the nutrient fueling production, demonstrating the importance of new nitrate brought to the region by the Anadyr Current.

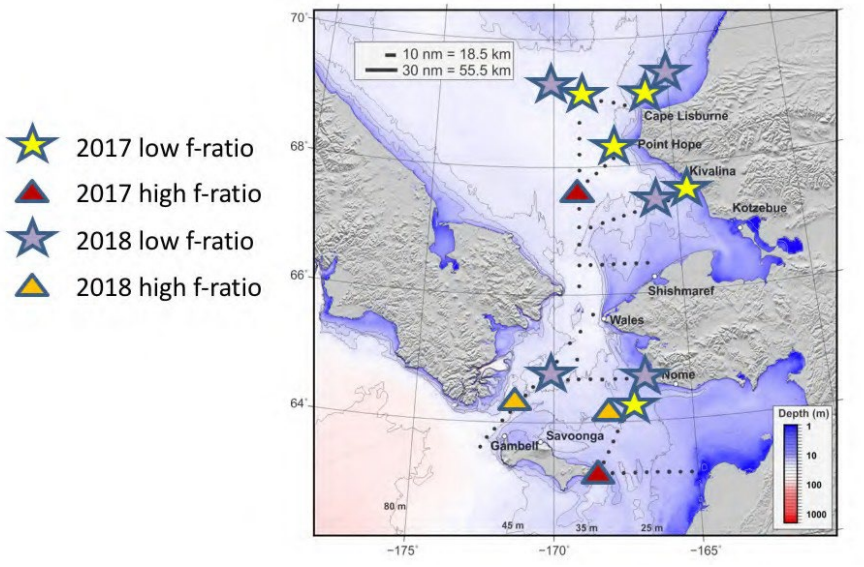

Figure showing locations at which primary productivity exhibit relatively low (stars) and high (triangles) f-ratios. This demonstrates variable sources of nutrients fueling primary production across the study region.

Synopsis: ASGARD Zooplankton Studies

Russ Hopcroft and Alex Poje

Why we did it. There are few observations of what zooplankton communities look like in the Bering Strait during spring as sea ice retreats and phytoplankton populations explode. A fundamental question is how much of that production may be channeled through the zooplankton at that time and ultimately into water column communities versus falls to the seafloor to feed those benthic communities.

What we did. To address our question, we need knowledge of the rates at which zooplankton grow, and how much of the food they consume is burned off through respiration as they go about their daily activities. We measured the growth rates of the domain zooplankton – copepods – by sorting zooplankton into narrow size ranges and seeing how much they grew over 10 days. We also examined how much energy the adults use to produce eggs each day. We studied respiration by putting individual copepods into tiny vials and constantly monitoring the decline of oxygen over a day. When combined with survey data of how much zooplankton is present we can compute how much phytoplankton they would have need to consume.

Growing copepods during ASGARD. Photo R. Hopcroft

What we learned. Depending on the species, copepods add 3-9% of their weight each day when younger, and adults can convert 9-15% of their weight into eggs daily. Contrary to expectation the largest copepod species grow fastest, while the smaller species are relatively better at producing eggs. Despite the cold temperatures during out study (4°C) adult copepods respire the equivalent of 5-20% of their body mass per day, with highest rates in smaller species. Thus, it appears all species have similar net growth efficiencies (~50%). At the time of our surveys, the given these rates and the biomass of zooplankton, they had limited potential for impacting the phytoplankton production.

Synopsis: ASGARD Fish

Brenda Norcross and Caitlin Forster

Why we did it:
Springtime patterns of biological productivity are driven by seasonal retreat of sea ice in the Chukchi Sea. Despite the biological importance of the ice melt in the Arctic ecosystem, logistical challenges have limited sampling efforts during the spring season. Additionally, there have been significant changes in the timing of the spring-melt season; over the past several decades, the duration of the melt process has decreased by nearly 30 days. The ASGARD cruise, as a part of the Arctic Integrated Ecosystem Program (IERP), investigated the dynamics of the spring season in the northern Bering and southern Chukchi Sea. Of particular interest, Arctic cod (*Boreogadus saida*) is a key forage fish in the Arctic marine ecosystem and provides an energetic link between lower and upper trophic levels. Despite its ecological importance, spatially explicit studies synthesizing polar cod distributions across research efforts have not previously been conducted in its Pacific range.

What we did:
We conducted trawl surveys in June 2017 and June 2018; fishes were targeted with a 3 m plumb-staff beam trawl at 21 stations. We then compiled demersal trawl data from 21 summer-season cruises conducted during 2004–2017 in the Chukchi and Beaufort seas, and investigated size-specific patterns in distribution to infer movement ecology of Arctic cod as it develops from juvenile to adult life stages. Finally, we compared spring and summer patterns in abundance to assess ontogenetic shifts in Arctic cod distribution in the Alaskan Arctic.

What we learned:
Springtime demersal abundance of Arctic cod in the southern Chukchi Sea was strikingly low compared to late summer abundance. Strong linkages between sea ice and Arctic cod life history suggest that the distribution of Arctic cod in the southern Chukchi Sea could be influenced by the distribution of sea ice. It is possible that Arctic cod tracks the springtime ice retreat and the wave of productivity that follows. If Arctic cod followed the ice edge in these years, then its distribution would be beyond the northernmost station sampled during the June (ASGARD) cruises, explaining the extremely low abundances of subadult and adult polar cod observed in the southern Chukchi Sea. Movement inferred from size-based and seasonal patterns in distribution describes a plausible migration scenario where Arctic cod move from nursery grounds as juveniles, feeding grounds as subadults, and spawning grounds as adults.

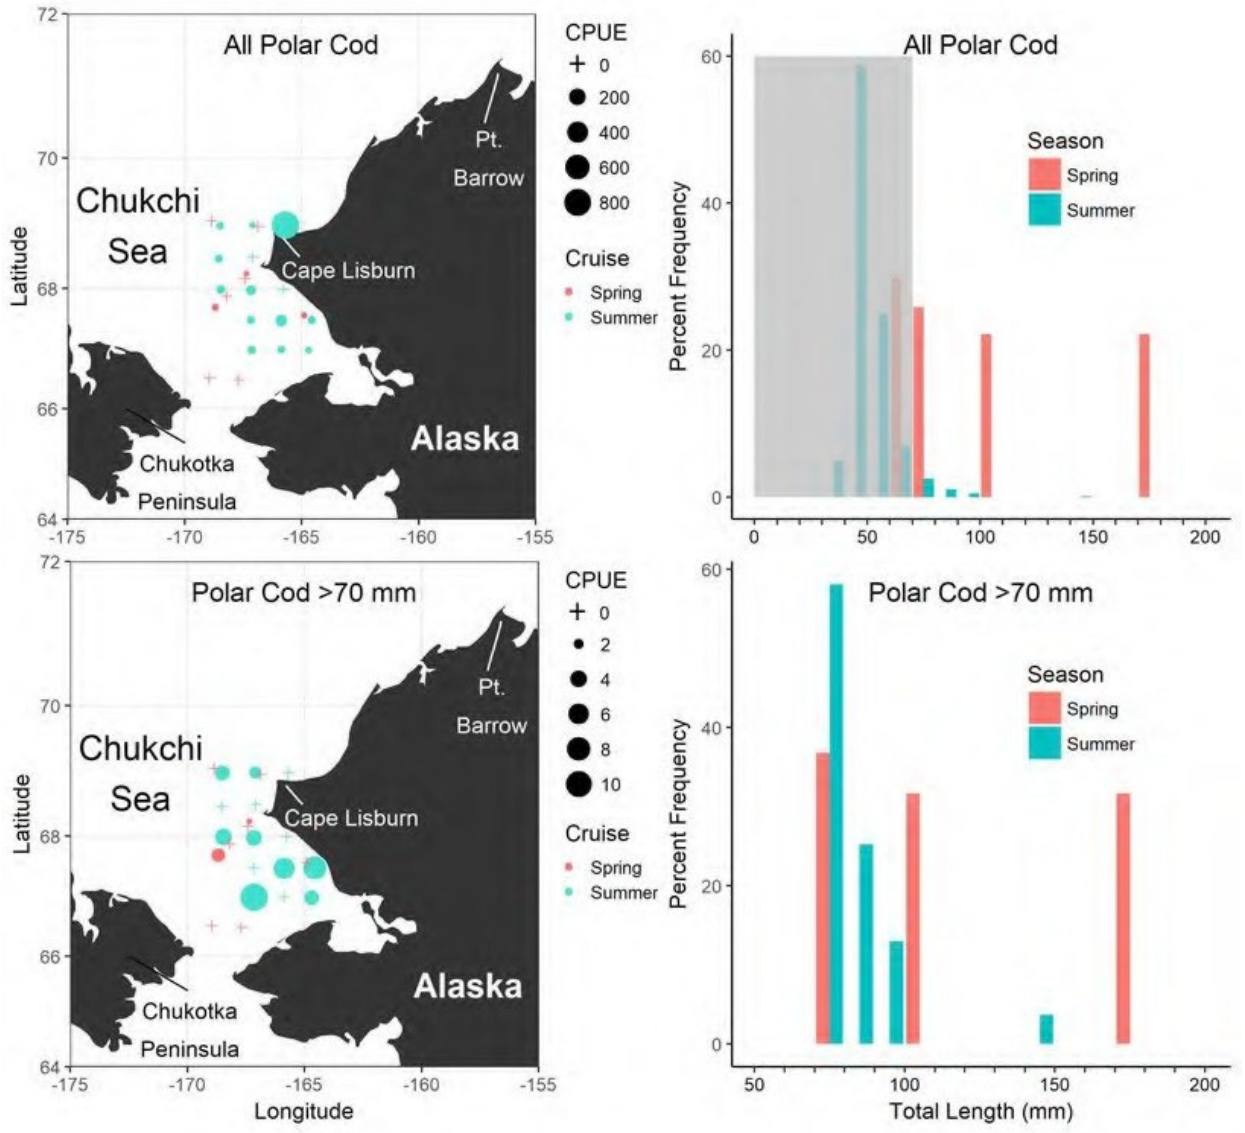

Figure: This is Figure 8, the seasonal Arctic cod distribution figure from Forster et al. 2020 (https://link.springer.com/article/10.1007/s00300-020-02631-4). Caption from publication is below in quotes. Note: figure and caption refer to polar cod, not Arctic cod, which is a naming convention difference in European vs. American journals. They are referring to the same fish species (*Boreogadus saida*)

"Figure 8. Distribution and length-frequency of polar cod in the Chukchi Sea in spring and summer 2017. Length-frequency scaled by CPUE. Top two panels are all captured sizes of polar cod, total CPUE (fish per 1000 m^2) spring = 6.43, summer = 984.40. Bottom two panels are only polar cod > 70 mm, total CPUE spring = 4.51, summer = 42.29; gray box in top right shows small fish excluded from lower two plots. Note difference in scale between top left and bottom left plot."

Arctic Integrated Ecosystem Research Program Final Report for

Arctic Integrated Ecosystem Survey (IES) Phase II: Oceanography and Lower Trophic Level Productivity (A92)

and

Microzooplankton biomass and grazing rates on the Arctic Program Cruises (A70)

C.W. Mordy, K. Axler, L. Copeman, A. Deary, J.T. Duffy-Anderson, L. Eisner, E. Goldstein, H. Tabisola, J.W. Krause, D. Kimmel, C. Ladd, M.W. Lomas, R.M. McCabe, J.M. Nielsen, A. Schnetzer, A. Spear, P. Stabeno

Preamble

The Arctic Integrated Ecosystem Research Program

The Arctic Integrated Ecosystem Research Program (Arctic IERP, 2016-2021) was motivated by the rapid changes occurring in the waters of the northern Bering and Chukchi Seas. While much research has been done in the region, many important questions remain. As a cohesive research endeavor, the Arctic IERP was designed to address a single, overarching question:

How will reductions in Arctic sea ice and the associated changes in the physical environmental influence the flow of energy through the ecosystem in the Chukchi Sea?

The report you are reading now is one of five final reports from the fieldwork phase of the Arctic IERP (a synthesis phase was initiated in 2022 after the completion of the Arctic IERP field-based projects). This preamble provides a brief overview of the Arctic IERP, both to place each final report in the broader context of the whole program, and to encourage readers to examine the other final reports to learn more about the research that was done. More detailed information about the Arctic IERP can be found at https://www.nprb.org/arctic-program.

The spatial domain of interest for the Arctic IERP extended across the Chukchi Sea Large Marine Ecosystem (LME) as redefined by the Arctic Council's Protection of the Arctic Marine Environment (PAME) working group, and the northern Bering Sea (north of 61.5° N) as it strongly influences dynamics in the Chukchi Sea from the upstream direction. The main focus has been on the greater Bering Strait region and the Chukchi Sea. The program included the Arctic Basin and Beaufort Sea insofar as processes in the Chukchi Sea are influenced by these adjacent areas.

Development of the Arctic IERP

Before any Arctic IERP research proposals were written, the NPRB administered an assessment program, the Pacific Marine Arctic Regional Synthesis (PACMARS; https://www.nprb.org/assets/uploads/files/Arctic/PacMARS_Final_Report_forweb.pdf), that applied $1.5M provided by Shell and ConocoPhillips to compile and synthesize existing information about the ecosystem and inform research priorities. This assessment included community meetings in 2013 in Savoonga, Gambell, Kotzebue, Nome, and Barrow (now Utqiaġvik), in which representatives from 17 communities between St. Lawrence Island in the Bering Sea and Barter Island in the Beaufort Sea participated. One major area of emphasis that emerged from these community meetings was concern about food security for the region's residents in light of the rapid environmental changes taking place. Results from the scientific assessment and input provided via the community meetings informed the creation of the Arctic IERP. The PACMARS report informed both the IERP Request for Proposals (https://www.nprb.org/arctic-program/request-for-proposals/) and the submitted proposals.

Following a proposal review process, the Arctic IERP formally began in 2016 with funding from the North Pacific Research Board (NPRB), the Collaborative Alaskan Arctic Studies Program (formerly the North Slope Borough/Shell Baseline Studies Program), the Bureau of Ocean Energy Management (BOEM), and the Office of Naval Research (ONR) Marine Mammals and Biology Program. Generous in-kind support was contributed by the National Oceanic and Atmospheric Administration (NOAA), the

University of Alaska Fairbanks (UAF), the U.S. Fish & Wildlife Service (USFWS), and the National Science Foundation (NSF). This coordinated program was developed in cooperation with the Interagency Arctic Research Policy Committee (IARPC) and the U.S. Arctic Research Commission.

The Research

The Arctic Integrated Ecosystem Research Program (IERP) invested approximately $18.6 million in studying marine processes in the northern Bering and Chukchi Seas in 2017-2021, beginning in the summer of 2017. The research was divided into three main, complementary projects. The Arctic Shelf Growth, Advection, Respiration, and Deposition Rate Experiments (ASGARD) project carried out research in late spring and early summer of 2017 and 2018 aboard R/V Sikuliaq. The Arctic Integrated Ecosystem Survey (Arctic IES) conducted fieldwork aboard R/V Ocean Starr in late summer and early fall 2017 and 2019. In addition to the vessel-based surveys, sub-surface moored sensors were deployed to gather biophysical information continuously from September 2016 to September 2019 and autonomous platforms were brought to bear (e.g., gliders, saildrones, air-deployed profilers).

In addition to the vessel-based work, a team of Arctic residents and social scientists, including members from eight communities in the North Slope and Northwest Arctic Boroughs and the Bering Strait region, met several times during the project to assess and analyze Indigenous observations and experiences with various types of change occurring in the region from Savoonga to Utqiaġvik. This group also compiled an annotated bibliography of Traditional Knowledge or Indigenous Knowledge (available through the data portal described below), to help researchers from other components of the Arctic IERP find information relevant to their studies.

Prior to the commencement of fieldwork, meetings were held in the three hub communities of Nome, Kotzebue, and Utqiaġvik. Scientists from the Arctic IERP and NPRB staff met with community members from each region to discuss the research purpose and plans. Research plans were also shared and discussed at meetings of the Alaska Eskimo Whaling Commission (AEWC), the Indigenous Peoples Council for Marine Mammals (IPCoMM), and with the Tribal Councils of Gambell and Savoonga on St. Lawrence Island. One result of these meetings was a shift in timing of the ASGARD cruises from May until June as well as a shift in timing and survey regions for the Arctic IES cruises, to avoid conflicts with subsistence hunting activities during what is traditionally the time for walrus hunting. Another result was the creation of communication protocols to avoid conflicts by alerting coastal communities to the presence of research vessels and adjusting the ships' routes to avoid areas where hunting was taking place. These communication protocols included regular radio broadcasts and daily emails to community members throughout the research area.

Results from the research are published in a growing list of peer-reviewed journal articles, as well as cruise reports that provide contemporary accounts of the cruises, and many social media postings that are available through the NPRB website. Data are publicly available as described below.

Collaborations

The NPRB collaborated and coordinated with several other U.S. agencies and organizations that fund Arctic marine research. NPRB staff worked closely with the U.S. Interagency Arctic Research Policy Committee (IARPC) and the U.S. Arctic Research Commission. As the Arctic IERP was developed, the

NPRB secured commitments for collaboration from 22 existing research projects that were detailed in Appendix A of the request for proposals, and made connections with new projects as they were funded.

International researchers also collaborated with the Arctic IERP via the Pacific Arctic Group (PAG), the North Pacific Marine Science Organization (PICES), and the Intergovernmental Consultative Committee (US/Russia - bilateral) as well as collaborations developed by individual investigators. PAG participants, including researchers from Canada, China, Japan, Korea, Russia, and the United States, have coordinated their cruise plans to sample standard stations in the Chukchi and Beaufort Seas termed the Distributed Biological Observatory (DBO). The Arctic IERP contributed to this effort. US-Russian data sharing initiatives were hosted in San Diego in 2016 and Vladivostok in 2017 to promote collaboration and exchange and to facilitate collaboration and synthesis of data and trends of patterns observed in the US and Russian waters in the northern Bering and Chukchi seas (PICES Press, Volume 26, Issue 1). ICC collaborations and other connections also brought scientists from the Russian Federal Research Institute of Fisheries and Oceanography (VNIRO), the Russian Pacific Scientific Fisheries Research Center (TINRO), and Hokkaido University to the US to participate in the Arctic IES cruises and co-author results. This collaboration is expected to connect research interests within respective EEZs (Russia/US) of the Chukchi Sea.

COVID-19

While the fieldwork of the Arctic IERP was completed before the outbreak of COVID-19, the final meeting of researchers in November 2020 was changed from an in-person event to an online format. Other plans for in-person events, such as meetings in hub communities within the US Arctic region (Nome, Kotzebue, and Utqiaġvik), were cancelled. Laboratory work and some collaborations were postponed or cancelled due to COVID-related restrictions and concerns. The NPRB made supplemental funds available to assist researchers with unanticipated expenses due to the pandemic. The overall productivity of the Arctic IERP was likely not greatly reduced, due both to good fortune in the fieldwork being completed and to the collaborative relationships that had been built or strengthened during the program.

Data Portal

Axiom Data Science, Inc. provided data management support to the Arctic IERP throughout the field program. Axiom staff assisted the scientists in authoring metadata and publishing the datasets to public archives. The data collected by the Arctic IERP are publicly accessible at https://arctic-ierp.dataportal.nprb.org/.

Executive Summary

The Chukchi Sea is undergoing dramatic sea-ice reductions and temperature increases, but resultant biological and trophic responses are poorly understood. The goal of Arctic IES Phase II (Upper and Lower Trophic Level Teams, UTL and LTL, respectively) was to improve understanding of processes that structure the Arctic ecosystem and influence the distribution, abundance and life history of lower (phytoplankton, zooplankton, ichthyoplankton) and upper (invertebrates, fishes, seabirds, mammals) trophic level species, and evaluate their vulnerability to the rapidly changing environment. The LTL (A92) component sought to better understand the climatological, physical, chemical, and biological processes that influence energy flow from primary producers to zooplankton and ichthyoplankton, and the UTL (A93) component worked to describe and understand how lower trophic processes reverberate through the food web to influence macroinvertebrate, fish, and seabird communities. Together, these programs addressed the following overarching hypothesis:

OVERARCHING HYPOTHESIS OF PROJECT: *Reductions in Arctic sea ice and the associated physical changes to the environment influence the flow of energy through the pelagic ecosystem in the Chukchi Sea. Specifically, we expect lasting changes in the seasonal composition, distribution and production of phytoplankton; in the distribution and standing stocks of large crustacean zooplankton that serve as the prey base for upper trophic level fishes and seabirds; in the assemblages, distributions, and abundances of larval and early juvenile fishes that influence the recruitment success of later life stages, and in the distribution and abundance of adult fishes.*

This report details the LTL program along with a program that was funded to fill a gap in the observational program; the Microzooplankton (A70) gap. We conducted comprehensive ecosystem surveys of Chukchi Sea physics, chemistry, biogeochemistry and biology using an integrated network of moored arrays, autonomous vehicles, and shipboard surveys.

Emerging results from the LTL component were combined with historical data and resulted in a number of insights and new findings.

Northward flow of water from the Bering Sea brings heat, salt and nutrients to the entire Chukchi continental shelf. The higher sea level in the Bering Sea compared to the Arctic Ocean results in a net northward transport. Approximately 40% of the flow through Bering Strait exits the shelf via Barrow Canyon. This flow on the Chukchi Sea is enhanced by northward winds and weakened by southward winds. During the last decade there has been an increase in the magnitude of northward flow on the shelf.

Phytoplankton serve as the energy source for the Arctic marine environment by converting nutrients and sunlight into a food base that ultimately sustains all marine life. In the Chukchi Sea, nitrate is a limiting nutrient for phytoplankton. Year-to-year differences in the amount of nitrate available to sustain spring production varies by about 50%. These differences result from the magnitude of transport through Bering Strait in the fall and winter, and the variability of nitrate concentration in the Bering Sea.

Changing conditions in the Arctic (e.g., warming and reduction in the duration and extent of ice) has altered the distribution, composition and food quality of phytoplankton. Shipboard observations show patchy distributions of phytoplankton and rapidly varying levels of primary productivity. Synechococcus (cyanobacteria) accounted for 20-40% of the total autotrophic biomass by the end of summer in 2019.

This finding suggests that multi-year periods of warmer than average conditions altered the seasonal phytoplankton succession pattern. Phytoplankton fatty acids serve as a measure of the food quality of algae and were used to strengthen predictions of food web functioning and energy transfer to the upper trophic levels in the northern Bering and Chukchi Seas.

Particulate organic matter that falls to the sea floor, including ice algae, dead phytoplankton, and zooplankton fecal pellets, provides nutrition that sustains organisms living in that realm. For example, as ice begins to melt in spring, algae living on the underside of the ice detach and fall to the sea floor. The Chukchi Sea shelf is shallow enough that sunlight can penetrate to depth and detached ice algae can continue to photosynthesize near the seafloor.

There appears to be two distinct communities of zooplankton in the Chukchi Sea: a local, Arctic community related to water masses within the Chukchi Sea, and a community advected from the Bering Sea. Thus, the relative magnitude of annual transport from the Bering Sea influences zooplankton community structure in the Chukchi Sea. Decreased transport and later ice retreat in colder years resulted in zooplankton communities that exhibited more diversity and had higher abundances of fat-rich copepods. In contrast, in years with increased transport from the south, expatriate zooplankton communities from the Bering Sea were prevalent in the Chukchi Sea. If the northward inflow of water into the Chukchi Sea were to increase with concomitant warming, changes in food-web structure and function are likely to result.

Similar to zooplankton, summer ichthyoplankton shifted northward. Shifts in community composition resulted from species-specific responses to temperature changes, ice cover, Bering Strait advection, and changes in the zooplankton prey base. By 2100, some bottom dwelling animals will find themselves in a habitat that is warmer than their preferred temperature range and perhaps even warmer than they can survive. These animals include prey for bottom feeding whales, pinnipeds, seals and walruses, seabirds, and benthic fishes. Snow crabs will likely benefit from warmer bottom ocean temperatures.

Unprecedented warming observed during the course of the Arctic IERP program during the survey years may offer a window into the future Arctic. The biological indicators reported here suggest that increased warming could alter ecosystem structure and function with as yet unknown consequences for the people that depend on marine resources in the region.

Table of Contents

General Introduction

Background

The overall goal of this Lower Trophic Level (LTL) project was to better understand physical, chemical, and biological processes that influence the flow of energy from primary producers to zooplankton and ichthyoplankton in the Chukchi Sea and to determine how a warming climate will influence these processes. This project was directly linked with an Upper Trophic Level (UTL) proposal that examined the distribution, abundance and condition of demersal and pelagic fishes, shellfish and seabirds. Together, these programs addressed factors that influence predator-prey relationships, and provide integrated ecosystem data to examine how relationships and mechanisms may be altered by climate change.

The Overarching Hypothesis embodied both the LTL and UTL components: *Reductions in Arctic sea ice and the associated physical changes to the environment influence the flow of energy through the pelagic ecosystem in the Chukchi Sea. Specifically, we expect lasting changes in the seasonal composition, distribution and production of phytoplankton; in the distribution and standing stocks of large crustacean zooplankton that serve as the prey base for upper trophic level fishes and seabirds; in the assemblages, distributions, and abundances of larval and early juvenile fishes that influence the recruitment success of later life stages, and in the distribution and abundance of adult fishes.*

Changes underway in the Chukchi Sea are unprecedented; the physical environment is experiencing increases in temperature, progressive declines in sea-ice concentration, earlier spring ice retreat, and delayed fall ice formation (Wood et al., 2015, and references therein). In the Arctic, the Chukchi Sea is showing the largest changes in sea-ice duration. In comparison to 1979/80, the region is experiencing later sea-ice advance (1-1.4 months) and earlier sea-ice retreat (1.6-1.9 months), resulting in a shorter ice-season duration of ~3 months (Stammerjohn et al., 2012). Such shifts in timing and physical structure are intimately tied to water column stratification and the magnitude of heat, salt, and nutrients on the shelf. The shift from ice-covered conditions to open-water conditions enhances solar warming of the ocean due to its lower albedo, resulting in increased ocean heat storage (e.g., Jackson et al., 2010). Changes in advective heat flux from the northern Bering Sea through Bering Strait (Woodgate et al., 2012) also play a role in heat content changes in the Chukchi Sea.

The Chukchi Sea consists of a broad shallow shelf incised by two major canyons at the slope – Barrow Canyon in the east and Herald Canyon in the west. Three water types enter the shelf through Bering Strait: Alaska Coastal water (ACW), Bering Water (BW) and Anadyr Water (AW). Water flowing through Bering Strait generally follows three pathways northward through the Chukchi Seat. Nutrient-rich AW flows through the western side of Bering Strait, providing a continuous flux of nutrients into the southwestern Chukchi. Most of the AW flows north towards Herald Canyon with a portion continuing through the canyon and into the basin, and a portion flowing eastward along the shelf break towards Barrow Canyon. In contrast, the ACW is warmer, fresher and nutrient-poor. It typically flows through the eastern side of Bering Strait and is generally confined to the Alaskan coast as it transits northward. BW is a combination of northward flow along the 100-m isobath, outer shelf and slope water (Stabeno et al., 2016). It is slightly fresher and less rich in nutrients than the AW. It flows through the middle of Bering Strait, although mixing of AW and BW does occur. It continues northwestward, with most entering Central Channel, flowing south of Hannah Shoal toward the head of Barrow Canyon. While some (<20%)

of the ACC turns eastward onto the Beaufort shelf, the majority joins the Chukchi Slope Current (Stabeno and McCabe 2020).

Moorings and hydrography along the Icy Cape transect capture flow and characteristics of both ACW and BW. Autumn/winter transport is highly variable while April-July transport is northeastward with lower variability (Stabeno et al., 2018). Monthly mean transport at Icy Cape is 25-50% of the transport through Bering Strait as measured. Transport through Bering Strait has been measured via moorings for over two decades. These moorings remain a high priority in Arctic research and measurements by R. Woodgate continue. In addition, the three moorings across Icy Cape are continuing and are recognized as part of NOAA's Arctic observing system. Mooring time series also show the seasonal variability of the system. In recent years, sea ice arrived at the Icy Cape line in early to mid-November, increasing rapidly to near 100% areal coverage with occasional periods of reduced coverage. The highest turbidity occurred in fall when winds increased while sea-ice coverage remained <80%. Through winter, ice continues to thicken, and nitrate is replenished by a combined influence of Arctic continental slope water and BW flowing up Central Channel.

Historically, the food web of the Chukchi ecosystem has been based on primary production driven by under-ice algal communities. The spring plankton bloom (initially ice algae) likely initiates under and within the ice. Seasonal ice retreat favors the export of aggregates of under-ice algae directly to the benthos, supporting the Arctic's rich, benthic-dominated ecosystem. Increase in percent oxygen saturation is often associated with this export event, suggesting that net primary production continues at depth (Berchok et al., 2015; Stabeno et al., 2020), albeit at a slow rate due to light limitation despite sufficient nutrients. Concentrations of these aggregates occur over large spatial scales and are sufficient to shade the bottom for several weeks.

Rising Arctic temperatures have contributed to reduction in the percentage of thick, multi-year ice and a shift to thinner, first-year ice (Comiso et al., 2008). This shift has contributed to earlier seasonal sea-ice retreat which favors open water phytoplankton primary production and benefits a pelagic ecosystem (Grebmeier et al., 2006; 2015; Moore and Stabeno, 2015). The increase in water column primary production occurs in shallow (<40m) water where light levels are adequate, as long as sufficient nutrients are available. During late summer, due to nutrient exhaustion in the upper mixed layer, phytoplankton in the northeastern Chukchi are typically found below pycnocline (subsurface). Thus changes in stratification will impact primary production through the inverse relationship of light availability from the surface and nutrient availability from depth.

Restructuring in the Chukchi ecosystem is not limited to a change from a benthic to a pelagic dominated system. Physical changes (e.g., increased stratification) are expected to influence nutritional quality of the prey base via a shift in the phytoplankton community to a greater fraction of small cells (Ardyna et al., 2011; Arrigo et al., 2014; Li et al., 2009). This nutritional shift is expected to re-shape zooplankton assemblage composition (Ershova et al., 2015a, 2015b) and energy content, increase food chain length, and decrease the trophic transfer efficiency among food web constituents. When sea ice structures the system, waters are nutrient-rich, prolific blooms of under-ice algae are supported, and the zooplankton community is dominated by large copepods and other large crustaceans that provide a lipid-rich source of energy to upper trophic levels. This food web is short and efficient, supporting large numbers of fish, birds, and mammals. In contrast, under warm, stratified conditions, near-surface waters contain fewer nutrients, the phytoplankton community is dominated by picoplankton and the zooplankton community is dominated by small, lipid-poor copepods. This food web is longer, less efficient, and of poor nutritional

quality (Richardson, 2008). We can examine these two temperature-dependent states using an ecosystem carbon model developed for the Bering Sea shelf. These food web changes will manifest as shifts in upper trophic level species distributions, changes in species assemblages at all trophic levels, seasonal changes in timing of life-cycle events (Beaugrand et al., 2002, 2003), less efficient feeding interactions (Berchok et al., 2015; Norcross et al., 2013; Logerwell et al., 2015), and overall reductions in biomass.

Data collected during Arctic Integrated Ecosystem LTL represents the second phase of arctic ecosystem surveys. Phase 1 was the Arctic Eis surveys in 2012 and 2013 (Mueter et al., 2017). These studies provide examples of interannual differences in the thermohaline properties, nutrients, and phytoplankton communities. Strength of stratification and locations of fronts differed between years primarily because of the regional winds (more persistent southwestward winds in 2013) which weakens the north-eastward flow of the Alaska Coastal Current (ACC), and led to retention of water and biota on the Chukchi shelf in 2013. The increased biomass of Arctic zooplankton in 2013 may also have been due to southeastward flow up Barrow Canyon and onto the shelf from the basin. In contrast, a more northward distribution of Pacific taxa in the Chukchi was observed in 2012. Recent studies show spatial variations in zooplankton community composition associated with variations in water masses, with temperature and salinity as key factors affecting composition (Hopcroft et al., 2010; Eisner et al., 2013). Transport variability through Bering Strait (Woodgate et al., 200) and at Icy Cape (Stabeno et al., 2018) has implications for nutrient availability, and phytoplankton and zooplankton production. Transfer of trophic energy to the pelagic may be intensified if advected North Pacific species are exposed to continued water column production and high phytoplankton or microzooplankton biomass. Increases in water column production are expected to benefit midwater planktivorous and piscivorous fishes, seabirds, and whales. Clearly, regional variations in atmospheric forcing and longer term climate changes have large impacts on the Chukchi shelf ecosystem as a whole.

Variability in physics and lower trophic production subsequently affects recruitment of Arctic fishes. Recruitment success of Arctic Cod (*Boreogadus saida*) and Saffron Cod (*Eleginus gracilis*), key components of the Pacific Arctic Region food web, are important to trophic transfer efficiency and upper trophic functioning. Because survival of the early life history stages is critical to year class strength, study of factors regulating the vital rates of young is central to understanding adult recruitment (Duffy-Anderson et al., 2016). Work from other Alaskan Large Marine Ecosystems has shown that variations in ice dynamics, ocean currents, and primary and secondary production impact survival of gadids through influences on spawning distributions of adults (Petrik et al., 2015), transport pathways of eggs and larvae (Vestfals et al., 2014), spatial overlap of young with zooplankton prey (Siddon et al., 2013), connectivity of spawning areas and juvenile nursery grounds (Cooper et al.,2014), and distributions of eggs and larvae (Boeing and Duffy-Anderson 2008; Atwood et al., 2010, Siddon et al., 2011; Busby et al., 2014). Studies that examine how bottom-up processes influence arctic gadids and other fish species during the early life period offer an opportunity to not only understand critical recruitment bottlenecks for arctic fishes, but also to understand whether those bottlenecks influence species replacements (e.g., Arctic and Saffron Cod) in a warming climate and the resultant implications for seabirds, mammals and humans.

To understand the mechanisms by which the complex interactions of biotic and abiotic forcing influence Arctic ecosystem productivity and functioning, and to refine predictions of future response, we conducted a comprehensive, integrated, multi-disciplinary field-based approach to examine the interacting factors that determine productivity and trophic dynamics in a changing Arctic. Our linked teams (Arctic IES

Phase II; LTL and UTL) expanded on our previous integrated ecosystem assessments, Arctic Eis Phase I and Bering Arctic-Subarctic Integrated Survey (BASIS), by undertaking an intensive, collaborative study of the Chukchi and western Beaufort ecosystems from physics to fish (Beaufort funded with other support).

Hypotheses

Specific hypotheses outlined by the LTL project included:

H1. The source of heat to the Chukchi Sea comprises relatively even contributions from advected heat from the northern Bering Sea and local atmospheric heat fluxes. The contribution of local atmospheric fluxes is expected to increase with future reduction in sea ice.

H2. Earlier ice retreat/melt will result in stronger stratification. The contribution of temperature to stratification is expected to increase, while the contribution of salinity to stratification is expected to decrease or remain unchanged.

H3. In the southern Chukchi Sea, the primary source of nutrients is from Bering Strait; while in the northern Chukchi, nutrient supply is a combination of Bering Strait and upwelled Arctic basin water. Remineralization of organic matter provides a local source of ammonium, and will decrease with earlier ice retreat/melt.

H4. Earlier ice retreat/melt will further shift the balance of spring primary production from ice-associated algae to pelagic phytoplankton, thereby reducing organic matter export to the benthos and increasing organic matter flow to pelagic zooplankton grazers early in the season.

H5. Warming ocean temperatures will increase upper-ocean stratification and reduce vertical nutrient inputs to the mixed layer resulting in the formation of more spatially and temporally extensive subsurface phytoplankton blooms and productivity maxima.

H6. Increased stratification will shift the phytoplankton community to a greater fraction of small cells, thus diverting more energy flow through the microzooplankton community.

H7. Nutritional quality of phytoplankton and their zooplankton grazers will decrease with increased warming (due to increases in stratification and reductions in nutrients).

H8. Summer zooplankton community will shift due to a) increases in the presence of Bering-Pacific fauna and a poleward retraction of arctic species, and b) changes in size structure of the copepod community to smaller-bodied microzooplankton and mesozooplankton as a consequence of the shift in size structure of phytoplankton.

H9. Ichthyoplankton community composition will shift due to a) species-specific responses to temperature changes, and b) changes in species composition and size structure of zooplankton prey base.

Objectives

O1. ***Stratification*** (H1, H2) Quantify the strength of stratification, its temporal evolution, and the relative contribution of temperature and salinity throughout the spring ice melt/retreat.

O2. ***Circulation*** (H3) Quantify transport in Herald Canyon (RUSALCA) and the eastern Chukchi shelf. Identify pathways of flow and their respective heat, salt, and nutrient concentrations.

O3. ***Heat Flux*** (H1, H2, H3) Estimate surface heat fluxes (summer) and compare to estimates of advective heat fluxes.

O4. ***Ice and Phytoplankton*** (H4) Examine the relationship among ice thickness, ice retreat, and the timing and magnitude of near-bottom chlorophyll that fuels benthic-pelagic coupling.

O5. ***Phytoplankton Abundance*** (H4, H5) Quantify the relative abundance of pelagic phytoplankton species compared to sinking ice-associated algae.
O6. ***Primary Production*** (H5, H6) Quantify spatial patterns in rates of total and new production, and phytoplankton community size structure as a function of water column physics and chemistry (nitrate and ammonium).
O7. ***Primary Production Model*** (H4, H5) Use new primary production data to validate and constrain a model of ocean primary productivity and fate in regions where subsurface productivity maxima are important.
O8. ***Secondary Production*** (H8, H9) Quantify the distribution, size, abundance, and species composition of zooplankton and ichthyoplankton throughout the US shelf waters of the Chukchi Sea. Compare data to relative oceanographic conditions and to historical estimates as derived from AFSC sampling 2003- present.
O9. ***Trophic Interactions – Hot Spots*** (H4, H5) Use primary production data to understand spatial variability in net community production and identify 'hot spots' of trophic connections between LTL and UTL, and how these might change in relation to other on-going projects in the region focused on detecting change (e.g., Distributed Biological Observatory [DBO]).
O10. ***Trophic Interactions – Nutrition*** (H6, H7, H8, H9) Determine spatial and temporal relationship between phytoplankton, zooplankton and ichthyoplankton. Link observations to UTL-derived data to provide mechanistic understanding of trophic relationships. Compare fatty acid profiles of seston (primarily phytoplankton) and zooplankton to relate carbon sources to nutritional condition of key forage fish (e.g., Arctic Cod).
O11. ***Ecosystem Connectivity*** (H8, H9) Examine connectivity and exchange of lower trophic biota (zooplankton, ichthyoplankton, juvenile fish) between ecosystems (northern Bering Sea, Chukchi, Beaufort) to determine if each region acts as a source or a sink of ichthyo- and zooplankton stocks.
O12. ***Arctic Cod and Saffron Cod*** (H9) Further resolve spawning and connectivity of Arctic Cod and saffron cod adults, larvae and juveniles by providing new field data on late-stage larvae in summer that will be used to ground truth results from biophysical transport model efforts.
O13. ***US/Russian Chukchi*** (H8, H9) Connect US Chukchi Sea IERP surveys to those planned in the Russian exclusive economic zone (EEZ; 2017, 2019; Melnikov, TINRO; Afanasyev, VNIRO).

Experimental Design and Methods

Physics, nutrients, primary and secondary producers in the eastern Chukchi Sea were concurrently examined using biophysical moorings, shipboard surveys, and uncrewed systems (autonomous vehicles) allowing us to capture the spatiotemporal variability of the ecosystem. Sampling occurred throughout the year. Shipboard measurements in late summer and early fall 2017 and 2019 by the combined LTL and UTL programs provided a comprehensive integrated ecosystem data set (physics to fish to seabirds) of the eastern Chukchi Sea. Year-round measurements were collected over two years from moorings deployed in 2017 (recovered in 2018) and 2018 (recovered in 2019). Moored data were especially valuable in providing critical information during ice-covered months by collecting information on timing of the chlorophyll "dump," drawdown of nutrients, light penetration, and respiration versus primary production (e.g., oxygen saturation). In addition, they provided temporal context for the shipboard measurements that were conducted in late summer and fall of 2017 and 2019, and for autonomous measurements that

sampled the region from ice retreat to freeze-up (e.g., saildrone and ALAMO floats). Close collaboration with our counterparts in the linked UTL component allowed us to understand the effects of these variables on upper trophic biological production. The program also leveraged observations from a number of other teams and programs including EcoFOCI's Bering and Arctic observing programs, NOAA's Marine Mammal program at AFSC, and the Innovative Technology for Arctic Exploration (ITAE) at NOAA's Pacific Marine Environmental Laboratory (PMEL).

Shipboard Work

Integrated ecosystem surveys of the eastern Chukchi Sea occurred from August to early October in each of two field years (2017, 2019) (Figure 1a, 1c). The surveys were conducted in three legs on the R/V *Ocean Starr* (Figure 3) with the first leg dedicated to servicing moorings and conducting hydrographic transects, and Legs 2 and 3 dedicated to gridded fish surveys which were accompanied by additional hydrographic sampling. The hydrographic transects included the Distributed Biological Observatory Line 6 (DBO6) in the Beaufort Sea (2017), and three transects in the Chukchi Sea that have been frequently occupied since 2010; the Icy Cape line, which includes three of PMEL's long-term moorings (C1, C2, C3); the Cape Lisburne line; and DBO3 which includes PMEL's long-term mooring C12. As shown in Figure 2, shipboard activities included CTD casts (1-m resolution of temperature (T), salinity (S), oxygen, chlorophyll-a (Chla) fluorescence, turbidity, and PAR); water samples from Niskin bottles (discrete samples for measurements of nutrients, oxygen, Chla, primary production, and phytoplankton and microzooplankton speciation); and bongo tows for zoo- and ichthyo-plankton.

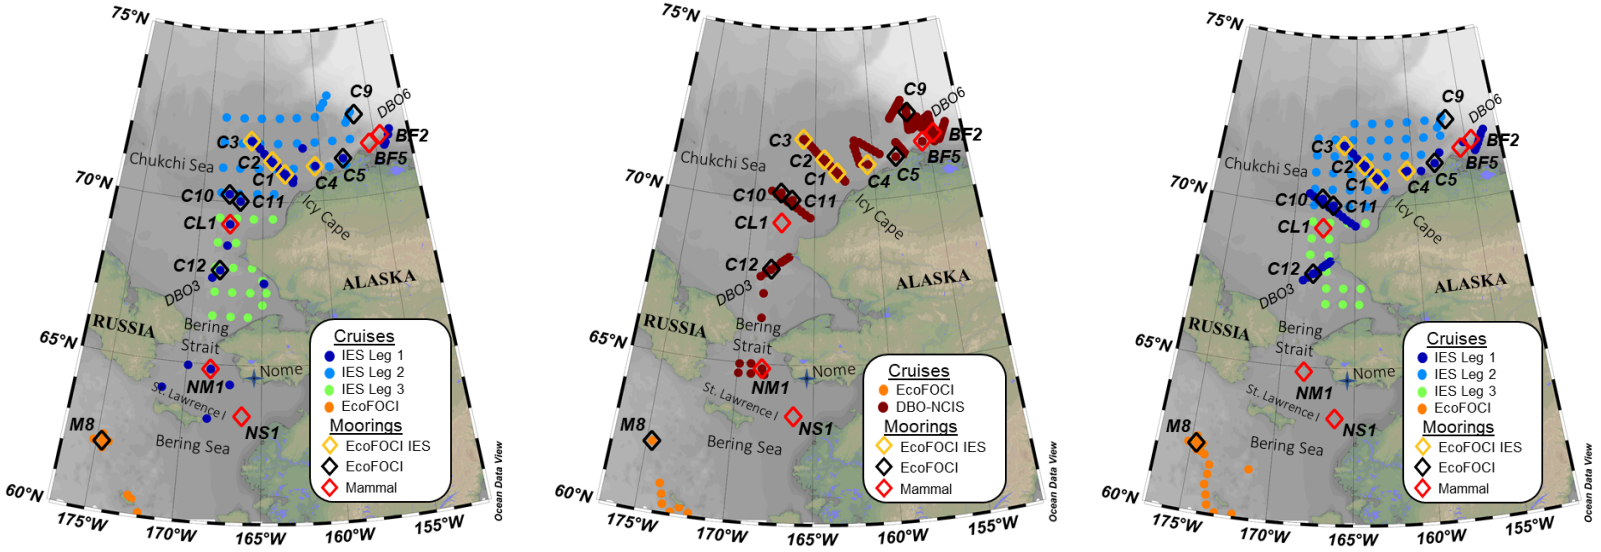
Biophysical Moorings

This project included two years of time series measurements at three sites; C1, C3, and C4 (Figure 1). EcoFOCI's mooring C2 on the Icy Cape line was leveraged as part of this program. In addition, EcoFOCI has maintained a suite of moorings in the Chukchi Sea since 2010, and in the northern Bering Sea since 2005 (M8 in Figure 1). For this program, moorings were deployed in 2017, recovered and redeployed during a DBO-NCIS cruise on the USCGC Healy in 2018 (Figure 1b), and recovered in 2019. These moorings (C1, C2, C3 and C4) measure current speed and direction (ADCP; RCM-9), near-bottom T and S, oxygen, nitrate (C1, C2, and C3), Chla fluorescence, PAR, bottom pressure and ice thickness (Figure 2). In partnership with AFSC's Marine Mammal program, passive acoustic moorings were also deployed at these sites. Note that measurements were contingent upon successful instrument recovery and operation.

Autonomous Platforms / Uncrewed Systems

This program leveraged ITAE and PMEL deployments of saildrones in 2017 and 2018 and ALAMO floats in 2017-2019. The saildrone is an autonomous vehicle that utilizes wind for propulsion and solar panels to power on-board systems. The saildrone derives its speed from a 4-m wing. Data (returned in real time) include position, atmospheric parameters (sunlight, barometric pressure, wind, air temperature and relative humidity) and oceanic parameters (T, S, Chla, and oxygen). The drones were launched from Dutch Harbor, sailed north through Bering Strait, and traversed the Chukchi Sea. The mission in 2017 was a proof of concept while the mission in 2018 was used primarily to complement UTL surveys in 2017 and 2019. Most of the atmospheric data from these missions were delivered to the Global Telecommunication System (GTS) while salinity, Chla and oxygen data are experimental.

The ALAMO float (Air- Launched Autonomous Micro-Observer [ALAMO]) is an ARGO-like float that is ice reinforced. It was developed by MRV Systems LLC in partnership with ITAE. These floats provide ~100 profiles of T, S and pressure the water column shortly after ice retreat. In partnership with the Woods Hole Oceanographic Institution and PMEL's Arctic Heat program, 29 ALAMO floats were deployed between 2017 and 2019, and that information is available at PMEL's Arctic Heat website (https://www.pmel.noaa.gov/arctic-heat/data).



(a) 2017 (b) 2018 (c) 2019

Figure 1: Maps of IES survey stations (dots) and moorings (diamonds) in (a) 2017, (b) 2018, and (c) 2019. Also shown are the following collaborative activities: EcoFOCI hydrographic surveys and the M8 mooring in the Bering Sea, AFSC marine mammal passive acoustic moorings, and the 2018 DBO-NCIS hydrographic and mooring cruise. Not shown are mooring deployment and recovery cruises in 2016 and 2020, saildrone track lines in 2017, 2018 and 2019, and trajectories of satellite-tracked drifters and ALAMO floats. Fall IES cruises OS2017 and OS2019 both had three legs, all involved with data collection.

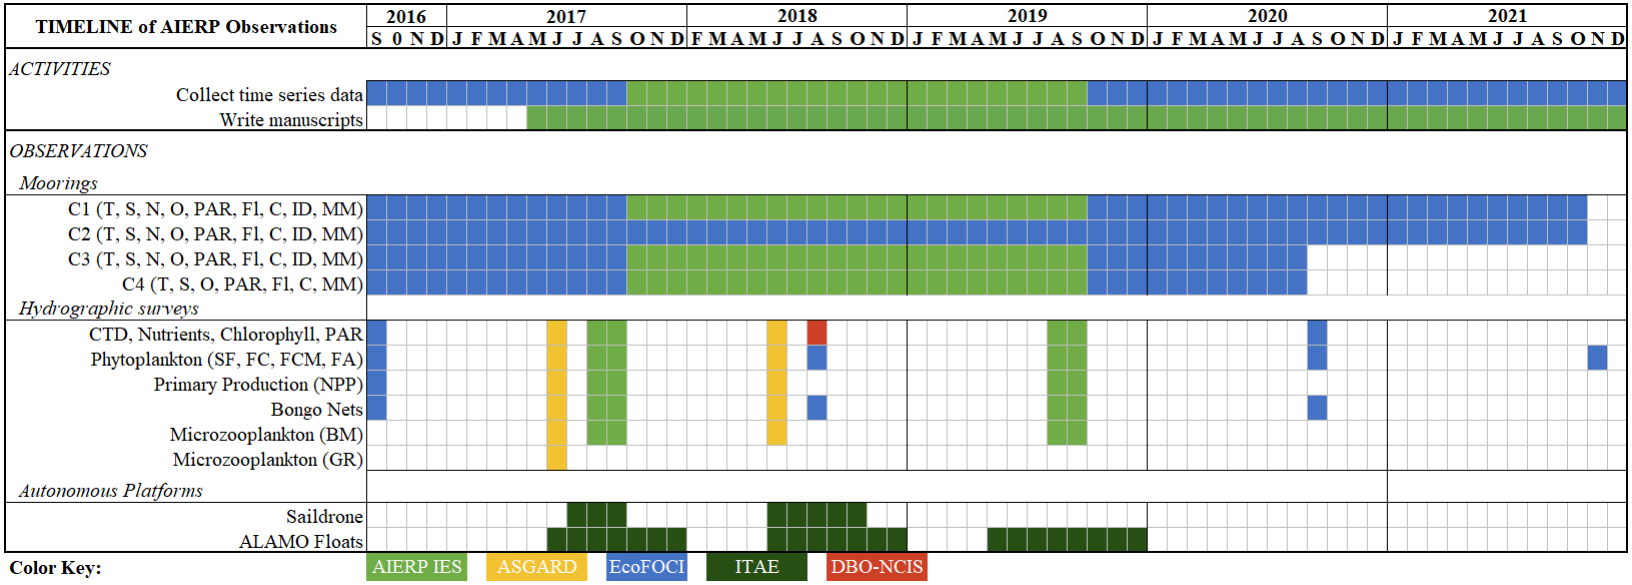


Figure 2. Timeline of activities and observations undertaken by this project. Mooring: Temperature (T), Salinity (S), Nitrate (N), Oxygen (O), Photosynthetically Available Radiation (PAR), Chlorophyll Fluorescence (FL), Currents (C), Ice Draft (ID), Marine Mammals (MM) Note that time series data are contingent upon successful instrument recovery and operation. Phytoplankton: Size Fractionation (SF), FlowCam (FC), Flow Cytometry (FCM), Fatty Acid Content (FA), Net Primary Production (NPP). Microzooplankton: Biomass (BM), Grazing Rates (GR).

Figure 3: R/V Ocean Starr dockside (Stabbert Maritime Inc.). Photo: D. Strausz, NOAA PMEL / CICOES

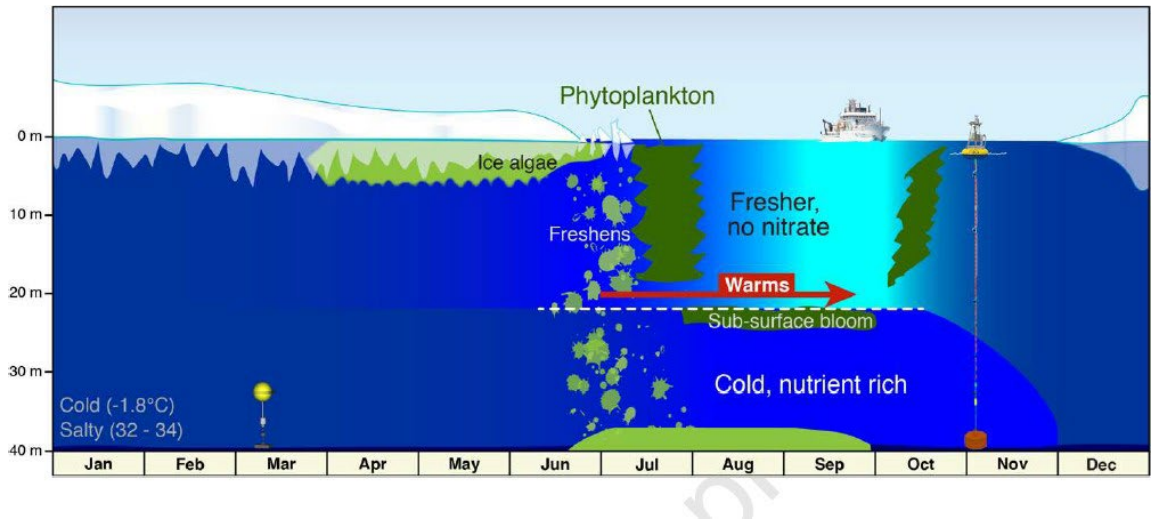

Figure 4. Seasonality of the lower trophic level of the ecosystem on the northeastern Chukchi Sea Shelf. Ice algae bloom occurs beneath the ice in spring, and with ice melt it is exported to the bottom, where there is sufficient light and nutrients to support further production. With ice retreat/melt the water stabilizes with a relatively warm, low salinity surface layer overlaying a cold more saline bottom layer. With this stabilization, a surface phytoplankton bloom can occur consuming the remainder of surface nutrients and support a subsurface bloom. With surface mixing in late summer, a fall phytoplankton bloom may occur (from Chapter 9).

Data and Metadata
Observational data from the A92 EIS program and the microzooplankton A70 programs.

General Discussion

The overall goal of the Lower Trophic Level (LTL) project was to better understand the mechanisms and processes that structure the ecosystem and influence the distribution, abundance, and life history of lower (phytoplankton, zooplankton, ichthyoplankton) organisms, and their vulnerability to the rapidly changing environment of marine ecosystems in the Arctic. The results of the LTL research was directly linked with results from the Upper Trophic Level (UTL) research component that examined the processes that influence the flow of energy from primary producers, zooplankton and ichthyoplankton to upper trophic species (fishes, seabirds, mammals), and how warming climate will influence these processes.

There were 13 specific objectives for this project. Discussed below are the highlights of our project organized by these objectives. More extensive discussion can be found in the individual Chapters.

Objectives

O1. **Stratification** (H1, H2) Quantify the strength of stratification, its temporal evolution, and the relative contribution of temperature and salinity throughout the spring ice melt/retreat.

Stratification includes thermal and salinity components. Hydrographic transects, surveys and moorings were used to ascertain the relative contribution of these components. During winter the water column is well mixed. In the northern Bering Sea, the water column becomes well mixed in November and begins to stratify in April/May, when ice melts reducing surface salinity and the ocean begins to warm from solar heating. Maximum stratification is in late August/early September. Vertical stratification is due in equal parts to salinity and temperature. Stratification in the Chukchi is also due to both salinity (ice melt) and temperature. Advection, however, modifies this and the influence of advection on stratification is still being resolved (McCabe and Stabeno, Chapter 17; McCabe et al., Chapter 18; Stabeno and McCabe, Chapter 22).

O2. **Circulation** (H3) Quantify transport in Herald Canyon (RUSALCA) and the eastern Chukchi shelf. Identify pathways of flow and their respective heat, salt, and nutrient concentrations.

The RUSALCA program was discontinued shortly after this proposal was funded, so the transport in Herald Canyon could not be resolved directly. Transport on the eastern Chukchi shelf was directly calculated via moorings and drifters and compared to flow through Bering Strait (Stabeno et al., 2018; Stabeno and McCabe, Chapter 22). The annual volume transport near Icy Cape ranged from ~0.3 x 10^6 m^3 s^{-1} (10^6 m^3 s^{-1} = 1 Sv) during September 2011 – August 2012 to ~0.7 Sv during September 2017 – August 2018, with a 10-year average of ~0.4 Sv. This transport accounts for approximately 40% of the flow through Bering Strait and varies seasonally, ranging from >50% of summer transport to only 20% of winter transport in Bering Strait. On an annual basis, there is enough heat exiting the Chukchi shelf through Barrow Canyon to warm the upper 100 m of the Beaufort Sea by approximately 0.5 °C (McCabe and Stabeno, Chapter 17).

In the Chukchi Sea, nitrate is a limiting nutrient for phytoplankton. Year-to-year differences in the amount of nitrate available to sustain spring production varies by about 50%. These differences result from the extent to which the Chukchi Sea is flushed with water from the Bering Sea during

winter, and the variability of nitrate in water being transported from the Bering Sea (Mordy et al., 2021; Hennon et al., Chapter 13; Mordy et al., Chapter 5).

There appears to be two distinct communities of zooplankton in the Chukchi Sea: a local, Arctic community related to water masses within the Chukchi Sea, and a community advected from the Bering Sea. Thus, the relative magnitude of annual transport from the Bering Sea influences zooplankton community structure in the Chukchi Sea. Decreased transport and later ice retreat in colder years resulted in zooplankton communities that exhibited more diversity and had higher abundances of fat-rich copepods. In contrast, in years with increased transport from the south, expatriate zooplankton communities from the Bering Sea were prevalent in the Chukchi Sea. If the northward inflow of water into the Chukchi Sea were to increase with concomitant warming, changes in food-web structure and function are likely to result (Spear et al., Chapter 7; Kimmel and Spear, Chapter 14).

O3. **Heat Flux** (H1, H2, H3) Estimate surface heat fluxes (summer) and compare to estimates of advective heat fluxes.

Danielson et al., (Chapter 2) discusses surface heat flux estimates from an atmospheric reanalysis model (ECMWF ERA5) over the Bering and Chukchi Seas within the context of a compilation of historical and more recent hydrographic profiles that capture significant ocean warming trends in the region. That study documented no trend in the shelf-wide Bering Sea surface heat fluxes (1979-2018). Over the Chukchi shelf, however, there was a trend toward greater surface heat losses during cooling months (October–March) and a trend toward greater heat gains during warming months (April–September). McCabe et al., (Chapter 18) detail in situ estimates of surface heat fluxes over the course of a ~2-month mooring deployment on the central Chukchi shelf in summer 2015 and compare those estimates to those obtained from the ERA5 reanalysis model. It presently appears that both the surface and advective fluxes contribute roughly equally to the total heat flux. McCabe and Stabeno (Chapter 17), quantify a decade-long estimate of the alongshelf transport of heat that transits the eastern Chukchi Sea and enters the Arctic Basin, discussing both the intra- and inter-annual variability. On an annual basis, there is currently enough heat exiting the Chukchi shelf through Barrow Canyon to warm the upper 100 m of the Beaufort Sea by approximately 0.5 °C.

O4. **Ice and Phytoplankton** (H4) Examine the relationship among ice thickness, ice retreat, and the timing and magnitude of near-bottom chlorophyll that fuels benthic-pelagic coupling.

The Chukchi Sea is highly productive even though the growing season is short. Particulate organic matter, including ice algae, dead phytoplankton, and zooplankton fecal pellets, falls to the sea floor providing nutrition that sustains organisms living in that realm. For example, as ice begins to melt in spring, algae living on the underside of the ice detach and fall to the sea floor. The Chukchi Sea shelf is shallow enough that sunlight can penetrate to depth and detached ice algae can continue to photosynthesize.

In Chapter 9 (Stabeno et al.) we identify the occurrence of primary production at multiple layers in the water column and hypothesize that near-bottom production is a result of disassociated ice algae near the seafloor. On the basis of this evidence, we propose the Multiple Production Layer (maple) hypothesis, where high production is promoted by a shallow seafloor, which allows multiple production layers (surface, sub-surface, sympagic ice algae, and disassociated ice algae

near the seafloor)(Figure 4). High production occurs because the amount of light near the seafloor in mid-spring to early fall is similar to that measured beneath a 1.5-m thick ice floe. With sufficient light near the seafloor (~40 m), ice algae continue to photosynthesize, utilizing nitrate and producing oxygen through summer; a unique feature that pertains to this shallow shelf. Bloom onset occurred in summer following ice retreat, whereas the end of the bloom occurred in September following loss of light. While this is a complex system, with multiple feedbacks and thus difficult to predict, our results do suggest certain possibilities. Even in a changing system with ice retreating later and arriving earlier, the primary change will be the timing of the export of ice algae to the bottom. Thus, the duration of near-bottom primary productivity will lengthen, because bloom onset occurs earlier.

O5. **Phytoplankton Abundance** (H4, H5) Quantify the relative abundance of pelagic phytoplankton species compared to sinking ice-associated algae.

The relative distributions of pelagic and ice-associated algae continues to be explored. Eisner et al. (Chapter 24) examined the abundance and production of phytoplankton. The contribution of ice-associated algae were derived from under-ice measurements that provided the timing of ice-algal growth and eventual disappearance as the ice substrate began to erode (Stabeno et al., Chapter 9). Koch et al. (2020) used lipid biomarkers in sinking organic matter to quantify export of ice-associated algae to the benthos. These results were presented by M. Sigler at the 2021 Alaska Marine Science Symposium in 2021 (Seasonal Patterns of Near-Bottom Chlorophyll Fluorescence in the Eastern Chukchi Sea: 2010–2019)

O6. **Primary Production and Phytoplankton Size Structure** (H5, H6) Quantify spatial patterns in rates of total and new production, and phytoplankton community size structure as a function of water column physics and chemistry (nitrate and ammonium).

Samples for total and new production from the ASGARD 2017 and 2018 cruises, and from gridded stations on the IES 2017 and 2019 cruises have been analyzed and rates calculated. Spatial analysis of patterns has not been completed at the time of writing this report, but will be conducted in the near future (Eisner et al., Chapter 24) .

Initial data confirm the stations/depths with highest chlorophyll-a biomass were associated with dominance by the larger size fraction (> 5 um). As expected, in spring diatoms were in higher abundance, primary production rates were higher although more patchy, and subsurface blooms were less prevalent than in fall. In summer, phytoplankton growth in surface waters were nutrient-limited at the majority of stations. Chlorophyll biomass and production of the small (< 5 μm) size fraction was higher in summer 2019 (the warmest year) than 2017. These changes in phytoplankton community, biomass, and primary productivity are likely to result in reduced food quality with potential negative ramifications for higher trophic levels (Lomas et al., Chapter 16; Nielsen et al., Chapter 20; Eisner et al., Chapter 24).

Highly productive ecosystems, such as the Bering and Chukchi Seas, are generally characterized by predominantly large phytoplankton (i.e., pelagic and ice algae diatoms), with picocyanobacteria making trivial contributions to phytoplankton biomass. Our findings challenge this premise by observing high abundances of the picocyanobacteria *Synechococcus*. Indeed, cell counts at some stations/depths exceeded those seen in oligotrophic ocean gyres. These stations with high Synechococcus abundances appear constrained to the warm, nutrient-depleted coastal

and shelf waters. Comparison of the carbon biomass contribution of *Synechococcus* to the total phytoplankton carbon shows that biomass contributions decline as total phytoplankton biomass increases (as expected), but that below a total phytoplankton carbon biomass of ~100 mg C/m^3 (~2 mg Chla/m^3), *Synechococcus* often accounts for 20% to >40% of the biomass. In a compilation of data from prior studies that enumerated *Synechococcus* in the Chukchi Sea, it appears the warming of this region has supported a greater net seasonal growth of *Synechococcus* over the past decade. This finding suggests that multi-year periods of warmer than average conditions are altering the seasonal phytoplankton succession pattern (Lomas et al., Chapter 16).

O7. **Microbial food web model** (H4, H5) Use new primary production data to validate and constrain a model of ocean primary productivity and fate in regions where subsurface productivity maxima are important.

Nielsen et al. (Chapter 21) use new empirical biomass and rate measurements data to validate and constrain a linear inverse microbial food web model. This modeling approach allows reconstruction of trophic flows and quantification of biological rates that are commonly challenging to measure. Preliminary simulations indicate seasonal differences in major carbon pathways. Higher carbon fluxes appeared to be available for benthic consumers in spring (in areas of high primary production) compared to late summer. Our initial analyses also revealed the importance of carbon uptake and transfer in microzooplankton and bacterial compartments, organisms and processes that are often underestimated on many ecosystem models.

O8. **Secondary Production** (H8, H9) Quantify the distribution, size, abundance, and species composition of zooplankton and ichthyoplankton throughout the US shelf waters of the Chukchi Sea. Compare data to relative oceanographic conditions and to historical estimates as derived from AFSC sampling 2003- present.

Zooplankton are the link between phytoplankton and higher trophic levels. Spear et al. (Chapter 7) and Kimmel and Spear (Chapter 14) found that in the warm years of the IERP surveys, fewer *Calanus glacialis* were found during late summer compared to earlier in the decade. *C. glacialis* is the main prey item of juvenile Arctic cod and is also an important prey for bowhead whales and seabirds. As the strength of warming and northward transport increased in 2019, most of the Chukchi Sea was covered in southern associated zooplankton species. These smaller zooplankton are less nutritious prey, having less overall caloric and fat content. Further warming will likely result in increased importance of these smaller zooplankton as the Arctic experiences longer ice-free periods. This will correspond with greater carbon flow through the pelagic as opposed to delivery to the benthos.

O9. **Trophic Interactions – Hot Spots** (H4, H5) Use primary production data to understand spatial variability in net community production and identify 'hot spots' of trophic connections between LTL and UTL, and how these might change in relation to other on-going projects in the region focused on detecting change (e.g., Distributed Biological Observatory [DBO]).

All primary production rates have been calculated and elevated primary production can be seen in regions of high nutrient availability (Eisner et al., Chapter 24). Spatial patterns in primary production rates have not yet been aligned with estimates of net community production, and UTL data to identify 'hot spots' of trophic connectivity, but this will be undertaken in the near future.

O10. **Trophic Interactions – Nutrition** (H6, H7, H8, H9) Determine spatial and temporal relationship between phytoplankton, zooplankton and ichthyoplankton. Link observations to UTL-derived data to provide mechanistic understanding of trophic relationships. Compare fatty acid profiles of seston (primarily phytoplankton) and zooplankton to relate carbon sources to nutritional condition of key forage fish (e.g., Arctic cod).

The determination of temporal and annual links between phytoplankton dynamics and zooplankton lipid storage is work that is currently in progress. Large Arctic zooplankton were found to have elevated lipid storage that is largely dependent on diatom production, which in the Chukchi Sea was found to be elevated in spring and in cold nutrient rich waters (Nielsen et al., Chapter 20). Lipid biomarkers in zooplankton and fish can help us understand the trophic component of their spatial and annual energetic variability. Recent shifts in zooplankton dynamics during warming, such as an increased abundance of small zooplankton (e.g., *Pseudocalanus* spp.), compared to large Arctic zooplankton (e.g., *Neocalanus* sp., *Calanus glacialis*) (Spear et al., Chapter 7; Kimmel and Spear, Chapter 14), have likely resulted in decreased zooplankton lipids available regionally in juvenile fishes diets. We measured a large drop in lipid-based condition metrics of juvenile Chukchi Sea Arctic cod and saffron cod from a current warm year (2017) compared to previous cold years (2012-2013) (Copeman et al., UTL Final Report, Chapter 11). This decline in gadid condition was linked to low *Calanus*- and diatom-sourced fatty acid biomarker in fish tissues. This work remains in progress. Future synthesis efforts will focus on: (1) spatial and annual links between phytoplankton quantity/quality and zooplankton lipids to understand mechanisms driving changes in zooplankton quality; and (2) combining newly generated species-specific Arctic zooplankton lipid values with climate-driven changes in zooplankton species composition to better forecast zooplankton quality that will be available to juvenile fish in a warming Arctic.

O11. **Ecosystem Connectivity** (H8, H9) Examine connectivity and exchange of lower trophic biota (zooplankton, ichthyoplankton, juvenile fish) between ecosystems (northern Bering Sea, Chukchi, Beaufort) to determine if each region acts as a source or a sink of ichthyo- and zooplankton stocks.

In warm years characterized by low sea-ice coverage and strong advection of water masses from the Bering Sea to the Chukchi Sea, we observed a northward shift and range contraction of the late summer Arctic larval fish assemblage (e.g., Arctic Cod, Bering Flounder, Arctic Sand Lance, and Arctic Shanny). Over the same time period, we observed a range expansion of warmer water assemblages (comprised of lower latitude, boreal species such as Yellowfin Sole, Pollock, and Capelin) and increasing species-level abundances in response to Arctic warming. The resulting structural changes to the larval fish community will likely continue with projected ocean warming and sea-ice loss, with consequences for biodiversity, food-web configuration, and trophic pathways in the Arctic (see Axler et al., Chapter 10).

With respect to zooplankton, yearly advection from the Bering Sea influences zooplankton community structure. Increased advection and earlier ice retreat results in zooplankton communities that exhibit less diversity and lower abundances of the lipid-rich copepod Calanus glacialis. These warm-year zooplankton communities are more closely related to water masses that are advected from the south (Spear et al., Chapter 7; Kimmel and Spear, Chapter 14).

O12. **Arctic Cod and Saffron Cod** (H9) Further resolve spawning and connectivity of Arctic Cod and Saffron Cod adults, larvae and juveniles by providing new field data on late-stage larvae in summer that will be used to ground truth results from biophysical transport model efforts.

Arctic Cod (*Boreogadus saida*) and Saffron Cod (*Eleginus gracilis*) are ecologically important forage-fish species in the Arctic. Their life histories have evolved in a system dominated by seasonal sea-ice dynamics, which is currently changing rapidly making these species vulnerable to the effects of climate change. For the first time, we were able to synthesize the seasonal distribution, abundance, and growth of two co-occurring Arctic forage fishes. Kotzebue Sound was likely a source of early-stage Arctic Cod and Saffron Cod found offshore of Point Hope / Cape Lisburne and in nearshore coastal areas to the north. However, Arctic Cod found in the Hanna Shoal region are not likely hatched from Kotzebue Sound, but from other areas such as Bering Strait and Chukotka Peninsula. Growth rates estimated in 2017, an extremely warm year in the Arctic, were higher than in previous studies, although this should be confirmed using otolith-derived growth rates (Deary et al., 2021; Deary et al., Chapter 3).

O13. **US/Russian Chukchi** (H8, H9) Connect US Chukchi Sea IERP surveys to those planned in the Russian exclusive economic zone (EEZ; 2017, 2019; Melnikov, TINRO; Afanasyev, VNIRO).

The IES cruises included participants from TINRO and VNIRO. Eisner, Ladd, and Duffy-Anderson collaborated with Russian oceanographers, Yury Zuenko and Eugene Basyuk at the Pacific Branch of Russian Research Institute of Fisheries and Oceanography (TINRO) to compile surface and bottom water temperature data and pollock abundance data (juveniles and adults) from the eastern and western Bering Sea. This effort resulted in a joint publication (Eisner et al., Chapter 4) with communication ongoing including plans for workshops and a special issue.

Application to Resource Management and Alaskan Communities

Recognizing the potential for commercial fishing activities to expand into the northern Bering Sea and the Arctic, and the lack of baseline information from these areas, the North Pacific Fishery Management Council (NPFMC) has taken several proactive measures to prevent the northward expansion of commercial fishing without prior assessment of fisheries resources. These measures include a ban on non-pelagic trawling in the Northern Bering Sea Research Area until a research plan can be developed and a ban on all commercial fishing in the US Exclusive Economic Zone of the Arctic under the Arctic Fishery Management Plan (FMP, https://www.npfmc.org/arctic-fishery-management/). Implementation of the FMP requires baseline surveys to assess the status of fisheries resources in the Arctic. Information on fish populations collected by this and other projects are critical to informing the NPFMC about the status of fish stocks in the Chukchi Sea and environmental mechanisms underpinning variation in their populations. The Arctic FMP identifies Arctic cod (*Boreogadus saida*), saffron cod (*Eleginus gracilis*) and snow crab (*Chionoecetes opilio*) as potential target species in the Chukchi Sea. An important and required element of any FMP is a description of Essential Fish Habitat (EFH) for each target species in the FMP. Data collected during our surveys already contribute to updating EFH descriptions for the three species named in the Arctic FMP using the best available scientific information.

Together, the LTL and UTL components provide a comprehensive view of the ecosystem and provide clarity on the changing ecosystem for resource managers and Alaskan communities. The LTL program found that there is an increased transport and heat flux into the Arctic basin, substantial interannual variability in the amount of nutrients available to sustain spring production, and that warming will increase the spatial extent of picocyanobacteria Synechococcus, a smaller less energy-rich phytoplankton that will negatively impact the flow of energy to higher trophic levels. There appear to be concomitant reductions in larger sized zooplankton, reducing the amount of prey available for larger, pelagic predators such as bowhead whales and seabirds. There will be winners and losers in the Arctic fishes as climate-driven distribution shifts are restructuring larval fish community composition and bioenergetic pathways that will influence the flow of energy to higher trophic levels. This will have cascading consequences for upper trophic level production that provides the basis for commercial fishing communities, and for local communities in the Arctic that rely on fishes, seabirds and marine mammals for food.

The UTL Arctic Integrated Ecosystem Surveys provide further information on the impact of climate variability on ecosystem function and fitness of fishes and invertebrates. During the research period (2016 to 2021), adult subarctic gadids moved into the northern Bering Sea in large numbers. Commercial fishing for Pacific cod (using longline) commenced within the northern Bering Sea and in Russia's exclusive economic zone in the Chukchi Sea. However, we did not find large numbers of adults of either subarctic or arctic gadids (Arctic cod and saffron cod) within the Chukchi Sea survey region. We did find large numbers of age-0 Arctic cod and saffron cod as well as age-0 subarctic gadids (walleye pollock) within the southern Chukchi Sea region. Pollock were largely absent in previous surveys of the same area in 2005, 2012 and 2013, but were the most abundant pelagic fishes in many areas in 2017 and 2019. In 2019, age-0 Arctic cod were found further north in the survey region than was reported during earlier surveys (Arctic EIS 2012 and 2013). In addition, we found that warming ocean temperatures and increased transport during summer months through the Bering Strait improves habitat quality for juvenile salmon within the southern Chukchi Sea. These changes are related to faster early marine growth and survival of young salmon, potentially leading to higher numbers of adult salmon returns to the Arctic.

Prey quality is likely an important consideration: for example, age-0 Arctic cod are more lipid-rich and energy-dense than walleye pollock. Additionally, environmental factors are likely to play an important role in food quality: although juvenile Arctic cod were very abundant at the end of the warm (2017) summer season, they had only half the fat storage and lower overall energy content than those collected during colder years (2012/2013). Similarly, saffron cod, capelin and sand lance had slightly lower energy content in warmer years. These changes in the distribution of abundant age-0 pelagic fishes are consistent with expectations under continued warming, and will likely continue as the Alaska Arctic continues to warm. These changes in the abundance, distribution and lipid content of small fishes are likely to impact food availability and quality for higher trophic level predators (piscivorous fishes, marine mammals, and birds) and for communities who depend on these food sources. For example, piscivorous seabirds require forage fish of high energy density to raise chicks to fledging during the short Arctic summer. Low quality prey can significantly increase the number of fish needed to raise chicks, increasing foraging effort and extending the chick-rearing period. Late fledging dates and low fledgling weight can reduce overwinter survival. Low recruitment in harvestable seabirds can impact the ability of local communities to gather eggs and adult birds.

In response to changes in prey, some seabirds, such as short-tailed shearwaters and thick-billed murres, have shifted their distribution farther north, and are remaining in the Arctic later into summer or fall, but they must still return south through the Bering Strait. Other marine birds, such as eiders, maintain the timing of their post-breeding southward migration through the Bering Strait region. Due to lack of sea ice, these southward migration patterns now overlap with increased vessel traffic during months of nighttime darkness, potentially resulting in higher risk of vessel-bird collisions. The new overlap of human activities during fall migration of marine birds could pose challenges to bird conservation and to management of vessel traffic lanes throughout the region.

Our results from the Arctic Integrated Ecosystem Survey indicate that our overarching hypothesis:

Reductions in Arctic sea ice and the associated physical changes to the environment influence the flow of energy through the pelagic ecosystem in the Chukchi Sea. Specifically, we expect lasting changes in the seasonal composition, distribution and production of phytoplankton; in the distribution and standing stocks of large crustacean zooplankton that serve as the prey base for upper trophic level fishes and seabirds; in the assemblages, distributions, abundances, and body condition of larval and early juvenile fishes that influence the recruitment success of later life stages, and in the distribution and abundance of adult fishes

is being realized.

Collaborations

C1. **Alaska Ocean Observing System, AOOS.** PI - Stabeno (2020-2022) provides support to improve observations on the northern Bering Sea (NBS) mooring observatory.

C2. **Bureau of Ocean Energy and Management, BOEM:** and Coastal Impact Assistance Program (CIAP) - Arctic Integrated Ecosystem Survey (Eis) Phase 1. PIs - Farley, Mueter, Eisner et al., (NOAA-BOEM IAA-AK-11-08b, 1/1/12-5/31/16). Summer surveys were conducted in the NBS and CS in 2012 and 2013. Observations included pelagic fish and groundfish, zooplankton, oceanography, and total and size fraction Chl-a. We will relate satellite derived estimates of phytoplankton community composition (outcome of our proposal) to in-situ total and size-fraction Chl-a. The validated satellite data can be compared to distributions of zooplankton and fish in this region.

C3. **NOAA Northwest Fisheries Science Center & Woods Hole Oceanographic Institution:** Harmful Algal Blooms. PIs - Duffy-Anderson, Stabeno, Eisner, and Kimmel collaborated with WHOI researcher Don Anderson and NWFSC researcher Kathi Lefebre to collect samples for work on the detection of high levels of paralytic shellfish toxins in Northern Alaskan food webs.

C4. **International Partners.** Russia PIs - Eisner, Ladd, Duffy-Anderson collaborated with Russian oceanographers, Yury Zuenko and Eugene Basyuk at the Pacific Branch of Russian Research Institute of Fisheries and Oceanography (TINRO) to compile surface and bottom water temperature data and pollock abundance data (juveniles and adults) from the eastern and western Bering Sea. This effort resulted in a joint publication (see Chapter 4) with communication ongoing. Canada PIs - Stabeno and Mordy collaborated with Catherine Lalande (Amundsen Science) in an NPRB project to enhance the M8 observatory with sediment traps that will enable the determination of export flux to the benthos.

C5. **NOAA Arctic Research Program - ARP.** PIs - Stabeno, Duffy-Anderson and Mordy supports moorings and annual scientific cruises to the Pacific Arctic region during which U.S. scientists take a wide range of physical, chemical, and biological samplings including Distributed Biological Observatory (DBO). The DBO has designated eight “hot spots" across the Bering, Chukchi, and Beaufort seas where multidisciplinary sampling is focused. We have partnered with the DBO Program to collect a suite of physical and biological measurements in the Chukchi Sea over multiple years and to make these observations available to the AIERP Program. The DBO is a collaboration between multiple U.S. federal agencies and academic institutions as well as from other Arctic nations.

C6. **NOAA Ecosystems and Fisheries-Oceanography Coordinated Investigations (EcoFOCI) Program and Recruitment Process Alliance (RPA) at NOAA PMEL/AFSC**. PIs - Stabeno, Duffy-Anderson, Farley, Axler, Copeman, Deary, Eisner, Gann, Goldstein, Kimmel, McCabe, Mordy, Nielsen, Spear, et al., This is an integrated long-term base-funded NOAA program that conducts research in the US Arctic. It maintains long- term ecosystem moorings in the Bering Sea (since 1995) and Chukchi Sea (CS; since 2010) and spends >100 days at sea each year. Field observations include: temperature, salinity, oxygen, currents, nutrients, phytoplankton (size-fractionated Chl-a, taxa, productivity), zooplankton/ ichthyoplankton, pelagic fish and groundfish. EcoFOCI’s goal is to improve understanding of ecosystem dynamics and apply that understanding to fisheries management. Field, laboratory and modeling studies are integrated to reach this goal.

C7. **NOAA PMEL Innovative Technology for Arctic Exploration program.** PI - Mordy (co-PI C. Meinig, PMEL). To better study arctic marine ecosystems and the rapid changes that are occurring, we are collaborating with the Innovative Technology for Arctic Exploration (ITAE) program as it works to develop innovative technologies, including sensors and platforms, to meet the scientific demand in these regions. The mission of the ITAE program is to conceptualize and build effective research equipment for the assessment of the Arctic environment and ecosystem with the operation of high-resolution sensors on autonomous platforms near sea ice. The dynamic and fine-scale nature of these regions requires responsive, high-resolution data collection over large areas in real time — a logistical challenge ideally suited to fast, mobile autonomous platforms rather than traditional ship-based operations. Existing autonomous platforms are both small and slow, limiting the observational capacity, responsiveness, and deployment capabilities. ITAE is a collaborative research effort by University of Washington (JISAO now CICOES) and NOAA engineers and scientists at the Pacific Marine Environmental Lab (PMEL). This program leveraged saildrone missions and ALAMO float deployments (in collaboration with PMEL's Arctic Heat program).

C8. **NOAA AFSC Marine Mammal Laboratory**. PI - Stabeno collaborates with Catherine Berchok (NOAA AFSC) to assess spatiotemporal variability of marine mammals in the CS and NBS. They coordinate in deploying passive acoustic moorings and in data analysis that helps to elucidate climatic, physical, and biological forcing of marine mammal distributions.

C9. **NOAA National Oceanographic Partnership Program (NOPP)** Expanding exploration and using innovative technologies to assess the rapidly changing Bering and Chukchi Seas. PIs - Stabeno, Mordy, Lomas (Bigelow), Duffy-Anderson, Farley, Logerwell, Berchok, Eisner, Kimmel, Gann, Nielsen, Du (OSU). The US Arctic ecosystems are undergoing dramatic, unprecedented changes in response to ocean warming and declines in sea ice. In addition to the physical changes, biological shifts across all trophic levels have been observed (e.g., phytoplankton community composition and bloom timing; zooplankton dynamics; spatial shifts in fish distributions). This project expands ecosystem observations in NBS and southern CS using traditional and new technologies. Emergent technologies include profiling platforms, speciation techniques ('omics), in-situ visualization, and unmanned vehicles. This project will create new Ecosystem Observatories in the US Arctic.

C10. **NOAA/NASA Joint Polar Satellite System (JPSS)** Satellite analysis of shifts in phytoplankton community composition and energy flow in the new Arctic. PI - Eisner, Lange (Blue Marble Space Institute of Science), Lomas, Mordy, Nielsen, Stabeno; Collaborators Gann (AFSC), Lefebvre (NWFSC, HABs), Robinson (UC Santa Cruz, CoastWatch/PolarWatch), Wilson (SWFSC, CoastWatch/PolarWatch), 6/1/21-5/31/2. The overall goals of this project are to: 1) analyze the variability of phytoplankton community size structure based on spectral slopes of absorption, backscattering, remote-sensing reflectance ($R_{rs}(\lambda)$), and empirical chlorophyll-a (Chl-a) -based algorithms from JPSS satellite data across time and space; 2) modify existing ocean color algorithms to exploit the unique $R_{rs}(\lambda)$ properties of Synechococcus in order to determine changes in this picoplankton group; 3) estimate diatom abundances from Chl-a-specific absorption; and 4) explore correlative methods to assess the probability of occurrence of harmful algae such as Pseudo-nitzschia spp. and Alexandrium spp. using Sentinel 3-A-OLCI satellite products to improve HAB predictions in the North Bering Sea (NBS) and Chukchi Sea (CS). Data from Arctic IERP will be used for ground-truthing satellite data.

C11. **National Science Foundation** What controls the transfer of diatom organic matter to age-0 pollock prey in the Bering Sea ecosystem? PI - Lomas et al., (#OPP-1603460, 11/2016-10/2019). This project explored both physiological responses of polar diatoms in culture, and the ecology (primary production and phytoplankton community) of phytoplankton in the BS and CS. The results from this and other collaborative projects listed below suggest that not only will the nutritional value of diatoms decrease as the BS and CS warm, but also the phytoplankton community, especially in the summer/fall period, will shift to small picoplankton (e.g., Synechococcus).

C12. **North Pacific Research Board (NPRB) and Bureau of Ocean Energy Management (BOEM)** Evaluating historical and future climate-driven changes to Pacific cod spawning habitat in the Bering Sea. PIs - Rogers, Mordy, Stabeno, et al., (NPRB #2003, 7/2020 - 6/2023). This project focuses on exploring the seasonal evolution of ocean temperature across the BS and its impact on spawning of Pacific cod. Specifics goals are to expand observations of seasonal oceanographic conditions in the eastern BS through deployment of an array of low-cost sensors to monitor bottom temperatures; use these data to validate and assess Regional Ocean Model System (ROMS) error and bias with respect to temperature dynamics; formally assimilate new data into ROMS; use ROMS and existing, experimentally-derived relationships between temperature and Pacific cod spawning success to characterize the extent, timing, and distribution of suitable spawning habitat; project the spatial distribution and timing of suitable spawning habitat under future climate scenarios; and introduce this information into the management process for Pacific cod. Changes in phytoplankton species and community structure, which will be directly assessed in the proposed research, impact ecosystem productivity with cascading effects on fish larval abundance and survival and spawning success.

C13. **NPRB** Monitoring export fluxes to detect seasonal and interannual changes in the pelagic ecosystem of the St. Lawrence Island Polynya Region. PIs - Stabeno, Mordy et al., (NPRB #1914, 2020 - 2024, 342,087). Climate change is rapidly affecting the NBS including the St. Lawrence Island Polynya (SLIP) where a large decline in sea-ice cover was observed in 2018, with potentially important consequences for the bird and marine mammal populations of the region. This project will deploy a sequential sediment trap to measure the magnitude and composition of the organic matter supplied to the benthic communities in the region. Sediment trap samples will provide continuous biological samples that will allow the monitoring of several aspects of the marine ecosystem from phytoplankton and zooplankton species to carbon supply to the benthos. This project will provide critical in-situ data for the proposed research, and addresses a pressing need for the long-term monitoring of the BS marine ecosystem to improve our ability to forecast and respond to the effects of climate change and provide deliverables to policy-makers.

C14. **PICES** WG44: NBS and Chukchi IEA. Chair - Logerwell. We are collaborating with PICES WG44 on the northern Bering-Chukchi Sea region to provide detailed assessment of the Pacific Arctic gateway, as well as detailed information that will inform understanding of connectivity of climate and ocean processes, species movements, shelf food web dynamics, fishing, trade, subsistence and food security, and human activities. The northern Bering Sea-Chukchi Sea (NBS-CS) region is experiencing unprecedented ocean warming and loss of sea ice as a result of climate change. Seasonal sea ice declines and warming temperatures have been more prominent in the northern Bering and Chukchi seas as almost all other portions of the Arctic.

C15. **Plankton Sorting and Identification Center,** Gdynia, Poland. Leads - Deary, Kimmel. AFSC collaborates with the Plankton Sorting Center to identify, size, and image zooplankton and ichthyoplankton collected from the northern Bering Sea and Chukchi Sea to document climate-mediated chiefs in plankton and larval fish abundance, size, distribution, and community structure.

Directions for Future Research

Through the combined LTL-UTL AIERP programs, key elements were identified for future research including maintaining long-term observations, incorporating new measurements into the observational programs, enhanced modeling of the region, and operationalizing new technologies. To further advance our understanding of ecosystem variability and climate-induced trends, we recommend the following elements for future research.

Monitoring

To establish baselines that will enable the assessment of trends and variability, we recommend the following activities be continued:

- Maintain moored observatories at key physical (e.g., Icy Cape, M8, C12,) and biological (e.g., C12) hot spots;
- Maintain hydrographic and zooplankton sampling transects (e.g., DBO, Icy Cape) and surveys (e.g., Northern Bering Sea Assessment);
- Continue planktonic monitoring to track ecosystem changes of phytoplankton, zooplankton and ichthyoplankton;
- Continue acoustics surveys and time series of fish as subarctic gadids begin moving into the Chukchi Sea;
- Maintain seabird observations on platforms of opportunity;
- Continue benthic sampling for fishes and invertebrates.

Expanding Observations

To address gaps exposed through this research and other program, we recommend the following:

- Expand the M8, M14, and C12 observatories with traditional (e.g., sediment traps, nitrate sensors, water samplers, eDNA samplers) and new (e.g., RISe profilers, imaging systems) technologies;
- Expand CTD, zooplankton, and fish (ichthyoplankton, juvenile, and adult stages) surveys to the Chukchi and Beaufort shelf break and western Beaufort Shelf;
- Measure taxon-specific grazing (e.g., grazing on Synechococcus) to determine if seasonal variability in growth is due to bottom-up (e.g., warming) or top-down control;

- Measure contributions of the pico fraction, nano-fraction and microplankton fraction to phytoplankton biomass (Chla) and productivity;
- Expand otolith-derived aging and microchemistry of early-stage fish species to enhance our understanding of habitat use, model parameterization, and energy allocation.

Modeling

To provide insights into biophysical processes and ecosystem trends and variability on spatiotemporal scales that cannot be realized through observational programs, we recommend the following:

- Enhance the ROMS based biophysical modeling suite while transitioning to regional MOM6;
- Validate and improve existing models using observational data from the Arctic IES;
- Assimilate observational data through targeted modeling sensitivity experiments;
- Use the modeling suite to understand mechanistic linkages within the biophysical system and align with the Synthesis, Analysis and Products listed below (e.g., quantify the transport of heat/salt, quantify drivers of nutrient flux, quantify extreme events);
- Integrate ROMS/MOM6 LTL modeling (up through zooplankton) with the AFSC Alaska Climate Integrated Modeling Project (ACLIM) that addresses marine ecosystem and fishery dynamics, and incorporates fishery economics.

Synthesis, Analysis and Products

- Quantify the transport of heat and salts;
- Quantify the physical and biological drivers of nutrient flux into the Chukchi Sea;
- Synthesize phytoplankton and zooplankton data to connect to other trophic level work including lipids in phyto- and zooplankton, fish distributions in comparison to plankton, kton, and zooplankton relation to seabird distributions;
- Conduct analysis of adult spawning stock biomass and fish egg data to determine if shifts in the distribution of species are due to increased larval transport and/or changes in spawning locations with warming;
- Conduct analyses of benthic-pelagic coupling to understand if a reorganization of the ecosystem in the northern Bering-Chukchi Seas ecosystem has occurred and what the impact will be on managed and subsistence resources;
- Develop metrics for Arctic ecosystem assessment.

Collaborations

To provide insights on the status of the Arctic ecosystem to stakeholders and the public; partnerships and collaborations must be enhanced. We recommend fostering existing collaborations identified earlier in

this report, and enhance collaborations with local communities and international partners (e.g., Canada, Russia).

New technology

To address observational gaps (e.g., seasonal transitions, phytoplankton and zooplankton speciation, under-ice production), we recommend expanded use of new and emerging technologies:

Imaging and Artificial Intelligence (AI)

- Employ phytoplankton imaging/AI on surface vehicles and moorings to derive speciation and identify and quantify species associated with Harmful Algal Blooms;
- Continue picophytoplankton counts to fill the phytoplankton size spectra and align with imaging methods;
- Monitor zooplankton communities using in-situ imaging/AI;
- Utilize towed and moored cameras with AI to assess decadal changes in the benthic community (e.g., epifauna, fish).

Platforms

- RISe (Refloating Ice Sensing) is a profiling mooring that submerges when ice arrives and refloats in the spring after ice retreat. The system includes a Prawler that moves up and down the mooring line measuring temperature, salinity, chlorophyll, and dissolved oxygen. RISe provides real-time information of the full water column during the entire open water season;
- Pop-up floats are deployed in the late summer/fall and rise to the surface under the ice the following spring. It can measure temperature, salinity, oxygen, fluorescence, PAR, and provide images on the seafloor and under ice;
- The MRV Systems ALAMO (Air Launched Autonomous Micro-Observer) is an autonomous vertically profiling float that is ice-reinforced for sampling through the winter;
- Benthic platforms (e.g., benthic rover, respirometers, microbial incubator, automated samplers) that can be used to assess shifts in the benthic community, nutrient cycling, and production;
- Optimize the use of saildrones and other uncrewed systems equipped with active acoustics to understand age -0 pelagic fish distributions and biomass (Chiodi et al., Chapter 1).

Synopsis

Why We Did it

To understand how reductions in Arctic sea ice and the associated changes in the physical environment influence the flow of energy through the lower trophic levels of the marine ecosystem in the Chukchi Sea.

What We Did

Researchers conducted Integrated Ecosystem Surveys (Arctic IES) aboard the R/V Ocean Starr (Figures 1a, 1c, 3) in late summer and early fall of 2017 and 2019. These surveys examined water properties (physics and chemistry) as well as phytoplankton and zooplankton assemblages. In addition to ship-board measurements, sub-surface moored sensors were deployed to gather biophysical information continuously from September 2016 to September 2019 including winter months when the system is ice covered. Autonomous platforms, such as gliders and saildrones, were used to complement the shipboard observations. .

What We Learned

Northward flow of water from the Bering Sea brings heat, salt and nutrients to the entire Chukchi continental shelf. The higher sea level in the Bering Sea compared to the Arctic Ocean results in a net northward transport. Approximately 40% of the flow through Bering Strait exits the shelf via Barrow Canyon. This flow on the Chukchi Sea is enhanced by northward winds and weakened by southward winds. During the last decade there has been an increase in the magnitude of northward flow on the shelf.

Phytoplankton serve as the energy source for the Arctic marine environment by converting nutrients and sunlight into a food base that ultimately sustains all marine life. In the Chukchi Sea, nitrate is a limiting nutrient for phytoplankton. Year-to-year differences in the amount of nitrate available to sustain spring production varies by about 50%. These differences result from the magnitude of transport through Bering Strait in the fall and winter, and the variability of nitrate concentration in the Bering Sea.

Changing conditions in the Arctic (e.g., warming and reduction in the duration and extent of ice) has altered the distribution, composition and food quality of phytoplankton. Shipboard observations show patchy distributions of phytoplankton and rapidly varying levels of primary productivity. Synechococcus (cyanobacteria) accounted for 20-40% of the total autotrophic biomass by the end of summer in 2019. This finding suggests that multi-year periods of warmer than average conditions altered the seasonal phytoplankton succession pattern. Phytoplankton fatty acids serve as a measure of the food quality of algae and were used to strengthen predictions of food web functioning and energy transfer to the upper trophic levels in the northern Bering and Chukchi Seas.

Particulate organic matter that falls to the sea floor, including ice algae, dead phytoplankton, and zooplankton fecal pellets, provides nutrition that sustains organisms living in that realm. For example, as ice begins to melt in spring, algae living on the underside of the ice detach and fall to the sea floor. The Chukchi Sea shelf is shallow enough that sunlight can penetrate to depth and detached ice algae can continue to photosynthesize near the seafloor.

There appears to be two distinct communities of zooplankton in the Chukchi Sea: a local, Arctic community related to water masses within the Chukchi Sea, and a community advected from the Bering

Sea. Thus, the relative magnitude of annual transport from the Bering Sea influences zooplankton community structure in the Chukchi Sea. Decreased transport and later ice retreat in colder years resulted in zooplankton communities that exhibited more diversity and had higher abundances of fat-rich copepods. In contrast, in years with increased transport from the south, expatriate zooplankton communities from the Bering Sea were prevalent in the Chukchi Sea. If the northward inflow of water into the Chukchi Sea were to increase with concomitant warming, changes in food-web structure and function are likely to result.

Similar to zooplankton, summer ichthyoplankton shifted northward. Shifts in community composition resulted from species-specific responses to temperature changes, ice cover, Bering Strait advection, and changes in the zooplankton prey base. By 2100, some bottom dwelling animals will find themselves in a habitat that is warmer than their preferred temperature range and perhaps even warmer than they can survive. These animals include prey for bottom feeding whales, pinnipeds, seals and walruses, seabirds, and benthic fishes. Snow crabs will likely benefit from warmer bottom ocean temperatures.

Why It Matters

Unprecedented warming observed during the course of the Arctic IERP program during the survey years may offer a window into the future Arctic. The biological indicators reported here suggest that increased warming could alter ecosystem structure and function with as yet unknown consequences for the people that depend on marine resources in the region.

Acknowledgements

We thank the captains, crew, and scientific staff who participated on the research expeditions conducted on the Ocean Starr and Sikuliaq. This study was funded by the North Pacific Research Board and numerous partners as outlined in the preamble. Additional funding was from NOAA PMEL and the Cooperative Institute for Climate, Ocean, & Ecosystem Studies (CIOCES) under NOAA Cooperative Agreements NA20OAR4320271 and NA15OAR4320063. This is contribution 2022-1215 to CICOES and 5330 to PMEL.

More high-quality, *in situ* observations of essential marine variables are needed over the seasonal ice zone to better understand Arctic (or Antarctic) weather, climate, and ecosystems. To better assess the potential for arrays of uncrewed surface vehicles (USVs) to provide such observations, five wind-driven and solar-powered saildrones were sailed into the Chukchi and Beaufort Seas following the 2019 seasonal retreat of sea ice. They were equipped to observe the surface oceanic and atmospheric variables required to estimate air-sea fluxes of heat, momentum and carbon dioxide. Some of these variables were made available to weather forecast centers in real time. Our objective here is to analyze the effectiveness of existing remote ice navigation products and highlight the challenges and opportunities for improving remote ice navigation strategies with USVs. We examine the sources of navigational sea-ice distribution information based on post-mission tabulation of the sea-ice conditions encountered by the vehicles. The satellite-based ice-concentration analyses consulted during the mission exhibited large disagreements when the sea ice was retreating fastest (e.g., the 10% concentration contours differed between analyses by up to ~175 km). Attempts to use saildrone observations to detect the ice edge revealed that *in situ* temperature and salinity measurements varied sufficiently in ice bands and open water that it is difficult to use these variables alone as a reliable ice-edge indicator. Devising robust strategies for remote ice zone navigation may depend on developing the capability to recognize sea ice and initiate navigational maneuvers with cameras and processing capability onboard the vehicles.

Keywords: Arctic sea ice, saildrone, USVs, satellite sea-ice concentration, remote navigation, air-sea fluxes, surface marine observations, ice navigation

INTRODUCTION

The spring/summertime retreat of Arctic sea ice exposes approximately 10^7 km^2 of the ocean surface to direct exchanges of heat, momentum and carbon dioxide (CO_2) with the atmosphere in an area referred to as the seasonal ice zone (SIZ; Steele and Ermold, 2015). Knowledge of these fluxes is necessary to understand Arctic weather, climate, and ecosystems (Danielson et al., 2020; Lu et al., 2020; Ouyang et al., 2020; Qi et al., 2020; Terhaar et al., 2020). Accurate knowledge of the fluxes and

the surface variables from which they are estimated, such as sea surface temperature (SST), surface pressure, humidity, air temperature, and wind speed and the partial pressure of carbon dioxide (pCO_2) is useful for a variety of applications, including accurate initialization and validation of numerical weather forecast models (Liu et al., 2015; Zhang et al., submitted).

Since satellite-based estimates of sea-ice extent became routinely available in the late 1970s, summertime minimum (September) Arctic ice extent has noticeably declined (Wang and Overland, 2009, 2012; Stabeno and Bell, 2019), the ice season has shortened (Wang et al., 2018; Stabeno, 2019) and Arctic surface temperatures have risen faster than global mean surface temperatures (Serreze and Francis, 2006; Danielson et al., 2020). Results from climate forecast model experiments have projected that Arctic surface temperatures will continue to rise significantly faster than the global mean (Alexander et al., 2018), partly as a result of the coupling between diminishing Arctic sea ice and its effects on the surface to atmosphere heat flux (Walsh, 2014; Kashiwase et al., 2017). Accurate knowledge of surface heat and momentum fluxes and how they change with varying sea-ice concentration is necessary for further development and verification of Earth system models.

Few high-quality, direct measurements of surface oceanic and atmospheric variables are available in the Arctic SIZ. The benefits of using automated, uncrewed sampling platforms to increase our ability to observe the SIZ has been demonstrated by several research programs (see Lee et al., 2017, and references therein). Recent SIZ sampling strategies include deploying instrumentation on or in the ice (e.g., Polashenski et al., 2011; Timmermans et al., 2014; Gallaher et al., 2017), or on autonomous underwater vehicles and open water platforms, such as moored-buoys and wave gliders (Wood et al., 2013). Surface drifters (e.g., Thomson, 2012; Banzon et al., 2020) capable of measuring environmental parameters such as air and water temperature and wind speed, have also been deployed in open water and partial ice cover. Uncrewed surface vehicles (USVs) that can navigate from open water through ice zones, while collecting the observations needed to estimate (Bourassa et al., 2013) surface fluxes, would add a key component to our existing high-latitude observing capability. In summer 2019, a collaboration between NOAA, University of Washington and NASA investigators led to the deployment of five USVs, saildrones, with the objective of collecting such observations and providing a subset of them to forecast centers in real time. Saildrones are wind-driven, solar-powered and outfitted for this mission to measure near-surface wind speed and direction, humidity, air temperature and barometric pressure, upper ocean currents, SST, sea surface salinity (SSS), downward longwave and shortwave radiation, and pCO_2, among other variables (Cokelet et al., 2015; Meinig et al., 2015; Mordy et al., 2017; Zhang et al., 2019). A main mission objective was to measure these quantities in the SIZ up to the ice edge. Other objectives of the mission included collecting *in situ* observations for improving calibration of satellite-based measurements of SST in polar waters, occupying four Distributed Biological Observatory lines (Grebmeier et al., 2019), performing pCO_2 sensor cross-calibration tests with instrumentation aboard the USCGC Healy, ocean current surveys of Hanna Shoal, the Chukchi Shelf Current and the Alaskan Coastal Current (c.f. Li et al., 2019) and collecting data for surface flux estimates over Chukchi Sea regions being sampled simultaneously by Air Launched Autonomous Micro-Observer (ALAMO) profiling floats (Jayne and Bogue, 2017) and Beaufort Sea regions being sampled simultaneously by Seagliders (Eriksen et al., 2001) deployed during the Stratified Ocean Dynamics in the Arctic (SODA) experiment (Lee et al., 2016).

The saildrones were launched from Unalaska, AK, United States, in early May 2019, and sailed northward through Bering Strait in early June 2019. In order to successfully complete the mission, they would need to navigate through the SIZ and return to Unalaska before the combination of the energy stored in the vehicle's batteries and availability of solar power diminished below levels necessary to sustain vital communication, navigation and sensor functionality. Navigational information such as vehicle speed over ground and heading was relayed to the navigational team, with typically a few to several minutes delay. Four cameras mounted on the wing also provided images, which took ~30 min to be transmitted. These photos provided three perspectives: (i) upward-looking views of the sky; (ii) downward views of the vehicle hull and surrounding environs (e.g., **Figure 1A**); and (iii) horizontal views fore and aft of the wing (e.g., **Figure 1B**). The downward-looking photos in particular provided clear confirmation of times when the vehicles were in contact with or immediately next to sea ice.

Modern ice-navigation strategies for ships (e.g., Stoddard et al., 2016; Transport Canada, 2018) pair information about ship structure and capability (e.g., IACS, 2016) with estimates of ice concentration and type to assess risks along a route. Navigation-relevant ice information is available from a variety of sources offering different spatial resolutions and collection intervals (e.g., Hui et al., 2017; Rainville et al., 2020). Satellite information available presently includes passive microwave estimates of ice concentration, optical imagery and synthetic aperture radar (SAR) imagery. SAR offers the advantages of all-weather capability and relatively high spatial resolution compared to passive microwave data (e.g., Zakhvatkina et al., 2017 evaluate ice-water classification from Radarsat-2 ScanSAR images with 50 m × 50 m pixel spacing; see also Bertoia et al., 2004; Hui et al., 2017). The general use of individual wide-swath and relatively high-resolution SAR images, however, is limited by the large proportion of them that are not publicly available (Zakhvatkina et al., 2019). Several national ice centers synthesize ice distribution information from multiple sources and expert analysis to produce weekly to bi-weekly ice charts for strategic planning. The "tactical," or most direct navigational utility of ice-distribution information is usually limited to <24 h from the time it was collected (Scheuchl et al., 2004; Rainville et al., 2020).

The suite of remotely produced ice information potentially available for a USV mission such as ours is basically the same as

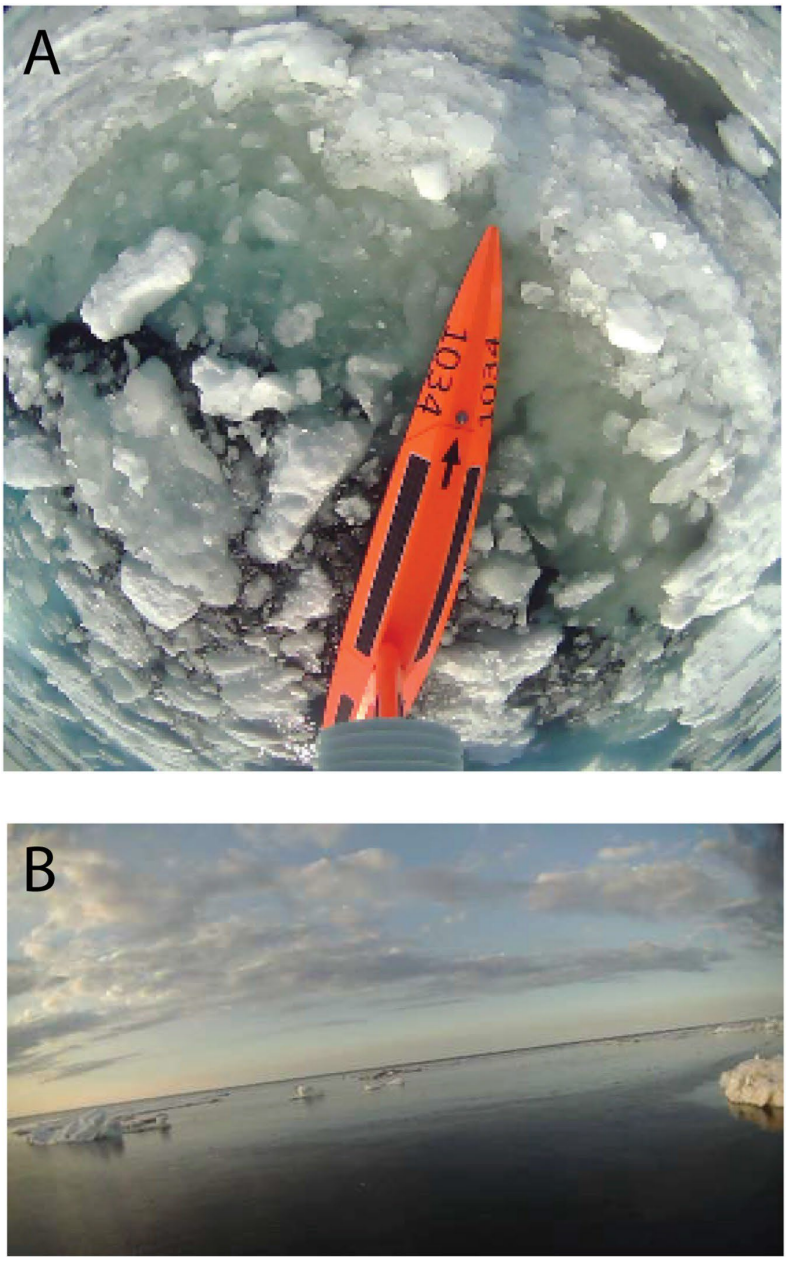

FIGURE 1 | Examples of (A) downward-looking image taken atop the saildrone wing while in sea ice, and (B) horizontal image from the saildrone wing with sea ice floes visible.

for ships. The questions asked of the ice information, however, may be somewhat different in each case. For example, Canadian Arctic experience has shown that sufficiently powered, ice-strengthened ships can make progress through first-year ice in concentrations up to 7/10ths without assistance from an icebreaker (Ice Navigation in Canadian Waters, 2012). Thus, navigating a Polar Class 6 or 7 ship (IACS, 2016) requires, particularly, information about where the ice distribution exceeds these criteria (c.f. Smith and Stephensen, 2013). Saildrones are not specifically designed to withstand collision with or push through sea ice, substantially limiting the range of ice conditions safely navigable compared to ice-strengthened ships. Most ships should also be able to "steer at slow speed around the floes in open pack ice [<6/10ths ice] without coming into contact with very many of them" (Ice Navigation in Canadian Waters, 2012). The capability to steer through floes is perhaps what most clearly distinguishes ship navigation from the situation faced by the USVs on our mission.

Saildrones navigate primarily by controlling the angle of the rudder and the vertically oriented, rigid wing, which

functions in roughly the manner of a mainsail on a traditional sailboat. They automatically navigate from waypoint to waypoint, accounting for wind and currents, while remaining within a specified corridor. The waypoints were decided by scientists and uploaded to the vehicles by Saildrone, Inc. pilots. The saildrones were not equipped during this mission with an automated capability to avoid collision; if their uploaded route intersected a floe, the vehicles would contact the floe unless re-routed by the pilot. In order for the objectives of this mission to be accomplished, the vehicles needed to repeatedly navigate in close proximity to sea ice. Several different types of information were considered or referred to during the mission to help with this navigational challenge. These sources included daily gridded satellite estimates of sea-ice concentration over the study region, natural color (optical) images of the surface provided by satellite radiometric measurements, SAR imagery and the daily 10% sea-ice concentration contour produced via multisensor analysis at the US National Ice Center (NIC). Information collected aboard the vehicles such as near-surface ocean temperature and salinity and the images from the vehicles' wings were also used.

The vehicle images and navigational metrics such as speed-over-ground provide a *de facto* record of when the vehicles were embedded in or in close proximity to ice floes. Here, we examine the relationships between this *de facto* record and the other (potential) sources of sea-ice distribution information that were considered or used while remotely navigating these five saildrones through the SIZ of the Chukchi and Beaufort Seas during May–October 2019. Our focus here is on products available publicly at daily, or higher, frequency and the observations and images collected by the USVs. Our objective in this article is to highlight both the challenges and strategies for improving remote ice navigation with USVs. Results may thereby provide a step forward for our wider objectives of understanding what sort of USV array is needed to monitor the Arctic (or Antarctic) SIZ in support of initializing and assessing the skill of operational numerical weather prediction systems and climate models, and validating numerical and satellite estimates of Arctic surface fluxes.

MATERIALS AND METHODS

In situ Observations

The saildrones deployed on this mission were part of a collaboration between Saildrone, Inc.[1] and the National Oceanographic and Atmospheric Administration (NOAA) Pacific Marine Environmental Laboratory (PMEL; Meinig et al., 2019) through a Cooperative Research and Development Agreement. Saildrones have ~ 7 m long hulls, rigid-wing heights 5 m above the water line, and keel depths of 2.5 m. The saildrone routes were coordinated with members of Alaska's North Slope and Northwest Arctic Boroughs and communicated through the United States Coast Guard Notice to Mariners to avoid potential interference with other uses of the Alaskan waterways. The vehicles' progress was monitored remotely by scientific and engineering team members. Batteries and solar panels power the onboard navigational electronics, which included automated identification system transceivers and Global Positioning System (GPS) navigational systems, as well as scientific instrumentation and satellite telemetry of data and navigational instructions. We designated the five saildrones deployed on this mission *sd-1033, sd-1034, sd-1035, sd-1036, and sd-1037*. Each was equipped with the following sensors: a Rototronic HC2-S3 sensor at 2.3 m height measured air temperature and relative humidity; a Sea-Bird SBE37 Microcat at 0.5 m depth measured seawater conductivity and temperature, which together provide seawater salinity; a Vaisala PTB210 Barometer on the hull (0.2 m height) measured sea level pressure; and a Gill model 1590-PK-020 anemometer atop the wing (5.2 m height) provided three dimensional wind velocity at 10 Hz. These wind measurements, along with synchronous measurements from the onboard inertial measurement unit (VectorNav model VN-300) and GPS, allowed for geo-referenced wind velocity to be calculated onboard and telemetered to the Global Telecommunications System and onshore data repositories as 1-min averages (as described in more detail in Zhang et al., 2019). The higher frequency data were stored onboard for access upon vehicle recovery. Zhang et al. (2019) reported that the auto-corrected saildrone wind speeds measured as a part of the Tropical Pacific Observing System – 2020 pilot study had RMS differences of 0.6 m s^{-1} with respect to the benchmark observations collected on the Salinity Processes in the Upper ocean Regional Study 2 (SPURS-2) buoy. This was based on hourly averages collected while the saildrones were within 12 km of the buoy, during which time the buoy measured a mean speed of 4.2 m s^{-1}, standard deviation of 1.9 m s^{-1} and maximum (minimum) wind speed of ~9.2 (0.2) m s^{-1}. A saildrone's speed over ground is dependent upon wind velocity, ocean current velocity, and navigation. Over the course of this Arctic mission, the vehicles measured an average wind speed of 5.4 m s^{-1}, and their average speed, with respect to the Earth's surface, excluding the times in which they were embedded in or left to drift with sea ice, was 0.96 m s^{-1}, or ~18% of wind speed. The maximum hourly averaged vehicle speed recorded during this mission was 2.9 m s^{-1} at an hourly mean wind speed of 12 m s^{-1} (sd-1035 on 19 July 2019). Sd-1033 and sd-1034 were equipped with Autonomous Surface Vehicle CO2 (ASVCO2; Sutton et al., 2014; Sabine et al., 2020) sensors capable of measuring pCO_2 in both the air and water. Along with wind speed, this pCO_2 information provided the basis for estimating the air-sea flux of carbon dioxide. ASVCO2 systems have been described and evaluated previously by Sabine et al. (2020) and found to provide pCO_2 observations within ±2 μatm of shipboard systems and moored autonomous pCO_2 systems. Sd-1033 and sd-1034 also had instruments capable of measuring solar irradiance, longwave radiation, ocean skin temperature (experimental), ocean color (Chl-a, CDOM), dissolved oxygen, pH and ocean current speed and direction (acoustic Doppler current profilers).

All of these saildrones, except sd-1037, were deployed with cameras mounted on their wings that provided three perspectives: (i) upward-looking views of the sky; (ii) downward views of the vehicle hull and surrounding environs (e.g.,

[1]saildrone.com

Figure 1A); and (iii) horizontal views fore and aft of the wing (e.g., **Figure 1B**). The saildrones sent back images every 5 to 60 min over most of the mission, but cameras were turned off during later stages of the mission to conserve power. The cameras on sd-1035 and sd-1036 collected images at a resolution of 1920 × 1080 pixels. The camera on sd-1034 was lower resolution (500 × 279).

The Saildrone-derived data used in this paper are hosted at PMEL by its Science Data Integration Group. These data are received from Saildrone during the mission and also as a bulk data acceptance post-mission. Data were delivered from Saildrone as discrete sampling geometry NetCDF files that included comprehensive documentation of the observations, including the standard and long names of the observed variables, their units, latitude, longitude and time of collection, as well as the name, vendor, serial number, installation height on the vehicle, installation date, date of last calibration, and sampling schedule of the sensor, among other information. During the mission, data files containing 1 min observations were delivered twice per hour, while high resolution (10 Hz and 1 Hz) data were delivered post-mission.

A subset of the 1-min observations received in near-real time were disseminated on the World Meteorological Organization (WMO) Global Telecommunication Service (GTS). The GTS is an operational network maintained by the WMO for the near-real time dissemination of environmental observations to be used in operational forecasting by global weather services. From this mission, an observation every 10 min was uploaded onto the GTS using the Global Ocean Observing System Observations Coordination Group developed Open Access to GTS framework, in partnership with PMEL and the NOAA National Data Buoy Center. This framework was developed to ease the process of globally distributing data in near-real time on the GTS for data producers such as Saildrone, Inc.

A saildrone (sd-1023) on a previous hydroacoustic survey in the Chukchi Sea (Levine et al., 2020) had a brief encounter with sea ice on 7 August 2018 at 71.5°N, 162°W. We analyzed its position, measurements and photographs with regard to various sea-ice products to obtain a preliminary evaluation of what information might be useful for guiding saildrones in sea ice.

To facilitate comparison between the *in situ* saildrone conditions and other potential sources of sea ice information, we define two *in situ* sea ice-related quantities. The first is called the "*In Situ* Sea Ice (ISSI)" record and is defined as 1 over the periods during which ice was visible in the downward or horizontal saildrone images and 0 when ice was not visible in the saildrone images. We use the term "ice free" in reference to the saildrone images. The resulting time series facilitates examination of the distributions of SST, salinity, and other observations collected while ice was or was not visible in the saildrone images. The second quantity is called "Ice-Blocked Vehicle (IBV)" and keys on the points at which the saildrones were blocked by ice on transects beginning in ice free water. Blockage points were determined based on un-commanded drops in vehicle speed-over-ground and inspection of saildrone images (discussed in more detail in the "Results" section). Knowing these ice-blockage points allows us to tabulate information about the changes in SST and salinity observed while approaching ice floes from open water. We use 3 h as the approach period based on preliminary examination showing that 3 h is long enough to capture some ice-free observations and the maximum negative SST and temperature gradients observed *en route* to the ice, yet short enough that ice-free measurements do not overly dominate the analysis and the vehicle route segments prior to IBVs did not, typically, include substantial changes in direction (e.g., change in USV heading of ~180°).

Satellite Information

The European organization for the exploitation of satellite measurements (EUMETSAT) offers daily gridded sea-ice concentration estimates based on radiances measured by the satellite-born Advanced Scanning Microwave Radiometer (AMSR-2). Hereafter, we refer to EUMETSAT's daily AMSR-2 ice concentration product as EA2. EA2 daily estimates are available starting in September 2016 on a 10 km horizontal resolution polar stereographic grid. Daily EA2 updates were typically available to us in the early local morning hours (Pacific Daylight Time = Universal Coordinated Time – 7 h) and were considered for use in route planning during the mission. The relationship between the EA2 values interpolated to the vehicles' positions and the *in situ* conditions encountered by the vehicles is further examined herein. To facilitate this examination, interpolated EA2 estimates have been binned at 1% concentration intervals with the first bin (labeled 0%) containing all 0% concentration estimates, the second, 1%, containing concentrations >0% and ≤1%, the third, 2%, containing concentrations >1% and ≤2%, and so forth. Herein, we calculate the ice extent of our study region as the area of EA2 grid cells within the region bounded by 145°W–180°W and 66°N–80°N with >10% ice concentration, in keeping with the definition used by the NIC. Lavelle et al. (2016) evaluated EA2 concentrations in reference to weekly ice charts produced by the NIC. This comparison was done on a grid point-by-grid point basis and found that the spatially aggregated percentage of Northern Hemisphere grid points with concentrations within 10% of one another was between 90 and 95% during their 1 January – 31 December 2015 analysis period, with the exception of mid-June through August when this percentage fell below 90% and reached a minimum of ~83% in mid-July. Lavelle et al. (2016) suggest summertime melt caused this drop in weekly ice-chart versus EA2 concentration agreement (c.f. Markus and Dokken, 2002).

A daily analysis of sea-ice information, based on multiple sources of near real-time satellite data, derived satellite products, buoy data, and other weather data was provided to us upon request by the NIC. A main component of this analysis was its ice edge, which is nominally defined as the 10% sea-ice concentration contour. The NIC 10% concentration contour is produced by NIC analysts with the aid of several types of satellite imagery, including Advanced Very High Resolution Radiometer, Special Sensor Microwave Imager, Moderate Resolution Imaging Spectroradiometer (MODIS), Visible Infrared Imaging Radiometer Suite (VIIRS) and SAR (e.g., Lavelle et al., 2016). The latitude and longitude points comprising the daily NIC ice-edge contour are freely available to the public

(U.S. National Ice Center, 2020). The NIC ice edge was consulted during mission days with an ice-navigation component, which included the majority of days when at least one vehicle was north of Bering Strait (5 June 2019 – 28 September 2019).

We occasionally requested extended analysis from NIC when the Radarsat-2 SAR images available to them (c.f. Bertoia et al., 2004) covered the saildrone positions. Radarsat-2 return periods from <1 to 3 days are typical for Chukchi and Beaufort Sea locations [interested readers can freely view reduced-resolution Radarsat-2 images on the European Space Agency Earth Observation Portal[2] as well as the SODA situational awareness data archive[3] (Rainville et al., 2020)]. High-resolution Radarsat-2 imagery, however, is not freely available to the public. The enhanced assistance received from NIC confirmed that the ability to geo-locate USVs on full-resolution SAR imagery within the tactical window (Scheuchl et al., 2004 suggests this to be <6 h) is a critical tool for remote ice navigation.

Satellite imagery from the European Space Agency Sentinel-1 SAR and Sentinel-2 MultiSpectral Instrument (MSI) missions is made freely available from the Sentinel Hub EO Browser[4] and was used during the mission. Sentinel-2 consists of a pair of satellites with MSIs measuring 13 spectral bands in the 443–2203 nm range with 10–60 m horizontal resolution (König et al., 2019). The return period for Sentinel-2 MSI images in the Chukchi and Beaufort Seas was up to 1 per day. Use of MSI imagery for ice detection, however, requires clear sky conditions. Sentinel-1 SAR provides all-weather capability (e.g., Nagler et al., 2015; Karvonen, 2017). Based on the EO Browser repository, however, the Sentinel-1 return period for a specific location in our study area was up to 12 days.

The natural color images made available at the NASA Worldview website[5], offered useful information about ice distribution, provided the local cloud cover was sufficiently sparse. Images are available on a daily basis from this site based on measurements collected by pairs of VIIRS and MODIS instruments aboard four different satellites, with a different image layer for each combination and a nominal horizontal resolution of 250 m. Because the cloud patterns tended to shift more than the ice between the different satellite overpasses during a given day, having multiple sensor-layers (e.g., the MODIS image from the Aqua v. Terra satellite) was sometimes useful for distinguishing sea ice from cloud.

RESULTS

Daily Gridded Sea-Ice Concentration From AMSR Measurements

Illustrations of the EA2 gridded sea-ice concentration estimates are shown in **Figures 2**, **3** on the days of the first and final ice encounter (ISSI and IBV) of the mission, i.e., 14 June 2019 and 23 August 2019, respectively. In these two cases, saildrones encountered sea ice near the NIC 10% concentration lines; however, other ice encounters occurred in a wide range of sea-ice concentrations.

Based on EA2, ice extent over the study region bounded by 180°–145°W and 66°N–80°N was ~10×10^5 km^2 at the start of the mission on 15 May 2019 (**Figure 4**). The vehicles encountered ice during different phases of the ice retreat over this region. A moderately paced decline of -0.92×10^5 km^2/month was observed in June 2019 based on a linear fit to the EA2 concentration estimates. A more rapid decline was seen in July and early August (-3.8×10^5 km^2/month). The pace of the decline in regional ice extent then slowed in mid to late August, during which time ice extent hovered near 2×10^5 km^2. The study area minimum ice extent of 1.28×10^5 km^2 occurred on 15 September 2019. Comparison reveals that the study region experienced an earlier decline in ice cover in 2019 relative to the previous two summers over which EA2 data are available (**Figure 4**). On 28 July 2019, study-region ice extent reached 5×10^5 km^2, a level not reached until 2 August in 2017 and 16 August in 2018. The return of ice to the study region in 2019 was also slower than in the previous 2 years: In 2017 and 2018 ice extent had risen to 5.6 and 6.2×10^5 km^2, respectively, by the end of October but was still at 2.4×10^5 km^2 at the end of October 2019, based on EA2.

The distribution of EA2 sea-ice concentration at the locations of sd-1034, sd-1035 and sd-1036 is shown in **Figure 5**. Based on EA2, these three vehicles collected observations in sea-ice concentrations from 0 to slightly over 20%. The most common EA2 estimate was for 0% concentration at the vehicles' locations (59%). Three percent of the observations have an EA2 estimate of 10% concentration or greater. A secondary maximum occurs at ~16% sea-ice concentration.

For the subset of observations taken while sea ice was visible in the saildrone images, the most common EA2 estimate at the vehicle locations was still 0% sea-ice concentration. A secondary maximum spans 3% and 4% ice concentration, each with ~36 h of saildrone observations (inset of **Figure 5**). There were 8.3 h of observations collected with sea ice visible in the saildrone images and an EA2 estimate of 15% sea-ice concentration. The saildrones encountered ice 1.5% of the time their EA2 concentrations were 0%, 5.8% of the time their EA2 concentrations were 1–10% and 4.1% of the total time they spent in EA2 concentrations >10%, although no sea ice was evident in the vehicle images when the EA2 estimates were >15%.

Ice Edge Information From the U.S. National Ice Center

The EA2 and NIC 10% contours did not always agree, as for example shown in **Figures 2**, **3**. We quantified the uncertainty between these two estimates of the 10% sea-ice concentration edge by calculating the minimum distance between each point on the NIC contour and any point on the EA2 contour, as well as calculating the minimum distance between each point on the EA2 contour and any point on the NIC contour. This calculation was performed in both directions because the ice edge geometry was often sufficiently complex that doing it in

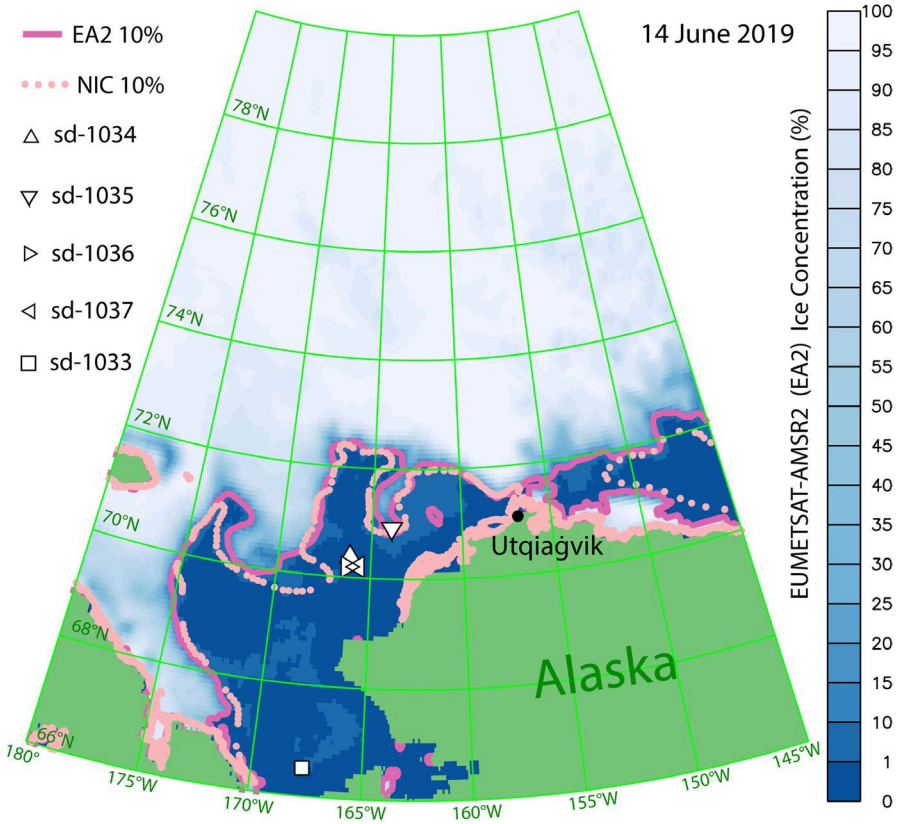

FIGURE 2 | The Eumetsat-AMSR2 (EA2) estimate of sea-ice concentration (blue-white hues) and 10% ice contour (solid purple curve) along with the NIC 'ice edge' 10% contour (pink dotted curve) and locations of saildrones sd-1033 (square), sd-1034, sd-1035, sd-1036, and sd-1037 (triangles) on 14 June 2019, the date of the mission's first ice encounter (sd-1035).

only one direction led to an incomplete estimate of distance. We did this for all points on the 10% contours within our study region (**Figures 2**, **3**) and over water; but not along the coast. The results of averaging these contour-separation distances over each day of the mission (**Figure 6**) reveal that mean minimum-separation distances varied by almost a factor of 20 during the mission, with lows of ~ 10 km in early June, late September and early October and highs near 175 km in August. The mean minimum distance between the EA2 and NIC 10% ice contours was greatest when the sea-ice coverage was declining rapidly (early to mid-August) and hovering (late-August) approximately 50% above the eventual minimum (c.f. **Figures 4**, **6**). Because the NIC 10% contour may be overestimating the extent of ice (see U.S. National Ice Center, 2020, p. 9 and **Figure 7**) we looked for better EA2 versus NIC agreement using 8% and 5% contours from EA2. The **Figure 6** results, however, remained qualitatively and quantitatively similar using these lower concentration EA2 contours. For example, the minimum, maximum and mean of Line C in **Figure 6** changed by ≤7% (see **Supplementary Figure 1**).

Figure 7 shows the number of hours that the saildrones with cameras (sd-1034, sd-1035, and sd-1036) were within a given distance of the NIC 10% ice edge between 5 June when they entered Bering Strait and the end of September when they turned south. Overall, ~40% of this time was spent within 40 km of the NIC ice edge; further, 18% of the period was spent in waters with >10% ice concentration according to NIC. Did the saildrone cameras agree with these NIC ice estimates? The answer is mostly yes; nearly all camera images that showed ice were for vehicles in >10% ice concentration according to NIC and ice free conditions were encountered 99.7% of the time the saildrones were in <10% concentration according to NIC. However, 80% of the images taken while the vehicles were in ≥10% ice concentration according to NIC showed no ice. The results confirm that the NIC ice edge corresponds to the boundary beyond which ice may affect vehicle navigation, although the NIC ice edge might be overestimating the extent of ice.

Satellite Imagery

The Terra/MODIS image shown in **Figure 8A** depicts a zonal ice band that was targeted for exploration on 13 July 2019, with the fleet 130 km to its south. Unfortunately, another clear image did not become available before the fleet contacted sea ice near this location in the first hour (UTC) of 18 July 2019, 5 days later (**Figures 8B–F**). Thus, waypoints estimated at the ice edge based on the 13 July 2019 image, but used for ice navigation on 18 July 2019, did not account for the distances that the targeted ice band might have moved, dispersed or otherwise changed shape over

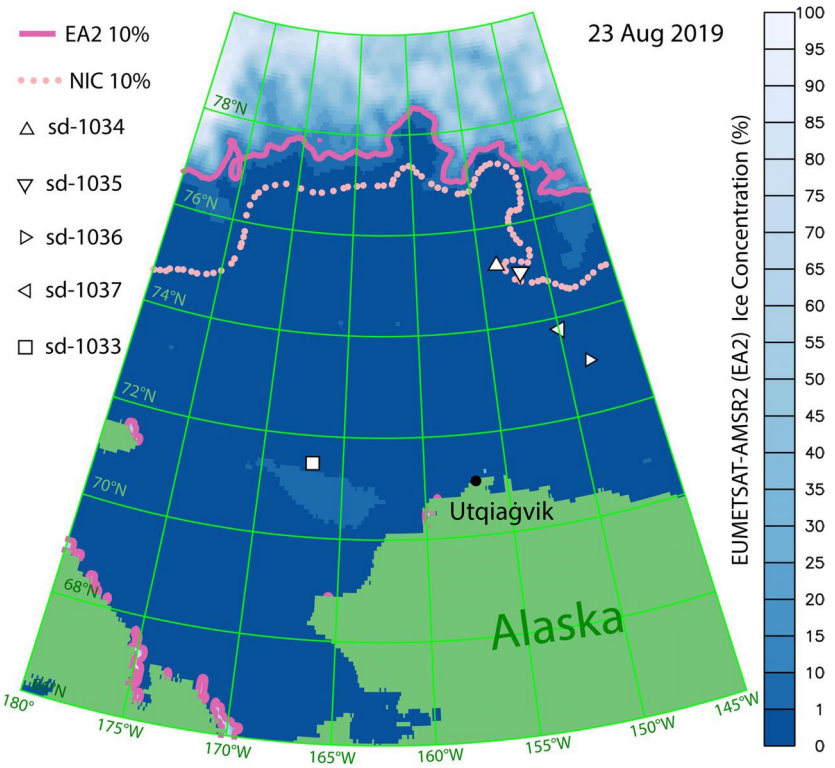

FIGURE 3 | The Eumetsat-AMSR2 (EA2) estimate of ice concentration (blue-white hues) and 10% ice contour (solid purple curve) along with the NIC 'ice edge' 10% contour (pink dotted curve) and locations of saildrones sd-1033 (square), sd-1034, sd-1035, sd-1036, and sd-1037 (triangles) on 23 August 2019, the date of the mission's last ice encounter (sd-1035).

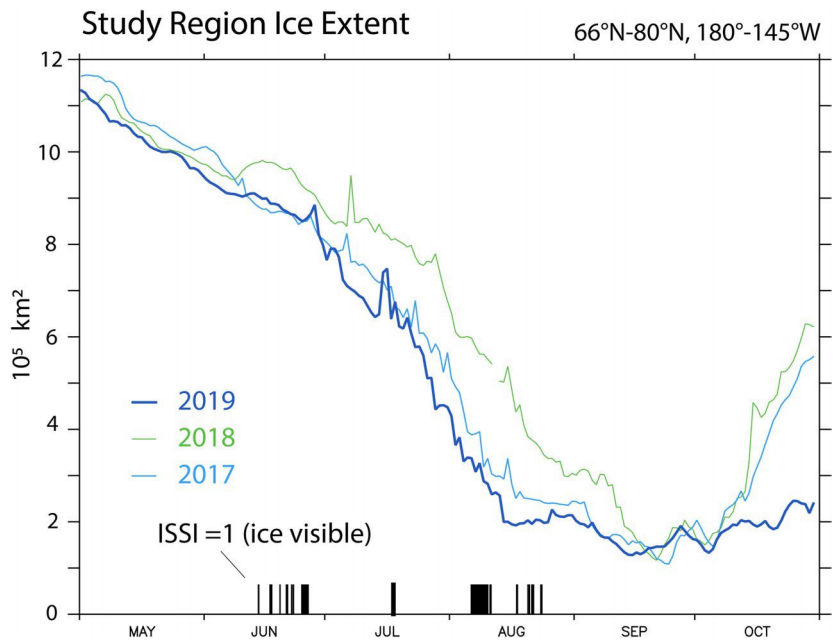

FIGURE 4 | Sea ice extent over the Chukchi and Beaufort Sea study region (180◦–145◦W, 66◦–80◦N) from the AMSR2 based ice concentration estimate provided by the EUMETSAT ocean and sea ice satellite application facility. Vertical lines on the time axis mark times when ISSI = 1, that is, sea ice was visible in either the horizontal or downward saildrone images. ISSI = 0 (images were ice-free) during all other times, which are not marked by vertical lines.

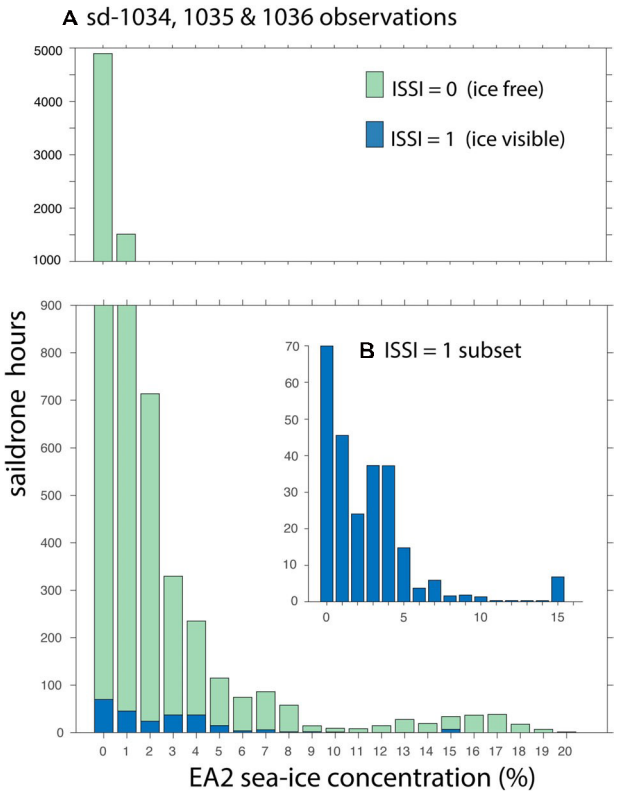

FIGURE 5 | (A) Histogram showing the number of hours saildrones spent in different EA2 sea-ice concentration levels. Data are from sd-1034, sd-1035, and sd-1036 and binned in 1% intervals over the period 5 June 2019 – 30 September 2019. (B) The inset histogram highlights the subset of observations collected when ISSI = 1, meaning sea ice was visible in the images taken from the saildrones.

these 5 days. As it turned out, sd-1034, sd-1036, and sd-1037 encountered sea ice on 18 July 2019 1 to 4 km north of where the southern ice edge was on 13 July 2019.

Visual inspection of the sequence of daily Terra/MODIS images revealed that mostly clear sky conditions, such as seen in **Figure 8A**, occurred over this location on about 70% of the days in June 2019, but only about 20% of the days in July 2019 and even fewer days in August. Such unobstructed images of the surface were useful for ice zone navigation when available. However, they could not be consistently relied upon throughout the mission because of cloud cover.

When cloud cover was sufficiently sparse, Sentinel-2 offered relatively high-resolution images (10–60 m), often ~24 h apart. Example clear-sky images encompassing sd-1034's route on 18 and 19 June 2019 are offered in **Supplementary Figure 2**. At the sensing time of the first image (18 June 2019 22:46), sd-1034 was 9 km south of a sparse band of ice extending east from the southern tip of denser pack ice (upper-left corner of **Supplementary Figure 2A**). By the sensing time of the second image (19 June 2019 23:06), sd-1034 had traveled ~18 km to the northeast and was ~1.5 km east of the dense pack ice. In between these two images, sd-1034 became embedded in ice (vehicle images collected at 19:00 UTC confirm ice in the downward view) and then freed itself around 22:15 UTC by sailing east into open water. This episode served as a reminder that the effective navigational resolution of satellite ice imagery is a function of the spatial resolution of the image, the speed of the vehicle, and the distance that the ice moves after the image is available. The ice moved ~10 km in this case.

A few days prior, at ~09:00 on 17 June 2019, sd-1036 and sd-1037's routes intersected an ice floe visible in the Sentinel-2 image collected at 22:56 on 16 June 2019 (see **Supplementary Figure 3A**). Sd-1036 was able to resume open water sailing within a few hours, but sd-1037 remained blocked by ice until 21 June 2019. Another clear-sky Sentinel-2 image was available on 19 June 2019 (**Supplementary Figure 3B**; collection time 23:05) that indicated sd-1037 was still encumbered in the same flow. While encumbered during these 4 days (17–21 June 2019), sd-1037's average speed-over-ground was 0.15 m s^{-1} and it moved 35 km to the east-northeast (67°).

The Sentinel-1 SAR offered a view of the saildrone study area on 22 June 2019 (**Supplementary Figure 4**). Such images, which offered a chance to detect ice even in cloudy conditions, were useful when available. However, the next Sentinel-1 swath covering the saildrone positions shown in **Supplementary Figure 4** was not available until 12 days later, on 4 July 2019.

Saildrone Photos

The vehicle images taken during the approach to the ice band described above, which was oriented roughly zonally along 73°N in mid-July, exemplifies their potential for navigational use. **Figure 9** shows the images collected at a 5 min interval by sd-1036, while en route to the ice. There are light hues on the horizon (**Figure 9A**) in the transmitted image taken at 00:23 UTC on 18 July 2019 that can be confirmed as sea ice from the following images. At 00:23 UTC, sd-1036 was heading north at 0.41 m s^{-1} and was ~1 km away from its northernmost point on this transect. Five minutes later, a similar image was telemetered with the vehicle ~700 m away from its northernmost point (**Figure 9B**). At 350 m out, the image taken at 00:33 UTC (**Figure 9C**) offers a more distinct view of ice along the horizon. Without this, the previous images could have easily been mistaken for reflections associated with cloud breaks. Sea ice is clearly recognizable below the horizon at 00:38 UTC with the vehicle 50 m out, still heading north at 0.57 m s^{-1} (**Figure 9D**). Five minutes later, sd-1036's northward progress was blocked by sea ice (**Figure 9E**). The time between an image being taken and its availability for viewing on shore was 30–40 min. If remote transmission and processing times were short enough (say, 1 min), vehicle instructions could be tailored based on images like those in **Figures 9C,D** to avoid sailing directly into sea ice. Alternatively, automated decision-making aboard a vehicle (e.g., Jin et al., 2020) might be able to avoid a sea-ice collision. In practice, the delay associated with being able to view the transmitted photos was long enough that the vehicles usually were impeded by the sea ice before a transmitted image revealed it. Vehicle speed and direction information was sent separately and faster than the images so that it was available within a few minutes. Early indications that the saildrones had encountered

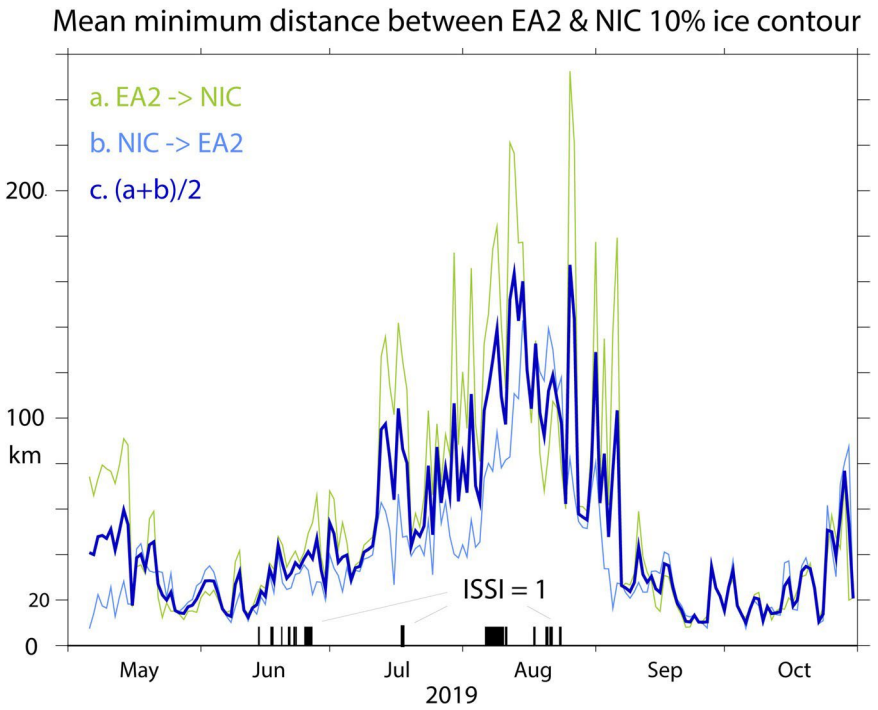

FIGURE 6 | Mean minimum-distances between the 10% ice concentration contour based on the NIC analysis and EA2 data. Vertical lines on the time axis mark times when ISSI = 1. ISSI = 0 during times unmarked by such vertical lines.

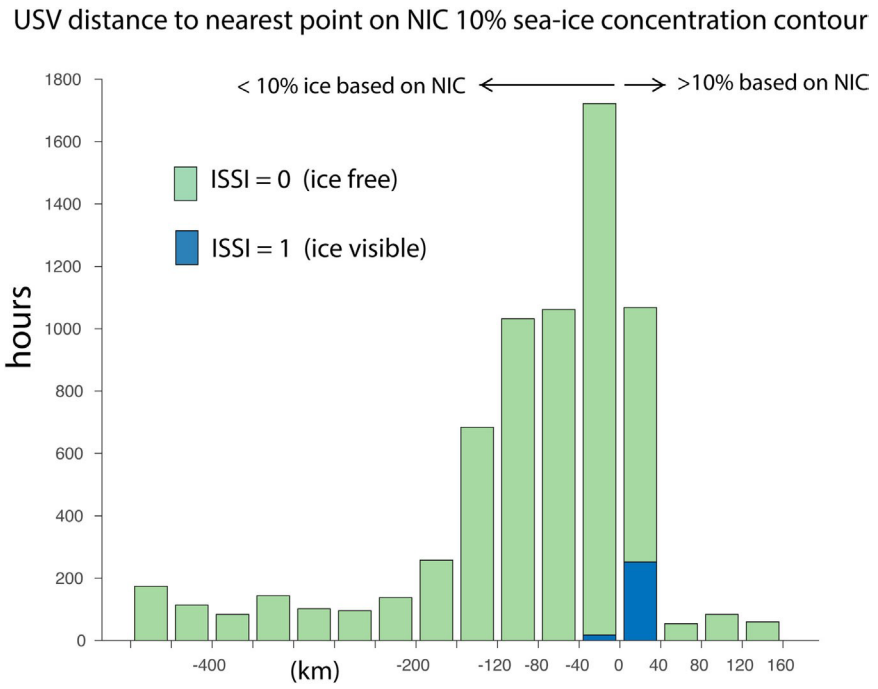

FIGURE 7 | Histogram showing the number of hours that saildrones with cameras (sd-1034, sd-1035, and sd-1036) spent at various distances to the NIC 10% sea-ice concentration contour. Results shown were calculated based on 6-h intervals over the period bounded by their northward transit of Bering Strait on 5 June 2019 through the end of September. The portion of the distribution with sea ice visible from the onboard horizontal or downward photos (ISSI = 1) is shown in blue.

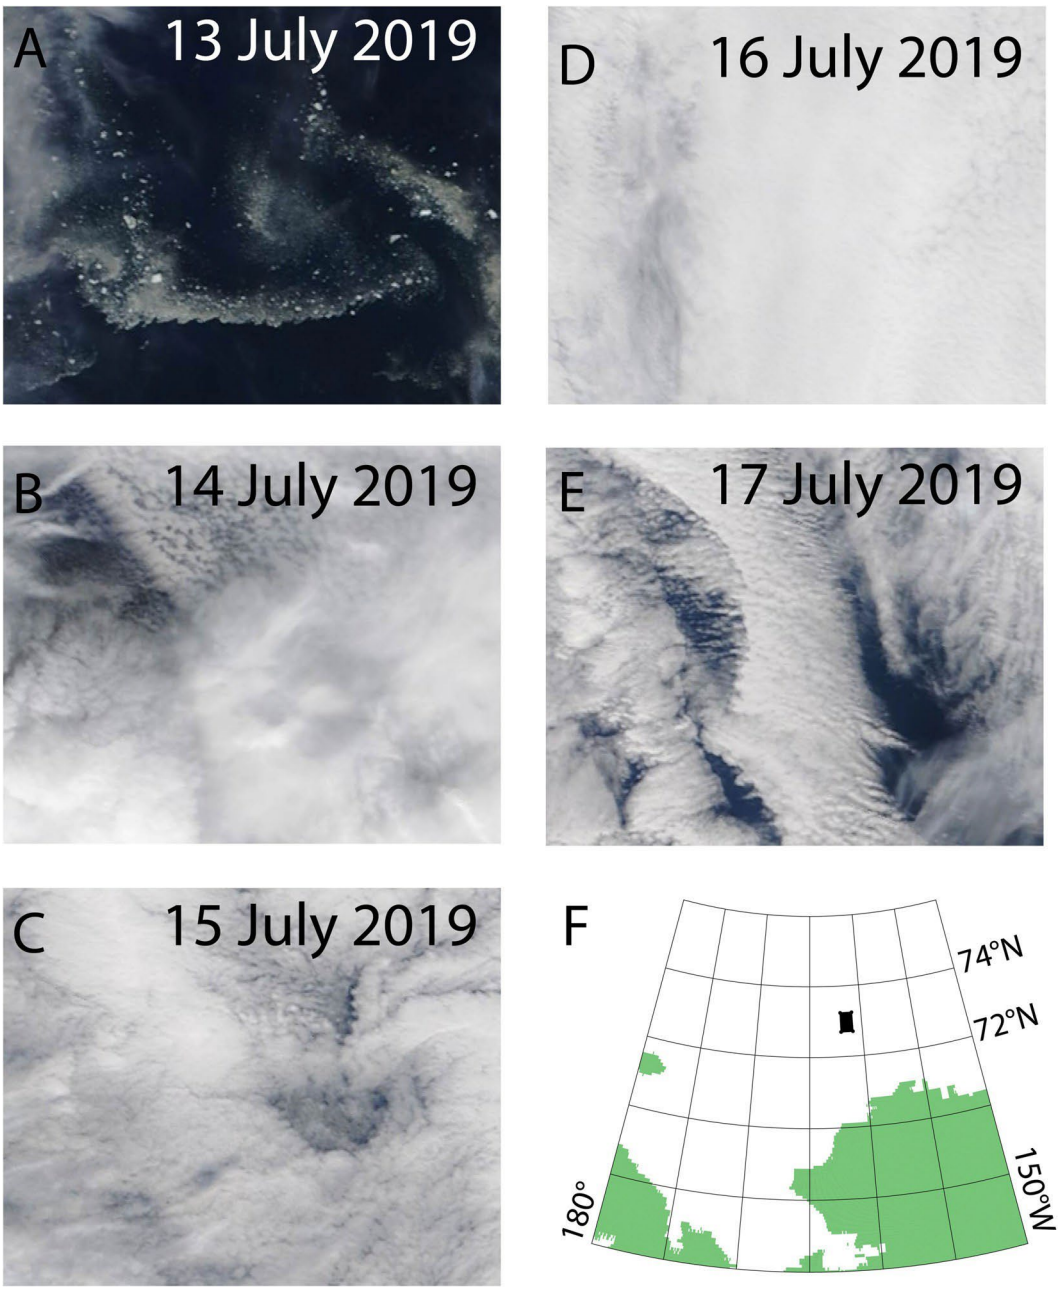

FIGURE 8 | Daily "natural color" images from the MODIS instrument aboard the Terra satellite. These images are centered at 161.46W, 72.97N and span approximately 60 km meridionally (vertical) and 18 km zonally (horizontal). The ice edge visible in panel (A) was targeted for exploration on 13 July 2019, but skies remained cloudy from 14 July through contact with the remnants of the band in the first hour (UTC) of 18 July panels (B–E). The black rectangle in panel (F) shows the location of the images.

sea ice usually included an unanticipated sudden drop in speed and a possible change in direction.

Surface Marine Observations From the Saildrones

Sea ice is known to affect the properties of the seawater around it (e.g., Gallaher et al., 2016; Dewey et al., 2017; Brenner et al., 2020). If the surface marine variables observed in close range of sea ice (say, while ice was visible in the horizontal photos from the vehicles) proved sufficiently distinct from those measured in ice-free water, then they might offer a navigationally useful indicator for the proximity of sea ice. For example, if seawater temperature and salinity falling below a certain level proved to be a sufficiently distinct characteristic of the presence of sea ice, measurements approaching those levels might

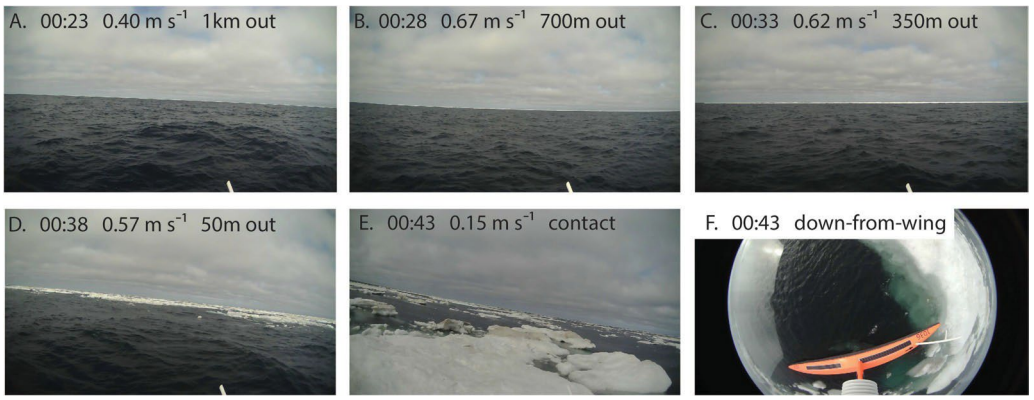

FIGURE 9 | Photos from the camera aboard sd-1036 as it approached the ice band targeted on 18 July 2019. Times in UTC. Distances listed are relative to the vehicle's northernmost point of travel, at which point it was blocked by ice. Panels (A–E) are looking north, along the vehicle's northward route. Photo (F) was taken looking down from the top of the vehicle's wing.

serve as a warning that vehicle contact with ice was imminent. Examination of the 1-min averaged surface marine observations and navigational metrics collected *en route* to ice, however, highlights difficulties associated with using surface marine measurements of temperature and salinity for this purpose.

The sd-1036 ice band approach pictured in **Figure 9** provides a useful example. The vehicle's navigational metrics help pinpoint intervals during which the vehicle's progress was impeded by sea ice. In particular, a drop in vehicle speed from ~ 0.8 to 0.3 m s^{-1} was evident between the 39th and 40th minute of 18 July 2019 (**Figure 10A**; denoted by vertical line). Wind speed remained above ~ 2.5 m s^{-1} and the vehicle's instructions were to maintain course during this time. We thereby infer that ice impeded sd-1036's northward progress between 00:39 and 00:40 UTC of 18 July 2019. As discussed above, an image confirming that sd-1036 was in contact with sea ice was taken at 00:43. The vehicle remained in the ice from ~00:40 to 01:08 UTC, after which it made its way back south.

Density, salinity, and temperature values during the ice-band approach are plotted in **Figures 10B–D** and on a Temperature–Salinity (T–S) plot in **Figure 11**. At the time of the initial ice contact, at 00:40 UTC, the 1-min averaged measurements for temperature and salinity were −0.18°C and 26.12, which equate to a seawater density near 1021 kg m^{-3} (**Figure 10**). A salinity drop of ~2.2 and temperature drop of ~0.2°C were observed in the few minutes following 00:40, which lowered the seawater density to ~1019.5 kg m^{-3}. But this fresher (salinity ~ 24) and cooler (temperature near −0.5°C) water was observed only after sd-1036 became embedded in the ice band. Even once embedded, temperatures remained above the freezing point (**Figure 11**). Prior to contact, there was a discernible increase in salinity observed as the vehicle moved closer to the floe (e.g., ~+0.4 from 00:20 to 00:40). Evidently, at this scale (~1 km), melting ice is not always located at the low end of an open-water, surface salinity gradient.

Seawater conditions observed just before the ice encounter (i.e., temperatures near 0°C and salinities near 26) were also often observed in ice free water. **Figure 12** shows the distribution of 1-min averaged temperatures and salinities collected by sd-1036 during June, July and August, with different symbols differentiating measurements taken while ice was (dots) and was not (open green circles) visible from the vehicle. The low-density (near 1019.5 kg m^{-3}) measurements observed after sd-1036 was embedded in ice on 18 July 2019 are the only ones separated in T–S space from other measurements. The correlation coefficient between sd-1036 temperature (salinity) and the sd-1036 *in situ* sea-ice time series (equal to 1 when ice was visible, and 0 when ice was not visible in the saildrone images) is −0.37 (−0.26). Based on Bootstrap/Monte Carlo sub-sampling, with replacement, of the respective sd-1036 time series (Efron and Tibshirani, 1991), the temperature correlation with *in situ* ice is statistically significant at the 99.9% confidence interval and the salinity correlation is significant at the 90% confidence interval. We thus conclude that temperature was more closely related to ice proximity than salinity (c.f. Johnson, 2011) but attempts to use threshold values of seawater temperature and salinity as a proxy for >0% sea-ice concentration in conditions such as were observed by sd-1036 will have a low probability of success.

The 18 July 2019 ice encounter described above stood out as a prime candidate for close examination in this context because it was associated with some of the coldest and least saline water observed during the mission. The other ice encounters were also examined for surface marine variable precursors to contact with the ice. Although each encounter differed in detail, when viewed from the perspective of trying to anticipate the transition from open water sailing to probable ice contact, they exhibited broadly similar characteristics. The encounter that led to sd-1035 being embedded in ice for approximately 6 h on 14 June 2019, which was the first such occurrence of the mission, exemplifies these characteristics (**Figure 13**). In particular, although the salinity and temperature measured while the vehicle was embedded in the ice were substantially lower than those measured when last sailing through open water – in this case temperature dropped by 1.6°C and salinity by 0.7 between 09:10 and 10:10 UTC – most of these changes occurred after the vehicle hit ice at 09:25 UTC. The important point for ice-avoidance navigation is this: The changes

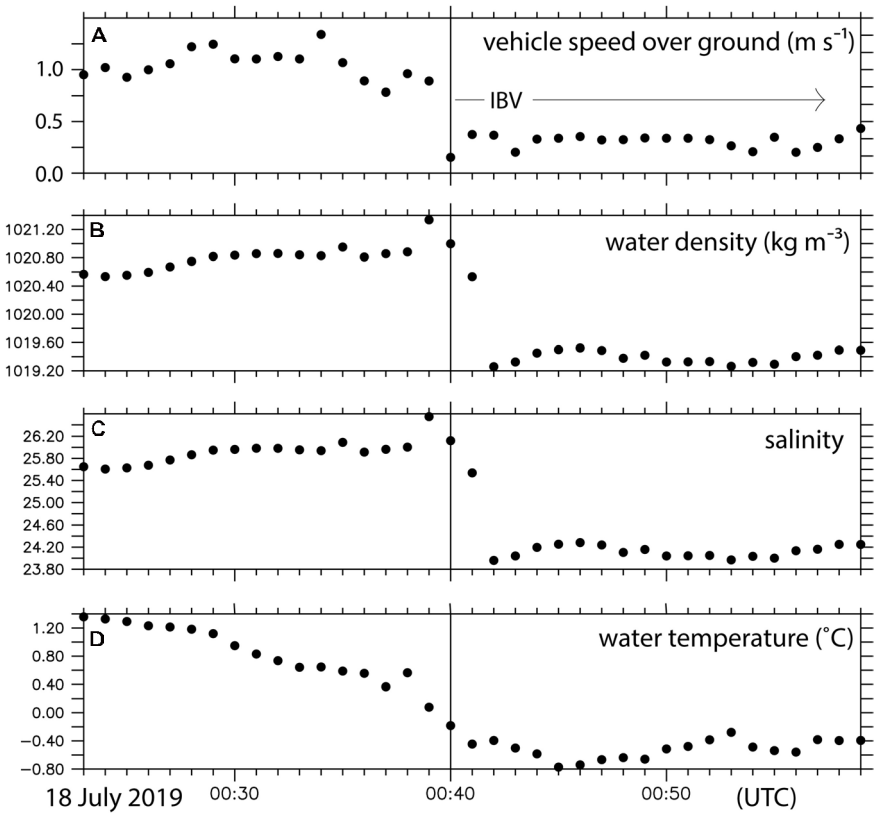

FIGURE 10 | One-minute averaged data just before and after sd-1036 was blocked by sea ice (IBV) on 18 July 2019. (A) The geo-referenced vehicle speed, (B) water density, (C) salinity, and (D) ocean temperature. We infer IBV from the drop in vehicle speed at 00:40 UTC (upper panel; marked with a black vertical line at 00:40 UTC) that sea ice impeded the vehicle's northward progress sometime between 00:39 and 00:40 UTC. An image confirming that ice was surrounding the vehicle was taken at 00:43 (Figure 9E).

observed prior to the point at which the vehicle was impeded by ice – in this case a temperature drop of 0.032°C min^{-1}, or 0.11°C per 100 m based on the 5-min averages centered at 09:10 and 09:23 – were not especially distinct from similar time and space scale changes observed in ice-free water.

We further examined the temperature and salinity gradients observed during the seven times sd-1036 sailed from open water into the marginal ice zone and was impeded by ice. These spatial gradients appear as temporal tendencies in the saildrone time series. The largest negative tendencies (hereafter, LNTs) observed <3 h before ice contact are listed in **Table 1**, based on 5 min averages separated by 20 min. The corresponding 1-min averaged temperature and salinity records from these seven ice encounters are also illustrated in **Supplementary Figures 5–11**. The LNTs preceding four of these seven ice encounters are not very distinct from tendencies seen during periods of ice-free sailing (**Figure 14**). Specifically, for the 23 June, (2) 6 August and 8 August ice encounters, there were 175–371 other, 3 h-long, ice-free periods that had temporal temperature and salinity LNTs lower than those observed *en route* to the ice (**Table 1**). Triggering ice-navigation maneuvers based on temperature and salinity changes in this range ($11S/11t$ = −0.0034 to −0.0082 min^{-1}, $11T/11t$ = −0.0029 to −0.0163°C min^{-1}) would likely introduce unnecessary inefficiency to SIZ sampling strategies because of the apparent abundance of false-positives. Three of these seven ice encounters, however, occurred after traversing stronger gradients than the other 4; the 17 June ice encounter was preceded by a −0.1133°C min^{-1} temperature (−0.158°C per 100 m) gradient located 4840 m from the ice-blockage point, the 22 June ice encounter by a −0.0371 min^{-1} (−0.055 per 100 m) salinity gradient observed just before contact with ice, and the 18 July ice encounter by a temperature gradient of −0.0885°C min^{-1} (−0.119°C per 100 m) and salinity gradient of −0.0686 min^{-1} (−0.092 per 100 m), each at distance of 1480 m from ice contact (**Table 1**). Turning the vehicles around based on gradients far from the ice would leave the remaining section of the vehicle route unobserved; thus, the longer of these distances-to-contact (~1.5 and 5 km) are likely too far for the associated gradients to be used for navigation on their own and still meet our objective of being able to collect observations in close proximity to the ice. The case of navigating based on gradients immediately adjacent to ice presents the opposite issue of needing enough time and space to detect the gradients and turn before contacting the ice; successfully implementing such a system may therefore require

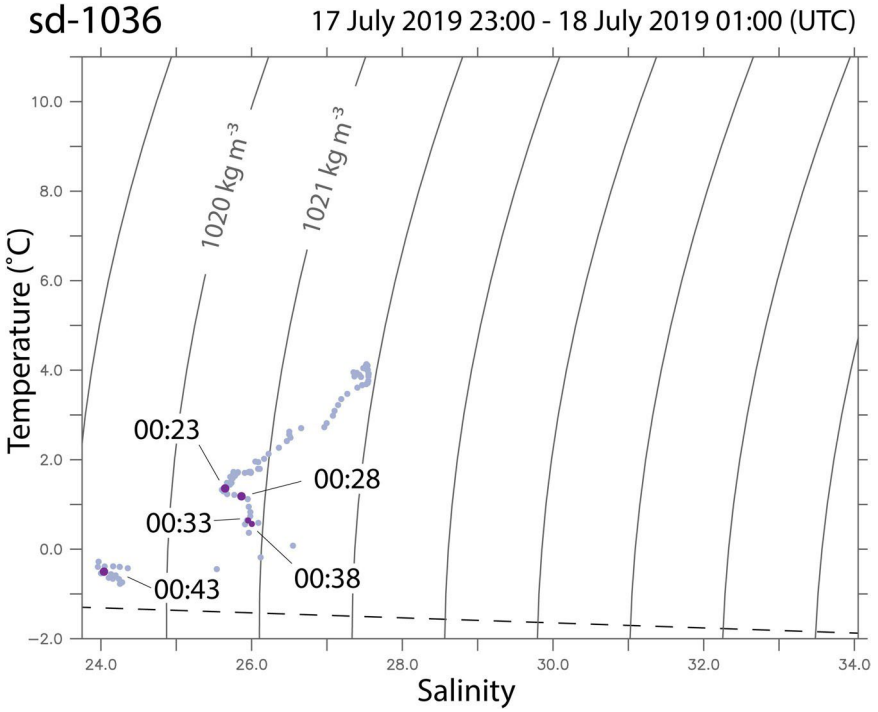

FIGURE 11 | One-minute average temperature and salinity measurements during sd-1036's initial northward transect into an ice band on 18 July 2019. Density contours every 1 kg m^{-3} (solid lines). Seawater freezing temperature calculated based on the equation suggested by Millero and Leung (1976) and used by Fofonoff and Millard (1983) is shown with a dashed line.

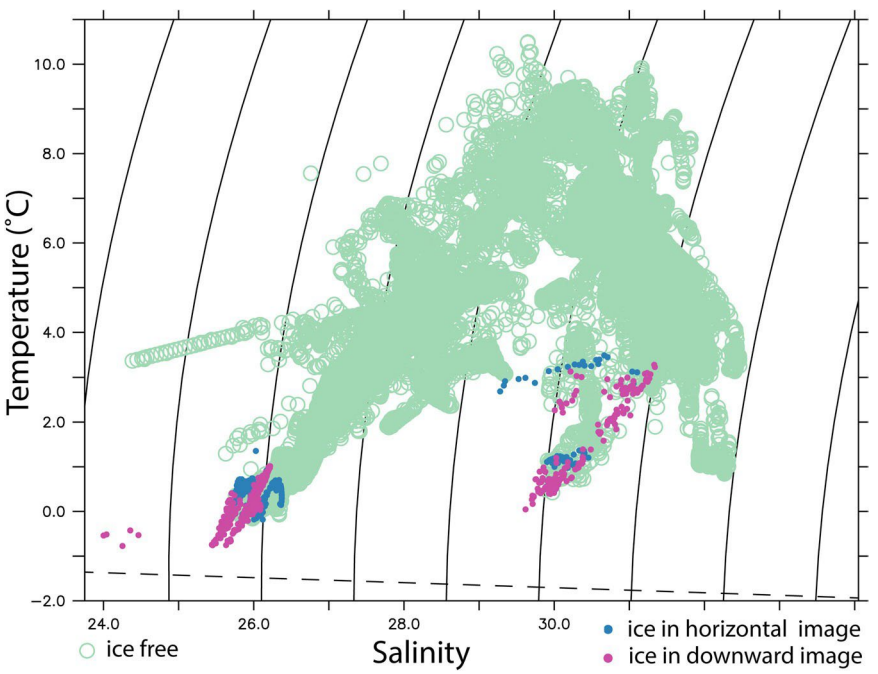

FIGURE 12 | Same as Figure 11 except for seawater temperature and salinity measurements collected by sd-036 during June, July and August of 2019. Light green circles denote times when no ice was visible in the saildrone images; light blue filled dots denote times when ice was visible in the horizontal but not in the downward saildrone photos; magenta dots denote times when ice was visible in the downward-looking saildrone images. Seawater freezing point is shown with a dashed line.

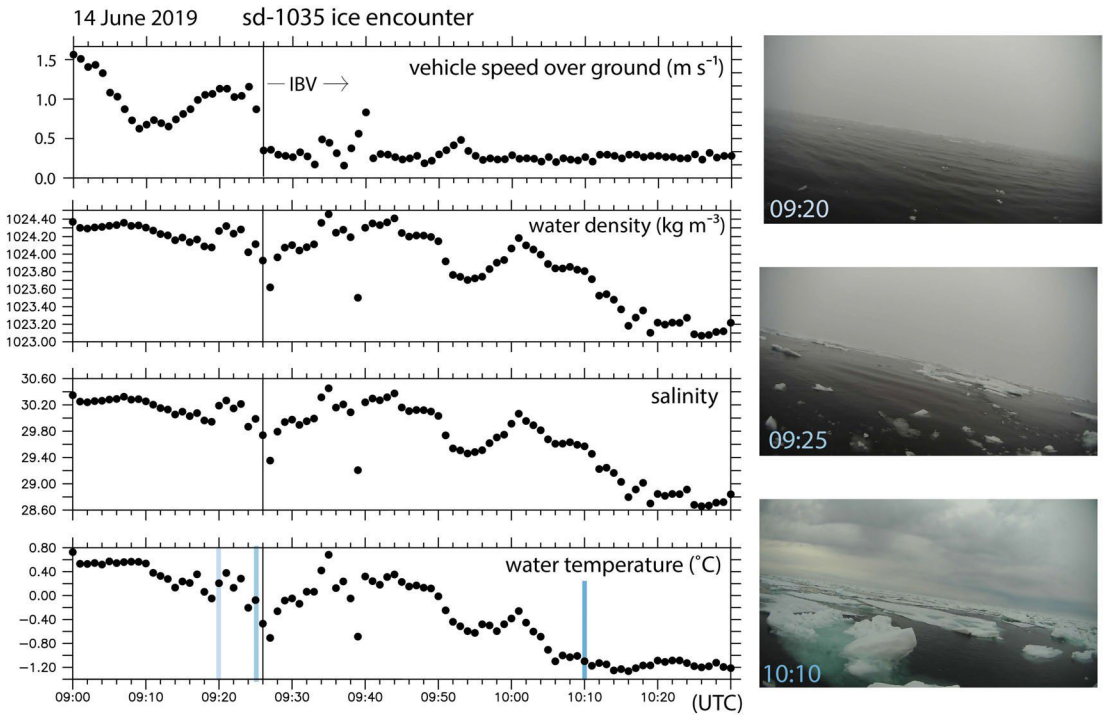

FIGURE 13 | As in Figure 9, except for sd-1035's 14 June 2019 ice encounter. In this case a horizontal photo revealing sparse ice was taken at 09:20 and a downward looking photo confirming ice surrounding the vehicle taken at 09:25 UTC. The drop in vehicle speed over ground between 09:25 and 09:26 (upper-left panel; marked by the IBV-vertical black line in each panel) confirms that the vehicle was impeded then. The blue vertical lines in the near surface water temperature plot (lower left) mark the times of the images shown on the right.

Date-times listed are for the ice-blockages. Tendencies are calculated based on the change between two 5-min averages separated by 20 min. The distances/times-to-contact listed are between the end of the second 5-min averaging period and the point at which vehicle progress was blocked by ice. The number of 3 h-long, open water sampling windows (non-overlapping) that contain 20-min temperature or salinity tendencies lower (more negative) than the respective ice approach minimums are listed in the open-water exceedances column.

refinement. Nonetheless, the stronger gradients associated with these three ice encounters had far fewer (1–19) open-water analogs relative to the other four sd-1036 ice encounters. This suggests that monitoring for negative temperature and salinity tendencies might be useful if a large enough threshold is selected and if supplemented with other ice-detection strategies (see section "Summary and Discussion").

We also considered other surface marine variables, such as near-surface air temperature and humidity, for use in this context, but failed to find a distinct subset of near-ice values in them (**Supplementary Figure 12**). The distribution of seawater temperature and salinity values observed while sd-1034 and sd-1035 were embedded in ice and sailing in open water were also examined and found to have character qualitatively similar to the distribution shown **Supplementary Figure 12**, in that, the subset of in-ice values was indistinct from other values measured in ice-free conditions (the near-1019.5 kg m^{-3} sd-1036 density values already discussed were the only ones with this distinction). The sd-1034 and sd-1035 temperature and salinity diagrams are therefore not shown for the sake of brevity.

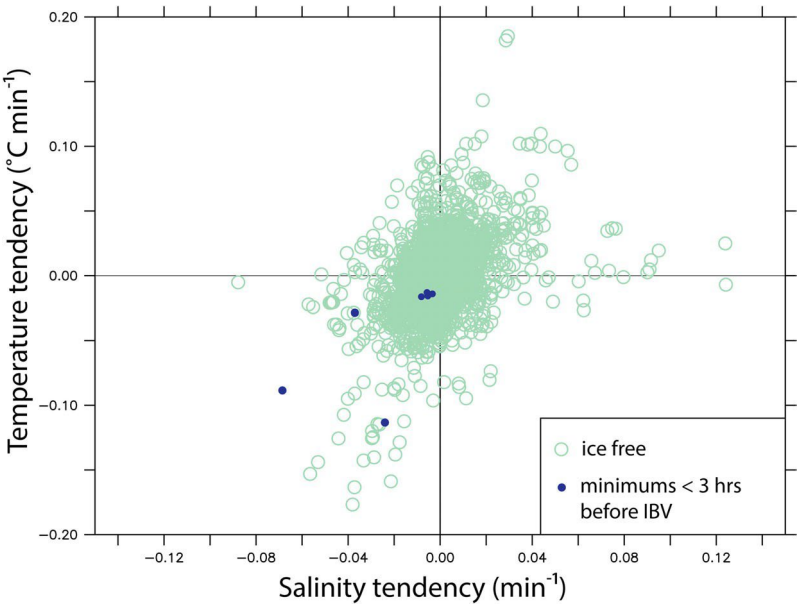

FIGURE 14 | The temperature and salinity tendencies observed while sd-1036 sampled ISSI = 0 conditions (no ice in saildrone images) are plotted with open circles, based on differences between 5 min averages separated by 20 min. The largest negative tendencies observed *en route* to ice (see Table 1) are plotted with dots.

SUMMARY AND DISCUSSION

On 15 May 2019 five saildrones were launched from Unalaska (formerly Dutch Harbor), AK, United States with the objective of observing the air-sea interface within the SIZ of the Chukchi and Beaufort Seas. This mission constituted a test of our ability to use saildrones to observe the SIZ with novel instrumentation packages capable of measuring air-sea fluxes of heat, momentum and CO_2. These saildrones, however, had not been specifically designed to navigate in close proximity to, or collide with, sea ice. Remotely controlled navigation near sea ice was a crux of this mission and will remain critical to future attempts to use similar means to provide high quality, *in situ* observations of surface marine variables in and near the marginal ice zone. Here, we have re-examined the sources of navigational information, based on post-mission tabulation of the sea-ice conditions encountered by the vehicles. Our objectives are to better understand the utility and limitations of this information and to identify opportunities for improving our ability to remotely navigate through the SIZ and near sea ice.

At points in the mission where the vehicles sailed in open water and decisions were being made about where and how to approach marginal ice zones, the EA2 gridded ice-concentration product, pseudo-true color satellite images of the surface and NIC 10% ice concentration contour were initially considered prime candidates for providing regional ice distribution information. However, on most days that the vehicles encountered ice, EA2 estimated zero ice at their location. The chances of seeing ice was not closely linked to EA2 concentration. For example, ice was encountered ~6% of the time EA2 estimated concentrations of 1–10%, but only ~4% of the time EA2 estimated >10% concentration. It was also the case that no ice was encountered or photographed by the vehicles on the handful of days in which EA2 predicted the highest ice concentrations (around 20%) at the vehicle locations. These mismatches between the EA2 estimates and *in situ* conditions encountered by the saildrones made it difficult to reliably use EA2 ice concentration data for SIZ navigation.

We also examined vehicle distances to the daily NIC 10% ice concentration contour on days in which ice was and was not encountered. Our experience with this analysis product largely supports its use as an identifier of ice-free (or nearly so) pathways of navigation over the study region. To put it another way, being on the open water side of the NIC 10% contour proved to be a useful predictor for clear sailing: in only three instances during the mission, specifically on 21 June and 17 August 2019 (sd-1034) and 18 July 2019 (sd-1036) was ice encountered when a vehicle was in waters with discernibly <10% ice concentration according that day's NIC analysis. And in these three cases the vehicles were close to (within a few to several km from) the NIC 10% contour line. Clear sailing was also encountered, however, most (~80%) of the time the vehicles were in >10% ice concentration according to NIC. Thus, other information was needed to plan vehicle routes when the navigational objective was not avoiding but sampling close to ice floes.

Satellite-based surface imagery from radiometric measurements in the near-visible range was at times quite useful in this context. On clear-sky days, Sentinel-2 provided relatively high-resolution (10–60 m) images in which ice floes could be distinguished from water with relative ease using imagery that is generally available to the public. MODIS and VIIRS imagery also provided this capability with moderately coarser, but still useful (up to 250 m) horizontal resolution. But this utility was conditional on skies being free enough from

clouds to offer clear views of the planetary surface, and this was not the norm during the mission. When cloud cover obscured the optical view of the planetary surface and high-resolution SAR imagery was available to us, it proved very useful, confirming the benefits from investments made in this technology by the European (e.g., Sentinel-1) and Canadian (e.g., Radarsat-2) Space Agencies. The combination of Sentinel-1 and Radarsat-2 coverage, however, suffered from significant time and space gaps in our study region.

The use of USV observations such as near-surface ocean temperature and salinity to help determine proximity to sea ice was examined. Unfortunately, the distributions of these variables exhibited a wide enough range of variability in open water that they often overlapped with characteristics observed just prior to coming into contact with ice floes. This was true for the absolute values of the variables as well as their rates of change in time and space. These overlaps likely preclude this approach from providing, on its own, a reliable indicator that a given vehicle is nearing sea ice. Ice detection, however, was not the main motivation for collecting the surface marine observations. We expect them to be valuable in many other respects. These include providing a basis by which high priority targets for improvements of weather forecast model initializations and predictions can be identified (Zhang et al., submitted) and heat transfer between sea ice and sea water can be estimated.

There might be several reasons for the difficulty of using observed temperature and salinity to detect when USVs are approaching sea ice. If ice floes are drifting toward ice-free water, the strongest temperature and salinity gradients would be very close to their edges facing the ice-free water. Likewise, if surface currents are toward ice bands, they would push relatively warm, saline water against the ice bands and cause the strongest temperature and salinity gradients to lie very close to the ice bands. In addition, sea ice can move quickly (~2% of the wind speed; Sullivan et al., 2014) leaving behind swaths of melt water that have complex geometrical relationships to the ice before they are mixed to ocean-gyre scales (e.g., Dewey et al., 2017). Other factors, such as the strength of surface wind that dominantly controls surface heat flux, would further complicate distributions of surface temperature relative to sea ice. Distributions of surface temperature and salinity in the SIZ need to be further characterized using the observations from the saildrones deployed in this Arctic mission to better understand both their relationship to sea ice distribution and the time-space sampling density needed to constrain flux estimates over the SIZ.

Based on a review of images taken from the vehicles as they approached waters containing varying concentrations of sea ice, it is not difficult to imagine that – in true real time – they could usefully aid remote navigation near ice bands. For example, they could be used to trigger navigational instructions to the vehicle to preempt unwanted collisions with the ice, or tailor the sampling to mitigate risk to the vehicles if near-ice sampling remained the objective; perhaps by reducing vehicle speed or steering along rather than into a denser ice band. In practice, we found that the delay associated with being able to view the telemetered images (~ 30–40 min, or 1.8–2.4 km traveling at 1 m s^{-1}) was too long for practical use in this respect. If this transmission time could be greatly reduced, we expect that the images could then play a key role in developing more robust ice zone navigation strategies. However, in the case that this monitoring and navigational decision-making depended upon continued human interaction, the burden this would place on the navigational team during a mission of this length should not be overlooked.

Ideally, artificial intelligence (AI) can be applied to the saildrone images to detect, in real time, sea ice in the distance and either automatically navigate the vehicles to avoid collisions or alert the navigational team. Promising onboard AI navigation strategies have been reported for other USVs previously (e.g., Huntsberger et al., 2011; Carlson et al., 2019; Jin et al., 2020). The power-constraints associated with operating on solar power for months in high-latitudes – and still having power for meteorological and oceanographic sensors – likely preclude many of the specific techniques employed on much shorter missions (e.g., stereo-video cameras, LiDAR) from being very useful for a next generation of Arctic saildrones. However, general advances made recently in image recognition capability (e.g., LeCun et al., 2015) provide a basis for developing this capability. The next generation of saildrones have already been equipped with onboard Artificial Intelligence (AI) navigation for ships (R. Jenkins, pers. comm.). It is unknown if the amount of ice image information collected from this mission is sufficient for a complementary AI application for sea ice. The possibility of applying AI to information from onboard images and *in situ* observations to develop an automated navigation algorithm for endurance-sailing on solar power in the SIZ should be explored; in this context the *in situ* saildrone observations (and perhaps satellite information) can be used to add confidence to the ice image detection algorithms. For example, the confidence associated with a possible ice detection in the image algorithm can be downgraded if temperatures are several degrees above the freezing point (SSTs reached 10°C but ice was not seen above 4°C during this mission) or upgraded if temperatures are low and strong negative salinity or temperature gradients are observed.

Although the limitations associated with the ice navigation information available for this mission made it difficult to consistently answer, in a navigationally useful manner, the question of where the ice was in relation to the vehicles without actually running the vehicles into the ice, the mission was completed in October 2019 with some notable successes; saildrones reached latitudes up to 75.49° N and as far east as ~151°W while traveling over 56,000 km. And although saildrones were not specifically designed to come into contact with ice, they did so on approximately two dozen occasions bracketed by ice-free sailing. Even so, all of the vehicles and the instruments deployed were successfully recovered, although some with damage.

In conclusion, this mission provided understanding toward the potential for USVs to substantially contribute to the development of high-latitude observing systems (e.g., Lee et al., 2017) by providing the capability to accurately monitor surface fluxes of heat, momentum and carbon dioxide throughout the

Earth's SIZ. Improved strategies for remote navigation of the ice zone are needed to accomplish this. Our analysis highlights what appears to be a useful and feasible next step in this process; automated detection of ice from cameras and processors installed on the vehicles that may then trigger navigational maneuvers. The repository of saildrone ice and non-ice images collected on this mission will be key to developing the necessary ice recognition capability. Work is planned to bring this to fruition.

AUTHOR CONTRIBUTIONS

AC co-managed the mission, analysis, design, and writing of this manuscript. CZ was a mission Principal Investigator (PI) and helped design, and write this manuscript. QY co-managed the mission. EC and QY studied a previous year's ice encounter. EC provided the seminal post-mission tabulation of sea-ice conditions. CMo and PS provided analysis results and aided the writing. CG was a mission PI. JC was a mission PI and helped write this manuscript. NL-S and CMe were instrumental in equipping the saildrones with the observational packages used during this mission. MS, MW, and DH helped organize and write this manuscript. HT led communications with Alaskan communities, helped coordinate the mission's preparation and progress, and helped write this manuscript. EB and KO'B managed the saildrone data curation, enabled the real-time data feed to the GTS, and helped write this manuscript. All authors contributed to the article and approved the submitted version.

FUNDING

AC was supported by funding from the NOAA Global Ocean Monitoring and Observation program (FundRef # 100007298). This publication is partially funded by the University of Washington's Joint Institute for the Study of the Atmosphere and Ocean under NOAA Cooperative Agreement NA15OAR4320063, Contribution No. 2020-1115. MS and CG were funded by the MISST3 Project, NASA grant 80NSSC18K0837. MW gratefully acknowledges support from National Science Foundation Grant 1751363 and the NOAA Arctic Research Program. This is PMEL contribution 5158 and EcoFOCI contribution 0959-RPPO.

ACKNOWLEDGMENTS

We thank the Saildrone Inc. team that worked on this mission, including pilots K. Neal, D. Nonweiler, and R. Jenkins who, among other tasks, led the effort to rescue sd-1035, which lost its ability to navigate following the mission's final ice encounter on 23 Aug 2019. We also thank the members of the Alaskan communities we corresponded with, including those who provided the small boat for sd-1035's rescue. We thank also Alaska SeaGrant Map Agent Gay Sheffield, NOAA's Candace Nachman and Amy Holman for continued support in communicating the testing of innovative technologies in the US Arctic. CDR Paul Kunicki helped facilitate communication with the US Coast Guard and researched options for sd-1035's rescue. We greatly appreciate the assistance from NIC analysists who shared their ice information expertise with us, including Alexandra Darden, William Walter, Chris Readinger, Katie Quinn, Evan Neuworth, Christopher Szorc and Sofia Montalvo. This mission benefited from collaboration and assistance from Kevin Wood, who led aerial reconnaissance of the saildrone positions on 17 July 2019, capturing thermal imaging video of the drones and deploying nearby airborne expendable bathythermographs. This mission benefited from helpful conversation with Luc Rainville and Craig Lee. Ansley Manke contributed FERRET software that calculated distance between saildrones, facilitating close-sail, inter-vehicle sensor comparisons at the beginning and end of the mission. We are also grateful to Stacey Maenner-Jones for remotely controlling the ASVCO2 systems. The saildrone mission was funded by NOAA PMEL Innovative Technology for Arctic Exploration program.

SUPPLEMENTARY MATERIAL

Abstract

Polar cod and saffron cod are dominant components of the fish community in the Chukchi Sea and are ecologically important forage fishes linking plankton to upper-level consumers. In 2017, we conducted a study as part of the Arctic Integrated Ecosystem Research Program to characterize the distribution, abundance, and growth of polar cod and saffron cod early life history stages (ELHS) in late spring and late summer in the Chukchi Sea. Ship-based plankton tows showed that polar cod and saffron cod larvae were centered in Kotzebue Sound in the late spring. By late summer, polar cod juveniles were centered offshore in the northern Chukchi Sea whereas saffron cod were distributed nearshore around Cape Lisburne. Empirical fish collections were paired with an individual-based biophysical transport model to examine connectivity and relate changes in seasonal distribution to potential environmental variables. Modeled drift trajectories and growth in spring for polar cod and saffron cod matched well with empirical observations, especially along the northern coastline of Kotzebue Sound, offshore of Point Hope/Cape Lisburne. Given the coherence between modeled and observed distributions, Kotzebue Sound is likely a source of gadid ELHS in the nearshore areas of the Chukchi Sea and offshore of Cape Lisburne/Point Hope, although it is not the likely source of polar cod over Hanna Shoal in the late summer. This is the first study to examine seasonal distribution, abundance, and growth of polar cod and saffron cod in the US Arctic and provides data necessary to evaluate the impacts of climate change on forage fishes in the Arctic.

Introduction

The Arctic has experienced accelerated warming at twice the rate of the global average, making Arctic ecosystems particularly sensitive to climate change (Graham et al., 2017; Tokinaga et al., 2017; Overland et al., 2018). The accumulation of heat in the Arctic has increased significantly since the late 1990s, which correlates to a reduction in sea ice thickness (Maslowski 2014), a 60% loss of multiyear ice, a 75% reduction in sea ice volume (Overland et al. 2018), and lower winter ice extent maxima (Graham et al. 2017). Loss of sea ice is expected to influence Arctic ecosystem dynamics through bottom-up changes to lower trophic production (Kahru et al. 2011), community structure (Spear et al. 2019), trophic linkages (Hunt et al. 2013), shifts in benthic-pelagic coupling (Grebmeier et al. 2015 and citations therein), and food web interactions (Li et al. 2009). Ecosystem changes also have potential economic ramifications such as range extensions of commercially important subarctic gadid species, such as walleye pollock (*Gadus chalcogrammus*), Pacific cod (*Gadus macrocephalus*), and salmonid fishes, into regions north of the Bering Strait (Falardeau et al. 2017; Stevenson and Lauth 2019) in the Pacific Arctic.

Although not fished commercially in the US Arctic (NPFMC 2009), polar cod (*Boreogadus saida*), a circumpolar species, and saffron cod (*Eleginus gracilis*) are crucial forage fishes in Arctic marine ecosystems. Both species support bioenergetic pathways that transfer energy from planktonic food webs to upper level consumers and apex predators (including humans) and are a dominant component of the fish community in the Chukchi Sea, although polar cod is more abundant than saffron cod (Whitehouse et al. 2014; Logerwell et al. 2015). It is estimated that seabirds and marine mammals consume approximately 75% of the polar cod production (Whitehouse et al. 2014). Changes to the Chukchi shelf ecosystem due to climatic warming, loss of sea ice, and perturbations to sea ice phenology (Graham et al. 2017; Overland et al. 2018) may have serious implications for these ecologically important species.

Despite their ecological importance and abundance in Arctic ecosystems, the life history of polar cod and saffron cod are still relatively unknown (Logerwell et al. 2015; Vestfals et al. 2019). Spawning

locations of polar cod in the US Arctic are largely unknown, although it is hypothesized that polar cod spawn under sea ice (Rass 1968) and that peak hatching likely occurs in May and June as the ice edge recedes (Bouchard and Fortier 2008; Vestfals et al. 2019). In the Pacific Arctic, development of larvae and early juveniles occurs along the shelf (Logerwell et al. 2015; Vestfals et al. 2019). Saffron cod are near-shore, demersal, under-ice spawners that deposit demersal eggs in nearshore areas on sandy-pebbly substrates (Vestfals et al. 2019 and citations therein) but exact locations are unknown in the US Arctic. Peak hatching for saffron cod occurs in April and May, earlier than for polar cod, and offspring are often found concentrated closer to shore and at more southerly locations within the Chukchi Sea (Vestfals et al. 2019). The life histories of polar cod and saffron cod are similar in that both are planktonic in shelf waters after hatching through the first summer, after which polar cod move deeper in the water column while saffron cod become demersal as juveniles (Logerwell et al. 2015; Vestfals et al. 2019).

Growth of polar cod and saffron cod is mediated by temperature (Laurel et al. 2016) and an additional consequence of a warming Arctic is that large calanoid copepod species, an important prey resource for Arctic gadids, will be replaced by smaller, less lipid-rich copepods (Aarflot et al. 2018; Møller and Nielsen 2020; Bouchard and Fortier 2020). Larvae and juveniles will be disproportionately affected by these changes relative to adults due to their higher weight-specific growth rates, and polar cod may be more sensitive than saffron cod because they are a stenothermic species (Laurel et al. 2016). Polar cod are adapted to support high growth and lipid allocation at a narrow range of low temperatures (optimal growth rate at 5°C), while saffron cod experience high growth and lipid allocation over a wider temperature range, particularly, at high temperatures (optimal growth rate >16°C) (Copeman et al. 2016; Laurel et al. 2016). As such, saffron cod may be better able to mitigate the effects of ocean warming in the Arctic than polar cod.

In 2017, the Arctic Integrated Ecosystem Research Program (Arctic IERP), funded by the North Pacific Research Board, conducted its first field season in the US Pacific Arctic. Concurrent with the Arctic IERP surveys, the Distributed Biological Observatory (DBO) project and the Arctic Marine Biodiversity Observation Network (AMBON) survey were also sampling the region, providing more coverage to this region that is often under-researched. In this inaugural year of sampling for the Arctic IERP, it was remarkable that the northern Bering Sea and Chukchi Sea were sampled for ichthyoplankton in both late spring and late summer, a first in the region. These sampling efforts provided an opportunity to assess the seasonal abundance, distribution, and growth of fishes during their early life history stages (ELHS). However, the summer of 2017 in the Chukchi Sea was also remarkable in environmental conditions, with an elevated sea surface temperature (+4°C relative to the historic average) and the lowest recorded March sea ice minimum in the 39-year history of the time series (Timmermans et al. 2017; Perovich et al. 2017), providing us with baseline vital rate data for polar cod and saffron cod, albeit during a warm year. Such baseline data, when coupled with further monitoring and modelling, can be used to determine the impact of climate warming on these two ecologically important species. In addition to empirical sampling, we used an individual-based model (IBM) as a tool to simulate larval transport and examine potential linkages and connectivity in polar cod and saffron cod abundance and distribution between the late spring and late summer sampling events. Our goals for this study were to (1) examine spatial patterns of distribution and abundance of polar cod and saffron cod during their larval (June; late spring) and early juvenile (August-September; late summer) stages in 2017; (2) assess the change in mean length to approximate daily growth rates in the summer for polar cod and saffron cod; and (3) evaluate potential sources of larval polar cod and saffron cod using an IBM to compare observed distributions and sizes with model output. This study coupled empirical observations with IBM output to synthesize, for the first time, the seasonal distribution, abundance, and growth of two co-occurring

Arctic forage fishes, providing a means to assess the biological impacts of warming on polar cod and saffron cod ELHS.

Methods

Specimen Collection

Polar cod and saffron cod ELHS were collected in 2017, using three different sampling gears, as part of several cooperating research projects (Table 1): the Arctic Integrated Ecosystem Survey (AIES; part of Arctic IERP), AMBON survey, the Arctic Shelf Growth, Advection, Respiration, Deposition (ASGARD; part of Arctic IERP) project, and the DBO project. Larval and early juvenile Arctic gadids were targeted with a 60-cm bongo (bongo hereafter) equipped with a flow meter and a 505-µm mesh net fished obliquely from 10 m off the bottom or a maximum depth of 200 m to the surface in the late spring and late summer during the AIES and DBO surveys and to 5 m off the bottom or a maximum depth of 200 m for ASGARD. Demersal juvenile Arctic gadids (age-0, age-1+) were targeted with a benthic-sampling 3-m plumb-staff beam trawl (Abookire and Rose 2005) equipped with 7-mm mesh and a 4-mm cod end liner during the late summer AMBON and AIES surveys (Table 1). The beam trawl was deployed from the stern of the vessel and towed at 1.5-2.0 knots for four minutes (Logerwell et al. 2015). Juvenile gadids (age-0, age-1+) were also collected from the midwater during AMBON using a 1.5 m wide by 1.8 m high Isaacs-Kidd Midwater Trawl Net (IKMT) equipped with 3-mm mesh and a flowmeter (Table 1). The IKMT was towed double obliquely at 3.5-4.0 knots and these data were used to look at length and growth of Arctic gadids in August, prior to the late summer AIES surveys.

All bongo samples were fixed at sea in 5% formalin buffered with seawater and processed at the Plankton Sorting and Identification Center in Szczecin, Poland. ELHS of all fishes were identified to species, enumerated, and up to 50 specimens per taxon at each station were measured to the nearest 0.1 mm. Since specimens were measured after formalin fixation, we applied a +1.9% correction factor to

the measured lengths to account for shrinkage (D. Blood, B. Laurel, NOAA, unpublished data; Vestfals et al. 2019). The identifications of ELHS gadids were verified by scientists at the National Oceanic and Atmospheric Administration's Alaska Fisheries Science Center using Matarese et al., 1989, Dunn and Vinter 1984, (and Ichthyoplankton Information System (IIS 2019). Due to concerns of Walleye Pollock (*Gadus chalcogrammus*) being mis-identified as Polar Cod, the Arctic gadids captured during AIES using the beam trawl were verified using genetic methods following Wildes et al. (2016). No specimens of juvenile Arctic cod (*Arctogadus glacialis*) were detected (S. Wildes, Alaska Fisheries Science Center (AFSC), personal communication), suggesting that *A. glacialis* was not present in our study region since the abundance of later stages is reflective of the abundance of the earlier stages (Bouchard et al. 2016). Catch per unit effort of polar cod and saffron cod was reported as the number of individuals caught under a sea surface area of 10 m^2 (count per 10 m^2). Trawl samples (IKMT and beam trawl) were processed at sea with all individual fishes being identified, enumerated, and measured to the nearest length in millimeters. Standard length (SL) was measured for individuals at flexion size or larger and notochord length (NL) for individuals smaller than flexion. The reported size of flexion is 11.0 mm for polar cod and saffron cod (IIS 2019). Catch for the AIES and AMBON beam trawl was expressed as number of individuals caught per unit area swept (count per 1000 m^2).

Data Analysis

All catch and length data were analyzed using R (ver. 3.5.2; R Core Team 2019). For the length data, to account for only a subset of larvae being measured (n = 50 maximum), the estimated proportion of individuals at each length was multiplied by the standardized catch at that station (catch-weighted length). Individuals of polar cod and saffron cod larger than 70 mm SL were presumed to be one year or older based on a cutoff identified in the length-frequency distribution and were excluded from the subsequent length analyses. Our use of 70 mm SL to delineate between age-0 and age-1 polar cod is smaller than the size of this transition identified in prior work determining length at age using otoliths

[84.0 mm fork length (FL) and 81.6 mm total length (TL), respectively] (Craig et al. 1982; Lønne and Gulliksen 1989) because standard length excludes measuring the caudal fin rays that are often damaged during collection. The transition of saffron cod from age-0 to age-1 is not as definitive as that for polar cod due to an overlap in size at these ages occurring between 55 and 110 mm FL in the Chukchi Sea (Wolotira 1985; Copeman et al. 2016; Helser et al. 2017). However, in Arctic samples collected in 2012 all individuals greater than 75 mm FL were age-1 based on otolith analyses, suggesting our size cutoff is reasonable for the region sampled (Copeman et al. 2016). Specimens were then aggregated into 2-mm length bins. For the AMBON samples collected with the IKMT and the beam trawl, subsamples of fish were measured to the nearest millimeter. Many of the smallest individuals (less than 50 mm) were not measured and were instead sorted into approximate 10-mm size bins, enumerated in the field, and then discarded. The binned individuals were combined with the measured individuals by simulating individual lengths of the binned individuals from a uniform random distribution within their assigned size bin. Other distributions (normal, beta) were considered for simulating lengths of the binned individuals but had minimal impact on the resulting length-frequencies.

Daily growth rates were estimated for each species as the change in mean length from June 19th, 2017, the median date of the late spring (June) ASGARD survey, and each late summer survey (AMBON and AIES) under the assumption that these individuals were from the same cohort. The median date of the AMBON survey was August 13th, 2017 and the median date of the AIES survey was September 1st, 2017. Mean length for late spring was based on all individuals collected during the survey using the bongo. Mean length for the late summer individuals was gear-specific and calculated based on all putative age-0 specimens collected during: (1) AMBON survey using a beam trawl, (2) AMBON survey using an IKMT, (3) AIES and DBO surveys using a bongo, and (4) AIES survey using a beam trawl. Data for these growth analyses did not include estimates from midwater-collected gadids sampled during the late summer AIES and DBO Project, but they were available from the IKMT fished during the 2017 late summer

AMBON survey, providing some estimates of growth of midwater-associated fishes. Daily growth rates are presented as a range; the estimate provided from the late summer bongo collections represent a low estimate as larger gadids tend to escape from the bongo net (Shima and Bailey 1994) and likely represent individuals that are smaller-than-average. Late summer beam trawl collections (AIES) represent a high growth estimate as the coarser mesh size of the trawl may select for larger individuals that are larger-than-average and generally resulted in the greatest mean size. For polar Cod, length-dependent mortality results in slightly greater length at age estimates (Thanassekos et al. 2012), suggesting our study will be overestimating growth since we are relying on changes in length of survivors (those individuals captured and measured by the various gear types) to estimate growth. A daily growth rate was also calculated using the IKMT data to explore differences in the apparent growth rates between age-0 fishes that are still pelagic and those that have become demersal by the time of sampling. We expected the apparent growth rate to increase as individuals become more demersally oriented. Size distribution from the IKMT and beam trawl are likely to be directly comparable as the IKMT mesh size (4 mm) was identical to that of the beam trawl liner.

Densities (catch per unit area) of polar cod and saffron cod were mapped to explore the seasonal distribution of ELHS of Arctic gadids in the northern Bering and Chukchi seas relative to sea ice concentration on June 19th and September 1st, 2017. Sea ice concentrations were obtained from the National Snow and Ice Data Center at 25 km by 25 km spatial resolution (Cavalieri et al. 1996; NSIDC 2019).

Individual-based biophysical model for polar cod and saffron cod

Late spring and late summer distributions were compared to simulated distributions from biophysical transport models parameterized for polar cod and saffron cod larval and early juvenile stages (Vestfals et al. 2021). Details on the model parameterization and the results of validation testing are described in

Vestfals et al. (2021). These models were developed to simulate the growth and dispersal of early life stages in the northern Bering, Chukchi, and Beaufort seas to identify possible spawning locations, which are largely unknown, as well as to examine gadid connectivity between these seas. An implementation of the Regional Ocean Modeling System (ROMS) (Shchepetkin and McWilliams 2005) set up in a Pan-Arctic (PAROMS) configuration (Danielson et al. 2016) was used to realistically simulate the three-dimensional (3-D) circulation field. PAROMS has a horizontal resolution of ~5 km south of the Aleutian Islands to 9 km in the North Atlantic and is approximately 5.5 – 6.0 km in the Chukchi Sea, and is forced by the Japanese 55-year atmospheric reanalysis JRA55-do (version 1.4) (Tsujino et al. 2018), which also provides estimates of freshwater runoff. Boundary conditions come from the Simple Ocean Data Assimilation (SODA) reanalysis (version 3.3.1) (Carton et al. 2018) prior to 2015 and the Hybrid Coordinate Ocean Model (HYCOM) (Chassignet et al. 2009) for more recent years. The Oregon State TOPEX/Poseidon Global Inverse Solution (Egbert and Erofeeva 2002) provides tidal forcing and the sea ice field is based on the single-category Budgell ice model (Budgell 2005). To simulate advection and growth of larvae, IBMs for polar cod and saffron cod were developed using the particle tracking tool TRACMASS that calculates Lagrangian trajectories from Eulerian velocity fields (Döös 1995).

Stage-specific and size-specific temperature-dependent growth rates were used to model the growth of polar cod and saffron cod (Porter and Bailey 2007; Laurel et al. 2016; Koenker et al. 2018) to 45 mm in length, the size at which these species are thought to transition from pelagic juveniles to more demersal juveniles, with enhanced swimming abilities. In addition, these stages correspond most closely to the stages captured by the water column sampling gear (bongo and IKMT) during the field campaign allowing for comparison between simulated and observed distributions of the two species. Similar to the growth rates calculated for the 2017 empirical data, mean daily growth rates were estimated for the simulated larvae for each species as the change in mean length from late spring (June 19th) to late summer (September 1st) divided by the number of days elapsed.

Hatching locations were identified through a thorough literature review, anecdotal evidence, and known areas of retention in the Pacific Arctic (Vestfals et al 2021 and references therein). However, due to the preponderance of early-stage individuals encountered in the Kotzebue Sound region during spring 2017, we focused this study on this region as a potential source of polar cod and saffron cod in the US Chukchi Sea. For our study, Kotzebue Sound will include the area that extends from the northwestern tip of Seward peninsula to Point Hope. Simulations were initialized from all PAROMS grid points falling within the eastern-most part of Kotzebue Sound as hatching location (Figure 1), with 10 particles released per 5 m depth increment to the bottom at each PAROMS grid point. The Chukchi Sea is often shallower than 40 m, which represents the maximum release depth of particles in the model (Vestfals et al. 2021). Based on results from initial particle simulations, dispersal simulations were conducted with larvae hatching on the 1st and 15th day of each month from March 1st through May 15th, for a total of six hatching events. Temperature-mediated growth and dispersal of larvae were simulated until September 1st, the midpoint of the late summer Arctic field surveys in 2017, so that the simulated distribution and size composition during summer could be compared to the observed distributions and size compositions of individuals captured during the surveys.

IBM parameterization- polar cod

Several vertical behaviors were developed for polar cod based on available literature (Borkin et al. 1986; Bouchard et al. 2016) and from laboratory observations (B. Laurel, AFSC, *unpublished data*). Of the five different vertical behavior routines tested, simulations with surface-oriented individuals, where all stages were found at 5 m matched best with prior field observations from acoustic-trawl surveys conducted in 2012 and 2013 (DeRobertis et al. 2017; Vestfals et al. 2021). Polar cod growth was based on growth equations described in Koenker et al. (2018) and Laurel et al. (2016). Simulated larval sizes

and distributions on June 19th (midpoint of the ASGARD survey) and September 1st (midpoint of AIES) from simulations originating in Kotzebue Sound were compared to field observations.

IBM parameterization- saffron cod

Similar vertical behaviors were used for the saffron cod simulations as for polar cod since no information on the vertical distribution of saffron cod larvae is available at present. Preflexion larval growth from hatch to 10 mm in length was based on temperature-dependent growth experiments (B. Laurel, unpublished data; Vestfals et al. 2021). At present, temperature-dependent growth models for saffron cod ELHS > 10 mm in length are not available. As growth of saffron cod at these small sizes is linear and resembles that of walleye pollock (B. Laurel, AFSC, unpublished data), the growth model described in Porter and Bailey (2007) was used to model saffron cod growth from 10 to 45 mm.

Results

2017 Field Data

Sea Ice

As of June 1st, just prior to the survey, sea ice was present in the Kotzebue Sound region (S. Danielson, University of Alaska Fairbanks (UAF), unpublished data). By June 19th, the mid-point of the late spring survey, sea ice was receding and the entire survey area was ice-free.

Abundance, Distribution, and Size of polar cod

In June, the highest densities of polar cod (> 640 individuals per 10 m^2) were found at nearshore stations of Kotzebue Sound and Point Hope transects and along the entire Cape Lisburne transect (Figure 2a). Polar cod density was lower south of the Bering Strait with most individuals being encountered along the northernmost transects sampled in the Chukchi Sea. By late summer (August and September), sea ice remained absent in the survey region south of 75°N, except in the nearshore area of Kotzebue

Sound. The overall density of polar cod decreased from an average catch of 1183 individuals per 10 m^2 in the late spring to 7 individuals per 10 m^2 in the late summer in the water column. The highest densities of polar cod in the water column (>10 individuals per 10 m^2) were observed in the northern portion of the survey area in the late summer, particularly around Barrow Canyon and Hanna Shoal (Figure 2b). The distribution of polar cod in the water column was similar to the distribution of demersal individuals. Demersal catches of juvenile polar cod (<70 mm SL) were highest offshore in the northern Chukchi Sea in the late summer in areas where bottom water temperatures were below approximately 5°C (Figure 3a and b).

In June, the mean length of polar cod larvae in the water column was 9.8 mm NL (*n*= 850), with most larvae being less than 12.0 mm in length (Figure 4a; Table 2). By the end of the summer, the length distribution of polar cod had expanded and the mean length increased to 30.1 mm SL ± 0.9 (*n*= 140) and 30.7 mm SL ± 0.4 (*n*= 433) for specimens collected in the water column with the bongo and IKMT gears, respectively (Figure 4c, e; Table 2). In late summer (August-September) the mean length of demersal polar cod was 39.7 mm SL ± 0.4 (*n*= 718) in the AMBON beam trawl samples and 47.8 mm SL ± 1.6 (*n* = 690) in the AIES beam trawl samples (Figure 4g, i; Table 2). Based on changes in length and an assumption that larvae collected in the late summer surveys were from the same cohort as fish collected in the late spring, the estimated daily growth rate for polar cod during 2017 ranged from 0.27 mm day^{-1} based on individuals in the water column to 0.53 mm day^{-1} based on individuals that had become demersal (Table 3), with an overall mean of 0.39 ± 0.06 mm day^{-1} (*n*= 4) based on all measured individuals.

Abundance, Distribution and size of saffron cod

The density of pelagic larval saffron cod in June was highest at the nearshore stations in Kotzebue Sound and Cape Lisburne, which were both ice covered on June 1st, prior to the mid-point of the survey, with densities ranging from 68 to 444 individuals per 10 m^2. The highest observed density of saffron cod was

at the innermost station along the southern margin of Kotzebue Sound (Figure 2c). Catches south of Kotzebue Sound were low (less than 30 individuals per 10 m^2). Densities of saffron cod were much lower later in the summer (August and September), with most of the stations yielding no saffron cod (Figure 2d). Unlike saffron cod in the water column, demersal larval and early juvenile saffron cod in later summer were rarely encountered offshore, with most individuals concentrated near Cape Lisburne (Figure 3c and d). Demersal saffron cod were observed in areas with higher bottom temperatures than demersal polar cod. In early August, saffron cod were concentrated in areas with bottom water temperatures greater than 7.5°C and by September occupied areas with bottom water temperatures greater than 5.4°C.

Saffron cod had a mean length of 9.3 mm NL ± 0.4 (*n*= 299) in June, with most individuals measuring less than 14.0 mm in length (Figure 4b; Table 2). By late summer, the mean length of saffron cod ranged from 18.5 mm SL ± 1.4 (*n*= 7) in the bongo to 40.3 mm SL ± 1.7 (*n*= 41) in the IKMT (Figure 4d, f). The mean length of demersal saffron cod was 51.6 mm SL ± 0.4 (*n*= 318) in the AMBON beam trawl and 55.1 mm SL ± 1.7 (*n*= 54) in the AIES beam trawl by late summer (Figure 4h, j; Table 2). The daily growth rate for saffron cod was estimated as 0.12 mm day^{-1} to 0.76 mm day^{-1} (Table 3), with a mean of 0.37 ± 0.16 mm day^{-1} (*n*= 4).

Comparison of distribution and size of polar cod and saffron cod

Catches of saffron cod were lower relative to polar cod regardless of season. In June, the core distribution of saffron and polar cod overlapped in Kotzebue Sound, with polar cod found farther offshore than saffron cod (Figure 2). Later in the summer, saffron cod were encountered in bongo samples of the water column at only 7 of the 136 stations sampled. Demersal juveniles of polar cod were observed farther offshore and to the north relative to saffron cod in the late summer. They were also most abundant offshore of the region between Cape Lisburne and Wainwright at stations with bottom water temperatures cooler than 5.0°C. In contrast, demersal juveniles of saffron cod were most

abundant nearshore off Cape Lisburne and in northern Kotzebue Sound where bottom water temperatures were warmer than 7.5°C (Figure 3b, d).

Polar cod and saffron cod were similar in mean size in June when their distributions also overlapped. Later in the season, far fewer saffron cod (*n*= 420) were captured and measured compared to polar cod (*n*= 1981). Demersal saffron cod were larger than those found in the water column in the late summer. The range of daily growth rates was wider for saffron cod than polar cod, but the mean daily growth rate was similar between saffron cod and polar cod at 0.37 ± 0.16 and 0.39 ± 0.06 mm day^{-1}, respectively (*n*= 4).

IBM Simulated Data

Simulated distribution and size of polar cod

On June 19th, simulated polar cod hatching in Kotzebue Sound between March 15th and May 15th had similar dispersal trajectories and were mostly found to be retained in and around Kotzebue Sound and in the nearshore region northward to Cape Lisburne (Figure 5). At Cape Lisburne, some larvae were transported offshore to the north and to the west, and were concentrated in two different trajectories, except for simulated individuals hatched on May 15th. Other individuals were transported northward along the coastline. Based on the 2017 simulations, no individuals were transported to the south in the late spring, though polar cod were observed in the late spring survey around St. Lawrence Island (Figure 2a; Figure 5). By September 1st, simulated polar cod were found in the nearshore region from Kotzebue Sound north to Wainwright (Figure 6). Simulated polar cod were advected offshore, almost due west, at Cape Lisburne/Point Hope. Hatch date did not greatly impact the end points of the simulated polar cod on September 1st (Figure 6). In the late summer, simulated polar cod were abundant offshore of Cape Lisburne/Point Lay and Wainwright but uncommon nearshore along the coastline from Kotzebue Sound to Wainwright (Figure 6), which was consistent with the empirical data (Figure 2b; Figure 3).

The mean size of simulated polar cod individuals hatched between March 1st and April 1st was larger than individuals captured in the field (Figure 4, Figure 7). Simulated individuals hatched on May 1st and May 15th were on average smaller than the field samples. For larvae that hatched on April 15th, the average size of simulated polar cod matched the average size of the captured individuals, although the range was broader for the individuals caught in the field compared to the simulated individuals (Table 2, Table 4). In the late summer, the average size of the simulated polar cod was smaller than the wild-caught specimens regardless of hatch date (Figure 7). The simulated sizes were most similar to polar cod captured using the bongo in the late summer (Table 2, Table 4).

Simulated distribution and size of saffron cod

The simulated distribution of saffron cod in the late spring and late summer was similar to that of polar cod (Figure 8). Similar to polar cod in the late spring, no simulated saffron cod larvae were found along the southern coastline of Kotzebue Sound, whereas saffron cod larvae were captured along the southern coastline of Kotzebue Sound and northern coastline of Norton Sound (Figures 2-3). In the late summer, simulated saffron cod were densely concentrated along the coastline extending from Kotzebue Sound to just north of Wainwright with two offshore advection areas at Point Lay/Cape Lisburne and south of Wainwright (Figure 9). Catches of saffron cod were low in the late summer but the areas with the highest catches corresponded to high density areas identified by the model, particularly offshore of Wainwright and Point Lay/Cape Lisburne (Figures 2-3; 9).

Regardless of season or hatch date, simulated saffron cod were smaller on average than field captured individuals (Table 2, Table 4). In addition, the length range of simulated individuals was narrower than the captured individuals in the late spring and summer (Figure 10). Unlike simulated polar cod, there was little overlap in the late spring and late summer sizes of simulated saffron cod (Figure 10). In the late spring, simulated saffron cod did not grow larger than 8.5 mm NL and had a mean size of 5.7 mm NL

± 0.0025-0.0037 for all simulated hatch dates (Figure 10, Table 4). In the late summer, the average size of simulated saffron cod ranged from 14.6 mm SL ± 0.024 to 14.9 mm SL ± 0.023 (Figure 10, Table 4).

Discussion

Spawning areas and drift

Sea ice was present in Kotzebue Sound at the approximate time of hatch for both polar cod and saffron cod until early June (S. Danielson, UAF, unpublished data; Cavalieri et al. 1996), suggesting that sea ice may be important for the newly hatched larvae of both species. Kotzebue Sound may indeed be a hatching area for polar cod and a source of juveniles to the north later in the summer. One of the main northward currents in the eastern Chukchi Sea is the ACC, which flows through Bering Strait and past the mouth of Kotzebue Sound and it is likely to entrain larvae originating in the Sound. Transport through Bering Strait has been increasing in recent years, which, in turn, has increased heat transport into the Chukchi Sea and the rate of sea ice retreat in the spring (Woodgate et al. 2012; Woodgate 2018), as well as current velocity that may increase the dispersal potential for ELHS entrained in the ACC. However, high polar cod abundance in the summer of 2014 corresponded to reduced transport through the Bering Strait (Randall et al. 2019), leading to decrease advection and higher local retention of ELHS. Simulations suggest that polar cod collected demersally and in the water column along the coast and in some offshores areas were likely hatched in Kotzebue Sound and were transported north by the ACC to the northern Chukchi Sea. We believe the likelihood of contamination of polar cod by Arctic cod (*A. glacialis*) is low and not of concern for our analyses. The identity of polar cod collected in the late summer AIES beam trawl was confirmed genetically (S. Wildes, Alaska Fisheries Science Center (AFSC), personal communication). Since the primary currents entering the US Chukchi Sea shelf flow from the south to the north (Danielson et al. 2017), it is unlikely that there is a source of Arctic cod, a high Arctic species, in the southern Chukchi Sea or Bering Strait that would substantially contribute to the larval gadid

community of the region (Aschan et al. 2009), especially considering the low sea ice and high water temperatures observed in 2017 (Timmermans et al. 2017; Perovich et al. 2017).

Saffron cod are caught in lower densities than polar cod in the late summer, likely due to their ELHS preferring nearshore habitats not sampled by our surveys (Logerwell et al. 2015; Vestfals et al. 2019). Similar to polar cod, Kotzebue Sound may be a hatching or early nursery area for saffron cod in the late spring. Demersal saffron cod were concentrated in the nearshore, warm waters in northern Kotzebue Sound and around Cape Lisburne, which was similar to the model-predicted distribution, suggesting that saffron cod hatched in Kotzebue Sound were the major source of demersal individuals in the late summer of 2017. Albeit speculative, the few larval saffron cod caught in the water column offshore of Wainwright and Barrow Canyon may be a result of a bet-hedging spawning strategy for saffron cod spawned in Kotzebue Sound and Bering Strait, such as has been documented in other sub-arctic gadids (Laurel et al. 2008; Hutchings and Rangeley 2011). Prolonged hatching periods will result in later hatched saffron cod larvae developing in warmer water where growth rates may be enhanced if mortality related to prey and predators is reduced (Laurel et al. 2008).

Growth and development

The daily growth rates calculated for polar cod and saffron cod were based on individuals collected in the water column and along the bottom using gears that collectively target larvae and juveniles and are used as a coarse estimate of growth in the US Chukchi Sea in the absence of otolith-derived growth rates. Assuming no size-selectivity over the range of sizes that were present, we were able to estimate a range of daily growth rates based on changes in mean length between specimens collected in the late spring and late summer of 2017. Our estimates assume that measured individuals were randomly selected from the same cohort sampled in the late spring and again in the late summer. However, it is probable that individuals from other hatching locations and cohorts were present in the northern Chukchi Sea in the late summer, violating this assumption (e.g., larvae originating from the other side of

the U.S. –Russian Federation maritime boundary). In our region in 2017, hatching was observed from January through May, with a peak in April (Z. Chapman, UAF, personal communication), based on the individuals captured during the late spring bongo samples. However, we are likely missing newly hatched larvae in the late spring bongo samples due to the extrusion of these individuals through the 505 µm bongo net mesh (Thanassekos et al. 2012), biasing our samples to individuals that hatched earlier or possessing higher growth rates. The daily growth rate results should be interpreted with caution without a more robust measure of growth using otolith-derived estimates, which is impossible for our study due to our specimens being preserved in formalin at sea. Otolith-derived ages would provide refinement of the length-based daily growth rates estimated in this study by determining individual growth rates and allowing for subsequent exploration of differences in growth trajectories by gear type, sampling season, and region. However, we did account for differences in growth rate by gear type and sampling time by estimating daily growth rates as a range, providing a conservative and a maximal estimate each late summer survey and gear type. Our length-based daily growth estimates also assume a constant growth rate over the sampling season, which is likely violated as individuals attain later stages and larger sizes (Thanassekos and Fortier 2012).

Daily growth estimated in this study for polar cod ranged from 0.27 mm day^{-1} to 0.53 mm day^{-1} with a mean of 0.39 ±0.06 mm day^{-1} (*n*= 4). Our most conservative growth estimate for polar cod (0.27 mm day^{-1}) agrees well with previous field studies (Bouchard and Fortier 2011; Thanassekos et al. 2012; Vestfals et al. 2019). Daily growth for polar cod in this study may also be higher than is typical due to the elevated water temperatures experienced in 2017. Even though polar cod are adapted to maximize growth at colder temperatures than saffron cod, warmer spring sea surface temperature and earlier ice retreat may be advantageous to larval polar cod due to the availability of zooplankton production supported by earlier ice algae and phytoplankton blooms. This would improve the temporal match of early hatching polar cod with their zooplankton prey (Bouchard et al. 2017). Under scenarios of continued warming in

the Arctic, polar cod may lose this growth advantage leading to reduced survival when thermal tolerances of their ELHS are exceeded.

This study is one of the first to estimate daily mean growth for ELHS of saffron cod (0.12-0.76 mm day^{-1}; 0.37 ± 0.16 mm day^{-1}; *n*= 4) collected within the Chukchi Sea. The conservative estimate for daily growth for saffron cod was based on bongo collections in the late summer. The lack of larger saffron cod in the bongo gear compared to the mid-water trawl suggests that larger saffron cod were present in the water column, but avoided the bongo net, which targets smaller individuals (De Robertis et al. 2017; Vestfals et al. 2019). A more realistic lower estimate for daily growth was derived from the mid-water IKMT at 0.56 mm day^{-1}. Saffron cod experience faster growth and better condition at higher temperatures than polar cod (Laurel et al. 2016; Vestfals et al. 2019), consistent with larger sizes and higher apparent growth rates in this study, therefore, a warming Arctic may favor saffron cod over polar cod. The growth advantage for saffron cod at higher temperatures may come at the expense of increased metabolic demands and a shift in the zooplankton community to smaller, less-lipid rich copepod species (Copeman et al. 2017; Aarflot et al. 2018; Møller and Nielsen 2020; Bouchard and Fortier 2020).

Model-data comparison

Kotzebue Sound was selected as the source of simulated polar cod and saffron cod ELHS in this study due to the preponderance of small larvae observed in this area in the late spring, highlighting the region's potential role as a key hatching and/or nursery habitat for the ELHS of these species. The observed distribution of Arctic gadids along the northern coastline of Kotzebue Sound in the late spring matched well with simulated larval distributions from the model. At Point Hope and Cape Lisburne, a portion of the Alaska Coastal Current (ACC) is often deflected offshore (Danielson et al. 2017), which is reflected in both the late spring model simulations and survey catch data. The IBM predicts that larval polar cod and saffron cod will be advected offshore and northward at Cape Lisburne. Consistent with the model simulations, we observed high catches of polar cod and saffron cod offshore of Cape Lisburne

during the spring survey. High abundances of polar cod and saffron cod may also be present north of Cape Lisburne in the spring as predicted by the IBM, but we lack the empirical data to test this as sampling did not extend north of Cape Lisburne. Additionally, the simulated distributions for saffron cod and polar cod from the IBMs were similar to each other. This is due to the use of a single release location (Kotzebue Sound) for both species and identical behavior routines so that differences in distribution in our study were associated with the species-specific temperature-dependent growth rates used to parametrize the IBMs (Vestfals et al. 2021).

There was no evidence from the model that larvae are advected south from Kotzebue Sound. Any spawning in Kotzebue Sound is likely not the origin of individuals that were caught around St. Lawrence Island or nearshore along the northern Seward Peninsula during spring. Recent modeling work suggests that polar cod hatching south of Bering Strait could be the source of larvae and early juveniles encountered in surveys in the northeastern Chukchi Sea in 2012 while Bering Strait and Kotzebue Sound were likely source regions for saffron cod in 2012 and 2013 (Vestfals et al. 2021).

In the late summer, the IBMs for polar cod and saffron cod indicated high concentrations of larvae and early juveniles nearshore from northern Kotzebue Sound to Wainwright, offshore of Point Hope/Cape Lisburne, and offshore of Wainwright. The modelled distributions agree with the observed late summer distribution of saffron cod where higher abundances were generally nearshore, especially around Point Hope and Cape Lisburne, with abundance decreasing offshore. This suggests that Kotzebue Sound is a center of abundance and potentially serves as an important spawning and hatching area for saffron cod in the Chukchi Sea, a possibility that has been suggested anecdotally (A. Whiting, Village of Kotzebue, personal communication; Vestfals et al. 2021). Larval polar cod were ubiquitous offshore in the Hanna Shoal region during the late summer surveys in 2017, which is consistent with polar cod distributions in other years (Logerwell et al. 2020), but was not captured well by the model, indicating that other hatching locations are major contributors to the observed age-0 aggregations in this area (Vestfals et al.

2021). The simulated distribution overlapped with the distribution of late summer polar cod ELHS individuals offshore of Point Hope and Cape Lisburne, as well as nearshore extending from Cape Lisburne to Wainwright, suggesting Kotzebue Sound may be a potential source of polar cod to these areas in the late summer.

Simulated lengths for both polar cod and saffron cod were smaller than observed specimens collected in the late spring and late summer from the water column or the bottom, with a much larger discrepancy for saffron cod than polar cod. This suggests that the model is underestimating growth, small larvae in the field experience higher mortalities than large larvae, temperatures in the model are underestimates, hatching occurs earlier than assumed, or a combination of these and potentially other factors. The growth equations for polar cod and saffron cod within the IBM are temperature-mediated (Vestfals et al. 2021), making simulated lengths and estimates of daily growth sensitive to thermal conditions in the model, which may differ from those experienced in the field. No growth model exists for ELHS of saffron cod larger than 10 mm in length and the growth model was parameterized using data for walleye pollock due to their similar, linear growth trajectories prior to 10 mm (B. Laurel, AFSC, personal communication; Porter and Bailey 2007; Petrik et al. 2015). However, saffron cod may deviate from linear growth trajectories at later stages or temperatures (Vestfals et al. 2021). Additionally, field estimates of apparent growth tend to be higher than those observed in the lab because of ecological interactions, such as size-selective predation (Houde 2009). The field-based growth calculations were relatively coarse, encompassing all the collected individuals aggregated from a large spatial area, over a two-month sampling period, and likely originating from multiple spawn locations, whereas the model is based on a single release location.

In the late spring, simulated polar cod hatched before April 15th were larger on average than the individuals captured from the water column, suggesting the model is realistically reflecting the enhanced growth rates of polar cod in the late spring due to earlier ice retreat and warmer water

temperatures in 2017 relative to average conditions. The narrow size range of individuals in the model compared to the field collections can indicate several potential scenarios. Firstly, Kotzebue Sound was selected as the source of polar cod and saffron cod larvae, but it is not the only source of larvae in the Chukchi Sea. For example, recent modelling work suggests that Bering Strait and Chukotka Peninsula were important hatching areas for polar cod in the Chukchi Sea in 2012 and 2013 (Vestfals et al. 2021). Secondly, the presence of smaller polar cod in the catch in the late spring may also suggest a simulated hatch date of April 15th or later, although the model does not capture the full range of observed sizes, particularly at the upper end. We selected to model hatch dates between March 1st and May 15th, which corresponded to the duration of peak hatching for polar cod in 2017, although hatching has been reported as early as January 1st for polar cod in the Arctic (Bouchard and Fortier 2011; Z. Chapman, UAF, personal communication). In polar cod, hatch date explains more variability in length than temperature conditions (Bouchard et al. 2017), therefore, some of the inconsistencies between the sizes, and subsequent calculated growth rates, of field collected and simulated individuals may be due to the hatch date variability. Thirdly, field estimates also differ from those observed under controlled laboratory conditions due to ecological factors that are difficult to account for (Bailey and Houde 1989; Houde 2009; Vestfals et al. 2019) such as patchy prey distribution and small-scale environmental variability (temperature, salinity, etc.). Polar cod are likely able to take advantage of a “big risk, big reward” strategy to forage for limited periods of time in warm, productive waters along thermal-salinity fronts to maximize growth relative to conspecifics (Laurel et al. 2016; Bouchard et al. 2017), which may contribute to the wider size range observed for the field-collected individuals compared to simulated individuals in the late spring.

Differences between simulated and empirical data may also be related to the onset of demersal behavior in polar cod and saffron cod, which is an adaptation to avoid predation, enhance foraging, and find areas of physiological preferred temperature ranges. Given the dominance of gadids by number and

biomass in demersal catches in the Arctic (Logerwell et al. 2015), fish predators of ELHS of polar cod and saffron cod are likely conspecifics. Cannibalism has been documented in other subarctic gadids and is mitigated by vertical partitioning between juveniles and adults (Bailey 1975; Bailey 1989). Adult walleye pollock in the Bering Sea are semipelagic and cannibalism was highest when juveniles moved deeper in the water column, overlapping with the adults (Bailey 1989). Cannibalism is considered rare for polar cod due to their planktivorous foraging strategy, although fishes do become an important prey category as polar cod grow, and instances of cannibalism have been documented (Bain and Sekerak 1978; Benoit et al. 2010; Christiansen et al. 2012; Whitehouse et al 2017). Polar cod forage primarily on copepod nauplii (e.g., *Pseudocalanus* spp.) when smaller than 25 mm SL and shift to foraging on the copepodite stages of copepods, specifically *Calanus* spp. and *Metridia* spp., and fishes when larger than 25 mm SL (Benoit et al. 2010; Christiansen et al. 2012; Bouchard et al. 2016; Bouchard and Fortier 2020). Saffron cod likely become more piscivorous with increasing size (Laurel et al. 2009), suggesting cannibalism may be more likely in this species than polar cod. Diet data are limited for saffron cod in the Chukchi Sea (Copeman et al. 2016). Increased water temperatures and constriction of available habitat for Arctic taxa may lead to increased cannibalism for polar cod and saffron cod as well as increased competition and predation if subarctic species move into the Chukchi Sea (Bouchard et al. 2017). A number of adult fish species from the Bering Sea, such as walleye pollock and Pacific cod, expanded northward in response to a reduced Cold Pool (bottom water temperatures < 2°C) over the Bering Sea shelf (Stevenson and Lauth 2019) and are possible competitors as well as predators of Arctic gadids in the Chukchi Sea if climatic warming persists (Marsh and Mueter 2019). Near bottom waters may also act as a thermal refuge for smaller Arctic gadids, particularly small polar cod that are not as tolerant to higher water temperatures as saffron cod (Laurel et al. 2016).

Summary

The late spring distributions of polar cod and saffron cod centered in Kotzebue Sound suggest that sea ice may be an important environmental factor influencing hatching, and it may provide a nursery habitat for newly hatched individuals of both species. Kotzebue Sound was likely a source of ELHS of polar cod and saffron cod offshore of Point Hope/Cape Lisburne and nearshore from Kotzebue Sound to Wainwright during 2017. Without otolith-derived individual growth estimates, it is difficult to know if polar cod and saffron cod experienced greater growth during 2017 compared to other years or regions due to elevated temperatures, although our daily growth estimates were higher than reported in past research (Bouchard and Fortier 2011). Saffron cod should benefit in a warmer Arctic if their ELHS are resilient to the loss of sea ice, and if energetic trade-offs can offset prey-mediated factors that may depress growth (i.e., reduced nutritional value, zooplankton community shift) (Llopiz et al. 2014; Spear et al. 2019) and an increase in competition and predation from sub-Arctic demersal fishes shifting to the north (Stevenson and Lauth 2019). With the forecasted warming in the Arctic and projected changes in sea ice dynamics, studies such as this one synthesizing the seasonal distribution, abundance, and growth of Arctic forage fishes are critical to assess changes in phenology, distributions, and abundance for these species and the impacts of warming on habitat availability for Arctic fishes.

Acknowledgments

The authors thank all of the boat and field crews of the USCGC *Healy*, M/V *Ocean Starr*, and R/V *Sikuliaq* who collected these data and without their tireless efforts, this project would not have been possible. We thank the Plankton Sorting and Identification Center in Szczecin, Poland and the ichthyoplankton team at the Alaska Fisheries Science Center for their taxonomic expertise that makes studies of the ecology of Arctic fishes possible. We also thank Jens Nielsen and Adam Spear for their assistance gathering and plotting the sea ice data as well as intellectual discussions on the interpretation of the data. Finally, we thank Katherine Hedstrom at the University of Alaska Fairbanks for providing the PAROMS model output and Caitlin Smoot and Cheryl Hopcroft, also at the University of Alaska

Fairbanks, for facilitating data collection and curation of ASGARD samples. Funding for this project was provided by the North Pacific Research Board through the Arctic Integrated Ecosystem Research Program. AMBON collections were made possible through a National Ocean Partnership Program (NOPP Grant NA14NOS0120158) by the National Oceanic and Atmospheric Administration, the Bureau of Ocean Management and Shell Exploration & Production. The findings and conclusions in the paper are those of the author(s) and do not necessarily represent the views of the National Marine Fisheries Service. Mention of trade names does not imply endorsement by NOAA or any of its subagencies. This is contribution number EcoFOCI-0XXX of Ecosystems and Fisheries-Oceanography Coordinated Investigations.

Author Contribution Statement

ALD, EAL, EDG, and JTD conceived and framed the key questions of the study. CDV conducted all IBM analyses, contributed code to generate figures related to the IBM, and provided text in the *Methods* sections. FJM, SLD, EAL, and RRH provided data that made the analyses possible. ALD wrote the manuscript and generated the figures. All authors read and approved the manuscript.

Declarations

Conflict of interest The authors have no conflict of interest to report.

Ethical approval All field sampling was done in accordance with NOAA NMFS policies, as outlined under the Animal Welfare Act and US Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training. Collections were made under the following permits approved by the Alaska Regional Office, National Marine Fisheries Service (CF-17-023), a US Fish and Wildlife Service Seabird Salvage Permit (MB035470), and a State of Alaska Resource Permit (CF-16-010).

Figure Captions

Figure 1 Survey stations sampled in 2017 in the Chukchi Sea, Bering Strait (BS), and northern Bering Sea. Bongo --Late spring black squares and late summer (August/September) gray squares; beam trawl– AMBON survey (August) blue inverted triangles and AIES (August/September) dark gray triangle; and

Isaacs-Kidd Midwater Trawl (IKMT) –AMBON survey (August) white circles. Simulated release locations from individual-based models in the eastern-most area of Kotzebue Sound (KS), which shaded in purple. Kotzebue Sound also refers to the broader region from the northwestern tip of Seward peninsula and Point Hope to the north. Depth contours extend from 50 to 350 m in 50 m increments.

Figure 2 Distribution of polar cod (*Boreogadus saida*) (a, b) and saffron cod (*Eleginus gracilis*) (c, d) in late spring (left column) and late summer (right column) 2017 collected in the water column with the 60-cm bongo net. Catch data are reported as catch-per-unit-effort (CPUE) and log(CPUE)+1 to highlight variability at lower abundances. Ice concentration (% cover) is plotted in the background. Black X's denote sampled stations where polar cod and saffron cod were not caught. Note the different scales for CPUE between the species.

Figure 3 Distributions of demersal juvenile polar cod (*Boreogadus saida*) from the late summer. AMBON (a) and AIES (b) beam trawl collections and of demersal juvenile saffron cod (*Eleginus gracilis*) from the AMBON (c) and AIES (d) beam trawl collections. The background color denotes bottom temperature in °C. Catch data are reported as catch-per-unit-effort (CPUE) and log(CPUE)+1 to highlight variability at lower abundances. Note the different scales for CPUE between the species.

Figure 4 Length distributions of polar cod (*Boreogadus saida*) (left) and saffron cod (*Eleginus gracilis*) (right) during the late spring (a, b) and late summer collections with 60-cm bongo (c, d), Isaacs-Kidd Midwater Trawl (IKMT) (e, f), AMBON beam trawl (g, h), and AIES beam trawl (i, j). Dotted black lines denote the mean length for each histogram. Blue bars represent individuals collected from the water column and brown bars represent those collected demersally. Specimens are binned into 2-mm length intervals and standardized by CPUE when all captured individuals were not measured (i.e., bongo).

Figure 5 Density of simulated endpoints from individual-based models in the late spring (June 19th, 2017) for polar cod (*Boreogadus saida*) larvae hatching in Kotzebue Sound. Hatch dates are: a) March 1st, b) March 15th, c) April 1st, d) April 15th, e) May 1st, and f) May 15th. Density is calculated in a 0.5 × 0.5 degree grid.

Figure 6 Density of simulated endpoints from individual-based models in the late summer (September 1st, 2017) for polar cod (*Boreogadus saida*) hatching in Kotzebue Sound. Hatch dates are: a) March 1st, b) March 15th, c) April 1st, d) April 15th, e) May 1st, and f) May 15th. Density is calculated in a 0.5 × 0.5 degree grid.

Figure 7 Length histograms of simulated polar cod (*Boreogadus saida*) larvae by hatch date from the individual-based model in 2017. Hatch dates are: a) March 1st, b) March 15th, c) April 1st, d) April 15th, e) May 1st, and f) May 15th. Blue bars represent late spring (June 19th) lengths and red bars represent late summer (September 1st) lengths. The dashed blue line denotes the mean size of the simulated polar cod in the late spring whereas the red dashed line denotes the mean size of the simulated polar cod in the late summer. Specimens are binned into 2-mm length intervals

Figure 8 Density of simulated endpoints from individual-based models in the late spring (June 19th, 2017) for saffron cod (*Eleginus gracilis*) hatching in Kotzebue Sound. Hatch dates are: a) March 1st, b) March 15th, c) April 1st, d) April 15th, e) May 1st, and f) May 15th. Density is calculated in a 0.5 × 0.5 degree grid.

Figure 9 Density of simulated endpoints from individual-based models in the late summer (September 1st, 2017) for saffron cod (*Eleginus gracilis*) hatched in Kotzebue Sound. Hatch dates are: a) March 1st, b) March 15th, c) April 1st, d) April 15th, e) May 1st, and f) May 15th. Density is calculated in a 0.5 × 0.5 degree grid.

Figure 10 Length histograms of simulated saffron cod (*Eleginus gracilis*) larvae by hatch date from the individual-based model in 2017. Hatch dates are: a) March 1st, b) March 15th, c) April 1st, d) April 15th, e) May 1st, and f) May 15th. Blue bars represent late spring (June 19th) lengths and red bars represent late summer (September 1st) lengths. The dashed blue line denotes the mean size of the simulated saffron cod in the late spring whereas the red dashed line denotes the mean size of the simulated saffron cod in the late summer. Specimens are binned into 2-mm length intervals.

ABSTRACT

Adult and juvenile (age-1) walleye pollock (*Gadus chalcogrammus*) were sampled by the US NOAA Alaska Fisheries Science Center summer bottom trawl survey in 2010, 2017, 2018, and 2019 in the northeastern and southeastern Bering Sea, with profiles of temperature collected concurrently. Similarly, the Russian Research Institute of Fisheries and Oceanography, Pacific branch, collected adult and juvenile pollock and temperature profiles on summer bottom trawl surveys in the northwestern Bering Sea. Results from these surveys show that adult pollock abundance in recent years (2017, 2018, 2019) has increased in northern regions of the Bering Sea shelf in both the US and Russian sectors. Lower abundances, compared to historic means, were observed in southern regions of the shelf, suggesting the pollock moved directionally from the south to the north. We relate changes in pollock distribution in recent intermediate (2017) and warm, low-ice years (2018–2019) to a prior cold, high-ice year (2010) and describe how these observations relate to our longer time series. We link temperature data from bottom trawl surveys (US and Russian), sea-ice indices (retreat timing and extent), as well as model-based estimates of ocean circulation to changes in pollock distribution and examine potential environmental factors driving the observed changes. Changes in sea-ice and bottom temperature (e.g., reductions in ice extent and shrinking of the cold pool), and changes in circulation (stronger northward currents over the northeastern shelf in warmer years, particularly in 2018) led to changes in distributions of adult and age-1 pollock. Adult pollock were concentrated north of St. Lawrence Island and had larger longitudinal distributions in warm years, 2017–2019; whereas they had a more southerly and narrow distribution over the outer shelf in the cold year, 2010. Age-1 pollock had higher densities over the inner eastern shelf in 2017–2019 compared to 2010. Northward flow around St. Lawrence Island (particularly in the spring) alternated between stronger flow on the west side of the island in 2010 and 2017 and stronger flow on the east side of the island in 2018 and 2019; variations in flow may have impacted the location of prey and movement of feeding pollock to the Chukchi Sea. Size structure comparisons between NW, NE and SE sections of the Bering Sea shelf suggest that movement of fish between US and Russian waters may have been highest in 2019, one of the two warmest years, and lowest in 2010, the coldest year. Spatial comparisons of distributions and size structure across the Bering Sea help provide a comprehensive view of factors affecting the movement of this highly important commercial fish species.

1. Introduction

Movement of fishes in response to environmental conditions is a well-documented, adaptive response to maximize reproductive success, growth, and survivorship. Typical activating factors include a suite of environmental (temperature and salinity gradients, precipitation and runoff, fluctuating current regimes) and biological variables (e.g., prey resources, habitat optimization, predator and/or competitor avoidance,

and mating and reproduction) that serve to initiate behavioral responses, either at the individual, population, or species levels. Climate change, particularly in the sensitive polar regions, exacerbates a number of these known drivers, prompting never-before-seen, population-level, spatial and distributional shifts (McLean et al., 2018; Mueter and Litzow, 2008). In the Pacific Arctic, large scale, northward movements of commercial stocks are underway as previously cold-dominated ecosystems warm and fish move directionally to higher latitude, relatively cooler environments. In the Bering Sea, such migrations have been recently documented among Pacific cod (*Gadus macrocephalus*), Pacific and Greenland halibut (*Hippoglossus stenolepis, Reinhardtius hippoglossoides,* respectively), and walleye pollock (*Gadus chalcogrammus,* hereafter pollock), (Kotwicki and Lauth, 2013; Spies et al., 2019; Stevenson and Lauth, 2019; Vestfals et al., 2016). In particular, shifts in the distribution of pollock are of special concern, as pollock in the eastern Bering Sea and Aleutian Islands (SE and NE shelf, Fig. 1) are the top US commercial fishery by biomass yielding over 1.3 million metric tons annually in recent years (2014–2017) (Fissel et al., 2019). In the western Bering Sea (including the NW shelf, Fig. 1) Russian pollock yearly yields are lower, ~0.4 million metric tons (Khen et al., 2013), but are still a highly important fishery. In addition to their economic importance, pollock are also a key ecological component of the Bering Sea food web across the shelf, serving as a critical link between lower (zooplankton) and upper (fish, seabirds, mammals) trophic levels (Buckley et al., 2016).

Adult and juvenile pollock distributions over the SE shelf have varied between cold, high seasonal sea ice (hereafter, ice) years and warm, low ice years over a 38-year time series (Kotwicki et al., 2005; Kotwicki and Lauth, 2013, Thorson et al., 2017). During cold years, an extensive "cold pool" forms on the eastern Bering Sea shelf below the pycnocline and persists through the summer. Although the cold pool is commonly defined as temperatures below 2 °C (e.g., Stabeno and Bell, 2019; Wyllie-Echeverria and Wooster, 1998), here, we use a cutoff of 0 °C (termed 0 °C cold pool in this manuscript), because adult pollock usually do not form feeding aggregations at temperatures below this threshold in the eastern Bering Sea (Baker, in press). Oceanographically, the eastern shelf has been classified into inner (<50 m), middle (50–100 m) and outer (100–200 m) domains, each separated by an oceanographic front (Coachman, 1986) (Fig. 1); the Aleutian Islands to 60°N, and 60°N to Bering Strait are considered to be the southern and northern Bering Sea respectively. Adults are typically located on the outer shelf outside (west) of the 0 °C cold pool during cold years, with distributions spreading eastward toward the middle shelf in warm years (Baker, in press; Baker and Hollowed, 2014; Kotwicki et al., 2005). Age-1 pollock tend to be distributed more northerly than adult pollock and are likely less able to avoid the 0 °C cold pool (e.g., Kotwicki et al., 2005; Thorson et al., 2017). Pollock over the NW shelf are typically observed off Cape Navarin in southern Anadyr Bay in cold or average years and also are limited by the 0 °C cold pool located northeastward from this area, but spread farther north and northeastward in warm years. Multi-year, warm-cold oscillations of the environment and pollock distribution have been fairly typical over the last 15+ years (Stepanenko and Gritsay, 2016; Zuenko and Basyuk, 2017), though recent years (2018–2019) have been extremely warm (with bottom temperatures anomalies of ~ + 3–4 °C on the northern middle shelf at mooring 8, southwest of St. Lawrence I), and characterized by a lack of sea ice during winter (Stabeno and Bell, 2019), a heretofore unprecedented event. Lack of winter ice has led to a cascade of observed ecosystem changes across multiple trophic levels (Duffy-Anderson et al., 2019; Huntington et al., 2020). During and just prior to this period (2017–2019), summer distributions of adult pollock also changed considerably, with large population biomass observed in the northern reaches of the Bering Sea (north of St. Lawrence Island and in northern Anadyr Bay).

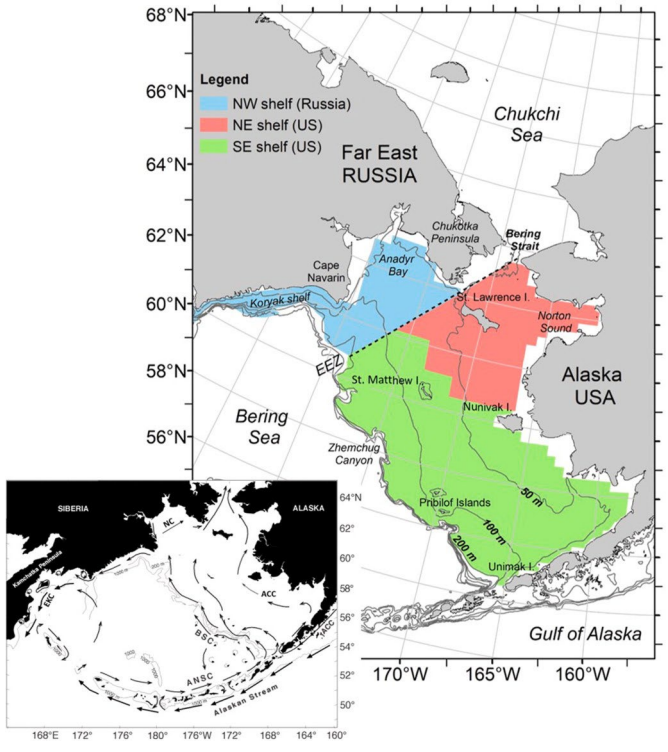

Fig. 1. Study Area. Regions sampled include the northwest (NW) shelf in the Russian EEZ, and the northeast (NE) and southeast (SE) shelf in the US EEZ of the Bering Sea. Contours denote the 50 m, 100 m, and 200 m isobaths. Inset figure shows currents in the Bering Sea. ACC = Alaska Coastal Current, ANSC = Aleutian North Slope Current, BSC = Bering Slope Current, EKC = East Kamchatka Current, and NC = Navarin Current.

Changes in summer pollock distributions are likely related, at least in part, to the extraordinary changes in sea ice and water temperature in the Bering Sea. The summer cold pool extent is determined by late winter ice extent (Wyllie-Echeverria and Wooster, 1998), and recent reductions in ice cover have drastically decreased the extent of the cold pool. In particular, 2018 and 2019 exhibited the smallest cold pool extent observed in at least the last two decades (Basyuk and Zuenko, 2019; Danielson et al., 2020; Overland et al., 2019; Stabeno and Bell, 2019). Retraction of the cold pool may be key to pollock northward distribution. Historically, the 0 °C cold pool was avoided by migrating adults. This effectively served as a barrier to fish passage from the southern to the northern Bering Sea. Profound, climate-mediated shifts in ice dynamics, coupled with associated oceanographic changes, may be altering this division, potentially creating a new paradigm of pollock dynamics across all reaches of the Bering Sea. For example, during fall and winter as ice is forming in the northern Bering Sea, pollock move south to continue feeding in warmer areas. Accordingly, in years with reduced ice extent, there may be less incentive to move to the most southern areas where their traditional spawning grounds are located. Early ice retreat and warmer temperatures during winter can also lead to earlier spawning and an earlier start of feeding migrations (Kotwicki et al., 2005). Changes in hydrography can lead to changes in currents, which then have large impacts on planktonic prey resources for adults (which follow prey) and on juvenile pollock (e.g., age-0 and age-1) and other forage fish species, that are smaller and more susceptible to current flow.

Mean flow on the eastern Bering Sea shelf is weakly (<0.05 m s^{-1}) northwestward (Fig. 1 Inset), along the shelf (e.g., Kinder and Schumacher, 1981; Coachman, 1986). The stronger Bering Slope Current (>0.10 m s^{-1} during winter) flows northwestward along the shelf-break, closer to the shelf-break during winter and farther off-shelf during spring and summer (Ladd, 2014). The Bering Slope Current splits in the northern Bering Sea with most of the flow feeding the southwestward flowing East Kamchatka Current, while a small part of the flow moves

onto the shelf toward Anadyr Bay and ultimately Bering Strait (Stabeno and Reed, 1994; Panteleev et al., 2011). This northward flow from Cape Navarin toward Bering Strait is known in Russia as the Navarin Current (Luchin and Menovshchikov, 1999). The turn to the north is associated with the density gradient between the low-salinity cold pool and the dense, high salinity cold water near the Chukotka coast, formed during winter ice formation. The Navarin Current is the only strong flow that penetrates deeply onto the shelf.

Historically, pollock distribution over the SE shelf is characterized by spatial separation of cohorts, which reduces competition among younger age classes for zooplankton prey, and minimizes cannibalism of younger stages by piscivorous adults (Duffy-Anderson et al., 2003). For example, age-1 pollock (unlike adults) are not able to perform long distance migrations (Kotwicki et al., 2005). Therefore, during their first winter age-1 pollock may not be able to migrate to ice free areas (as adults do), but instead many of them overwinter under the ice and stay in the cold pool throughout the summer. Adults avoid the cold pool, which results in a narrower spatial distribution. A result of this dynamic is a reduction in cannibalism of adults on age-1 pollock during cold years. Separation occurs in both the vertical and horizontal dimensions, and is precipitated by predation dynamics, differences in temperature tolerance, ontogenetic factors, diel shifts, and feeding and diet differences. On the NW shelf, however, spatial separation of pollock cohorts is absent; both adults and juveniles feed in the same area, though often in separate aggregations (Stepanenko and Gritsay, 2016). Climate-mediated shifts in ice and cold pool dynamics could alter the spatial partitioning for both the eastern and the NW Bering Sea, disrupting established feeding, refuging, and migrations across cohorts.

In order to fully assess the potential for broad-scale changes in pollock distribution over the Bering Sea and environmental factors driving these changes, it is critical to evaluate distributions across the entire shelf in both US and Russian sectors. The NOAA Alaska Fisheries Science Center (AFSC) bottom trawl survey now has 4 years of sampling (2010, 2017, 2018, and 2019) in the NE Bering Sea in conjunction with the ongoing annual sampling (1982-present) in the SE Bering Sea. These surveys are used to evaluate adult (age-4+) and juvenile (age-1) pollock distributions. The Pacific branch of Russian Research Institute of Fisheries and Oceanography (TINRO) has conducted similar bottom or midwater trawl surveys on the NW Bering Sea shelf since 1986, including the same 4 years. Our goal is to compare summer distributions and size structure data from SE, NE and NW shelf waters for these years, to decipher the extent of the pollock movement among these regions, and the environmental factors that influence these distributions. We lack information on large scale pollock distributions for seasons other than summer, therefore we are unable to fully evaluate the impact of environmental factors on winter, spring or fall distributions.

1.1. Three main questions will be addressed

1) How do adult and age-1 pollock summer distributions vary across the Bering Sea shelf in high-ice/cold (2010) compared to recent intermediate and low-ice/warm (2017–2019) years?
2) How do environmental factors (ice, water temperature, currents) influence the summer adult and age-1 distributions?
3) Are population size structures similar for US (SE and NE) and Russian (NW) collected pollock (suggesting mixing of the US and Russia origin populations)?

Our evaluations are intended to allow fisheries managers and commercial fishers to gain a better understanding of current changes in stocks and potential factors driving these changes.

2. Methods

2.1. Survey data

Pollock were sampled in 2010 and 2017–2019 on bottom trawl surveys (primarily) during summer months (June–August, Table 1) over the SE, NE and NW Bering Sea shelf (Fig. 1). Timing of the SE and NE surveys was consistent among years. The SE surveys were conducted in June through July with sampling starting with the easternmost stations within Bristol Bay and progressing westward toward the Bering Sea continental slope edge (depths > 200 m) and the US-Russia transboundary line. Sampling for the NE surveys were scheduled to start after the completion of SE survey and a port call to Nome, AK, to re-provision the vessels. NE survey sampling occurred during the first 2–3 weeks of August with a north-to-south progression. The timing of NW surveys varied more, in particular the 2017 survey was conducted in June through July, whereas surveys in the other years occurred from mid/late July to mid-August/early September. Therefore, survey timing overlapped most for the NE and NW surveys in 2010, 2018 and 2019 and for the SE and NW surveys in 2017. Measurements of water temperature were collected at all trawl stations. We lacked the data (e.g., higher temporal resolution data on pollock distribution outside of our survey date) to normalize the trawl data to a specific date (unlike the bottom temperature, described in 2.2.1. below). However, surveys were planned to take into account the timing of pollock movements, and therefore provide a general picture of fish distributions. The differences in survey timing described above can be used to understand finer scale differences among years and regions.

2.1.1. SE and NE bottom trawls

Bottom trawl survey data have been collected by the NOAA AFSC Groundfish Assessment Program on the SE Bering Sea shelf annually during the summer since 1982 (Fig. 1). The survey is based on a systematic design consisting of 376 fixed sampling stations located in the center of 37.04 × 37.04 km (20 × 20 nautical mile) grid squares with the survey ranging from 54.5°N to 62°N latitude and bounded by the 20 m and 200 m isobaths and the US – Russia Convention line to the northwest. Bottom trawl survey data using the same methods were collected

Table 1
Survey timing and mean surface and bottom temperatures (T, °C) for surveys on the SE, NE and NW shelves. See Fig. 7 for differences in areas surveyed among years (e.g., no sampling in Anadyr Bay (NW) in 2019 or Norton Sound (NE) in 2018).

Year	SE	NE	NW
2010	June 3 – August 4	July 23 – August 15	July 10 – September 6
Surface T	5.34	9.35	9.00
Bottom T	1.42	2.01	1.97
2017	June 3 – July 31	August 1 – August 26	June 7 – July 30
Surface T	7.99	9.63	9.08
Bottom T	2.67	4.37	2.46
2018	June 3 – July 30	July 31 – August 14	July 31 – August 18 (midwater trawl)
Surface T	7.59	10.23	9.80
Bottom T	4.14	3.94	2.94
2019	June 3 – July 28	July 29 – August 20	July 26 – August 8
Surface T	9.24	10.85	9.69
Bottom T	4.34	5.75	2.44

in the NE Bering Sea in 2010, 2017, 2018, and 2019. The NE Bering Sea shelf survey was designed as a continuation of the same systematic design established for the SE shelf survey, effectively extending sampling to 65.5°N latitude (Fig. 1). Note that in 2018 the survey extent and station spacing in the NE Bering Sea were non-standard, grid spacing was 55.6 km (30 nm) instead of 37 km (20 nm), and the Norton Sound region was not sampled. Sampling from the bottom trawl surveys in the SE and NE Bering Sea followed standard methods developed by AFSC (Lauth, 2011; Lauth et al., 2019; Stauffer, 2004). Vessels were equipped with 83–112 eastern otter trawls, which have a 25.3 m headrope, 34.1 m footrope, and a 32 mm liner in the codend to aid in retaining smaller animals. The mean effective opening of the trawl is 16.6 m horizontally and 2.7 m vertically.

Catch sampling followed standardized procedures described in detail by Wakabayashi et al. (1985) and Stauffer (2004). Catches with a total weight of 1150 kg or less were sorted and weighed in their entirety, whereas larger catches were randomly subsampled. Fishes were identified and sorted to species to the extent possible, weighed, and counted. For the predominant fish species encountered, including pollock, a random subsample was weighed, sorted by sex, and measured to the nearest centimeter (cm) fork length (FL). Relative abundance was calculated by determining the catch-per-unit-effort (CPUE). CPUE values from each survey are provided for age-1 and adult pollock and were calculated as total weight (kg) per km^2. Based on the results of pollock aging studies, fish were assumed to be age-0 at $<$ ~10 cm FL, age-1 at 10–19 cm, age-2/3 at 20–34 cm, and age-4+ adults at $\geq$ 35 cm (Kimura et al., 2006). Note that the majority of pollock $<$35 cm are less than 4 years old (Fig. A1), and are not consistently caught with the US gear (83–112 eastern otter trawl), with the exception of age-1s (Lauth, 2011).

Temperature and depth profiles were collected using a Sea-Bird Electronics (SBE) 39 datalogger that was attached to the headrope of the trawl. Observations were collected at 3-s intervals during the full duration of each tow. Mean bottom temperature was calculated as the mean temperature sampled between on- and off-bottom events, determined by the bottom contact sensor for each tow.

2.1.2. NW bottom and acoustic/midwater trawls

Bottom trawl data were collected in 2010, 2017, 2019, and a midwater trawl survey coupled with an acoustic survey was conducted in 2018 on the NW Bering Sea shelf and continental slope with bathymetry $<$500 m (Fig. 1). There was no survey in Anadyr Bay in 2019. The bottom trawl gear consisted of a DT-27.1/24.4 net with a horizontal opening of 16.26 m, vertical opening of ~3.6 m and a 10 mm mesh cod end (Savin, 2011). The midwater trawl RT/TM-80/396 had a 40 m opening and a 8 m cod end with 10 mm mesh; the layer from 350 m depth or from the shelf bottom to the sea surface was fished. Acoustics were done with an echo sounder SIMRAD EK-60, using the operating frequencies 38 and 120 kHz; the data were processed with SIMRAD software, with quantitative estimations based on the 38 kHz signals.

For bottom and midwater trawls, every catch was sorted and weighed entirely. Fishes and invertebrates were identified and sorted to species to the extent possible, weighed, and counted. For the predominant fish species encountered, including pollock, a random subsample was weighed, sorted by sex, and measured by centimeter intervals of fork length. Pollock density distribution was estimated following standard methods (Savin, 2011, 2018).

Temperature and salinity data were collected from CTD profiles using a SBE-19plus or SBE-25 deployed to the sea bottom at each station, immediately after trawling. All CTD data were processed with SBE software following standard methods and binned into 1-m bins. Bottom temperature was estimated as the deepest value of the profile.

2.2. Data analysis

2.2.1. Environmental variables

Environmental variables evaluated include sea-ice concentration during the preceding winter, summer bottom temperature, and spring and summer modeled bottom currents for 2010, 2017, 2018, and 2019.

Sea-ice maximum extent and timing of retreat were evaluated using satellite measurements from NOAA/NSIDC Climate Data Record of Passive Microwave Sea Ice Concentration, Version 3 (Meier et al., 2017; Peng et al., 2013) downloaded from the Alaska Ocean Observing System (AOOS) data portal (portal.aoos.org). Ice retreat timing was calculated as the day of year when ice concentration in each pixel reached (and remained) less than 30%. Winters 2009/2010, 2016/2017, 2017/2018 and 2018/2019 were designated as 2010, 2017, 2018 and 2019, respectively.

Bottom temperature data from the SE, NE and NW shelf surveys were combined. The total number of temperature profiles varied from 532 in 2018 to 957 in 2010 (Fig. A2). The following procedure was used to estimate synoptic (normalized to July 15) bottom temperature from the surveys (data collected at different survey dates): 1) climatological bottom temperatures ($T_{clim}(x_i,y_i,t_i)$) were estimated from the World Ocean Atlas 2013 (WOA2013) version 2 monthly climatology (Locarnini et al., 2013) using linear interpolation; 2) for each measurement ($T_i(x_i, y_i,t_i)$), an anomaly from the interpolated climatology was calculated for the observed date and location ($T_{anom}(x_i,y_i,t_i) = T_i(x_i,y_i,t_i)-T_{clim}(x_i,y_i,t_i)$), thus removing any effect of the timing of observation; 3) bottom temperatures were then normalized to July 15 as the sum of the July 15 climatological value and the anomaly ($T_{norm}(x_i,y_i,15\ July) = T_{clim}(x_i,y_i, 15\ July) + T_{anom}(x_i,y_i,t_i)$).

Mean bottom currents for spring (March, April, and May average) and summer (June, July, and August average) over the Bering Sea shelf were examined using output from a regional ocean-sea ice model in the Bering Sea with 10 km horizontal resolution (named Bering10K hereafter). Bering10K is based on ROMS (Regional Ocean Modeling System) (Haidvogel et al., 2008), a terrain following vertical coordinate ocean general circulation model with tides, and is coupled to a dynamic-thermodynamic sea ice model (Budgell, 2005). Over the time period of examination, Bering10K is forced by prescribed surface atmosphere and ocean lateral boundary conditions from NOAA Climate Forecast System Reanalysis (CFSR) and its operational extension (CFSv2-OA). CFSR and CFSv2-OA are reanalyses products where a suite of satellite and in situ observations are assimilated into a coupled climate model (Saha et al., 2010); as such, they represent a best estimate

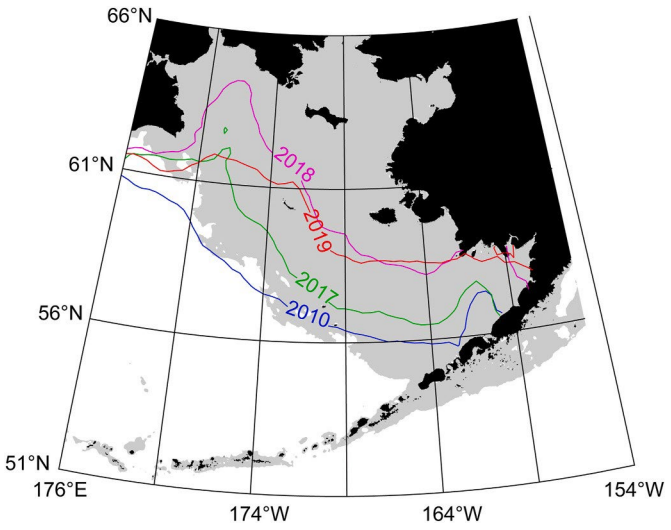

Fig. 2. Maximum sea-ice extent (defined as 30% concentration) in the Bering Sea for 2010, 2017, 2018, 2019.

of past historical climate conditions. The transport through the northern boundary (Bering Strait) is relaxed to the observed value of 0.8×10^6 $m^3 s^{-1}$ (Woodgate and Aagaard, 2005); sensitivity studies tested whether a seasonally varying open boundary condition could better replicate flow patterns in the northern portion of the domain, but the simple relaxation condition was found to perform equally well (Kearney et al., 2020). Bering10K modeling framework and detailed model evaluation are provided in Kearney et al. (2020).

2.2.2. Pollock distribution and size structure

The pollock distribution data were combined from US (SE, NE shelf) and Russian (NW shelf) surveys. Prior to combining data, the US data were corrected for density dependent efficiency of the survey bottom trawl (Kotwicki et al., 2014). The correction was applied using formula $CPUE_o/q$ where $CPUE_o$ is observed CPUE and q averaged 0.75 across years used in analysis and ranged between 0.73 and 0.77. This correction was applied because it has been established that corrected estimates are less biased and more precise with respect to the mean CPUE and variance (Kotwicki and Ono, 2019). The Russian data were not corrected, because for the years used in the analysis we did not have data to compare the efficiency of the US and Russian survey bottom trawls. However, data from years 1982–1990, when both Russian and US surveys were conducted over the SE shelf, suggest that the median sampling efficiency ratio for the Russian survey relative to the US survey for pollock biomass was 0.7 ± 0.16 (O'Leary et al., in review). Because bottom trawl efficiency values in the past were close and we do not have data to estimate these values for the recent surveys we decided that the best approach was to not correct Russian CPUE data. Adult distribution maps were plotted in biomass units (kg km^{-2}), but juveniles (age-1) were plotted in abundance units (number km^{-2}) because of the highly variable weight of juveniles. Maps of pollock distribution overlain with bottom temperature contours (0 °C and 6 °C) were made with ArcMap (version 10.3,2014, ESRI, Inc.) by inverse distance weighting CPUE data (kg/ha) for adult and age-1 pollock in each survey year for the SE and NE shelf.

The preferable bottom temperature and bottom depth range for adult and age-1 pollock was evaluated by comparing mean proportions of pollock abundance relative to bottom temperature and depth for data collected in the SE and NE Bering Sea from 1987 to 2019. We were unable to perform these analyses for pollock collected on the NW shelf.

Pollock size distribution data were plotted as histograms for the three areas of the Bering Sea shelf. Percent frequency of occurrence (proportion of individuals) was plotted for each 1 cm length bin. In 2018, size structure was evaluated only for the NE and SE Bering Sea shelf since the NW pollock data were collected with midwater trawls, which likely collect smaller fish than bottom trawls and could bias the size estimates for comparison. Note that in 2019, the NW fish collection was limited to the Koryak shelf and Cape Navarin (southern part of NW shelf, Fig. 1).

3. Results

3.1. Environmental variables

Of the four years (2010, 2017, 2018, and 2019), maximum sea-ice extent was greatest in the winter of 2010, followed by 2017 (Fig. 2). Maximum extent was comparable in the two years 2018 and 2019 in the eastern Bering Sea. However, on the NW shelf (Anadyr Bay), 2018 exhibited a notable lack of sea-ice compared with the other years. The timing of sea-ice retreat at a given location was much earlier in 2018 and 2019, followed by 2017, then 2010 (Fig. 3). For example, ice retreated southeast of St. Lawrence Island in April 2018 and 2019, May 2017 and June 2010.

Bottom summer temperature data (normalized to July 15) show the

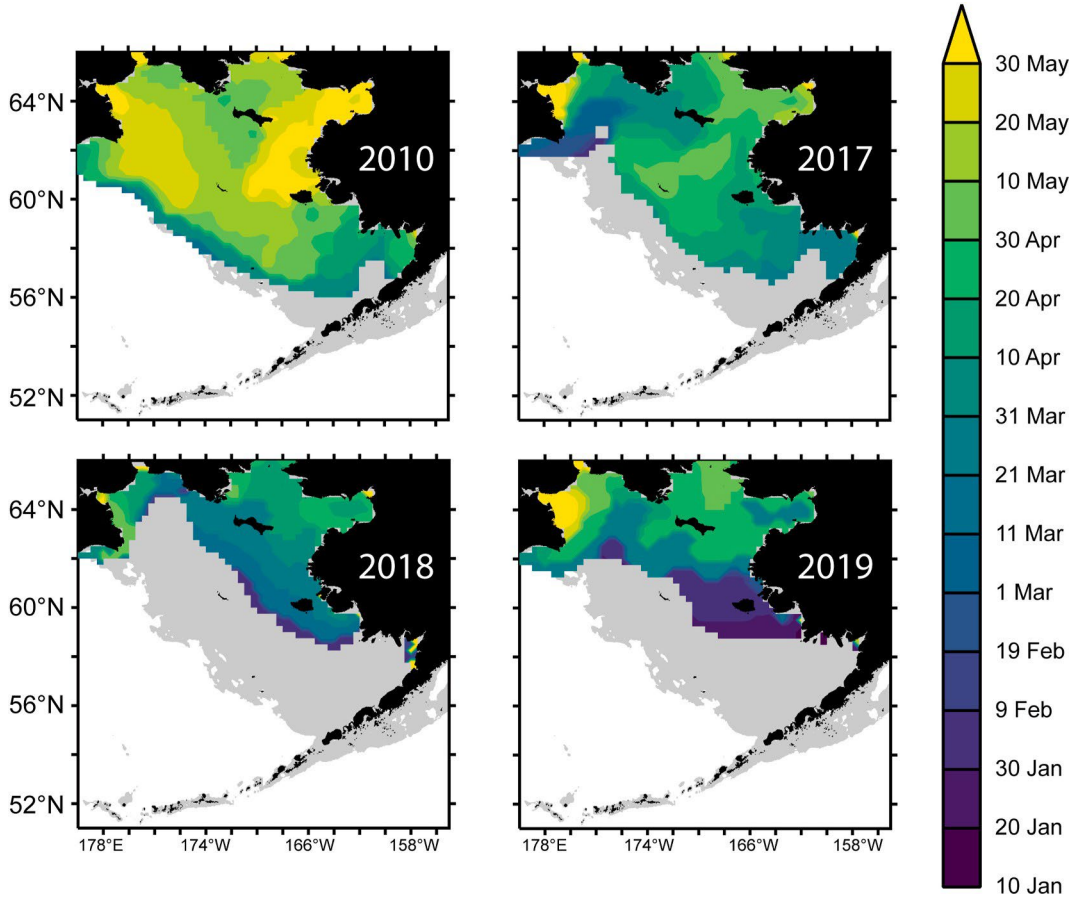

Fig. 3. Ice retreat day of year: the date when sea-ice concentration fell below 30% and remained below 30% for the remainder of the summer.

cold pool extended into the southern shelf in 2010 and 2017, but not in 2018 or 2019 (Fig. 4). Water colder than 0 °C was almost nonexistent in 2018 and was limited to south and west of St. Lawrence Island in 2019. In 2017, on the southern shelf, the water colder than 0 °C was limited to a small area compared to 2010 when the low temperatures extended over almost the entire middle shelf. Bottom temperatures were extremely warm (12–15 °C) along the eastern Inner Domain in 2017, 2018 and 2019, but ≤ 10 °C in the same region in 2010. Otherwise, temperatures in 2010 remained <2 °C, aside from small areas in outer Anadyr Bay (2.5 °C), just north of St. Lawrence Island (3 °C), and outer Norton Sound (2–3 °C). In 2017 and 2018, larger areas with higher temperatures were observed in Anadyr Bay, north of St. Lawrence Island and in Norton Sound. Data were not available for 2019 in Anadyr Bay.

Bottom currents on the northern shelf from Bering10K show that the strongest spring (March, April, May) and summer (June, July, August) currents (>5 cm s^{-1}) in all years were found NW of St. Lawrence Island and in Bering Strait (Figs. 5 and 6). In the spring, northward flow between St. Lawrence Island and the Chukotka Peninsula was strongest in 2010 and 2017 while flow on the east side of St. Lawrence Island was stronger in 2018 and 2019. During summer, flow west of St. Lawrence Island was strongest in 2017 while east of the island, flow was weaker and did not exhibit the same interannual variability as observed in the spring.

In Anadyr Bay during both spring and summer, flow into the bay (toward the northwest) was strongest in 2017, feeding the flow around the Chukotka Peninsula toward Bering Strait. During spring, flow was predominantly out of the bay (toward the southeast) in 2018 and 2019. In 2010, spring flow was weak and spatially variable in the bay but stronger across the bay mouth (toward the northeast). During summer, flow in all years was predominantly directed into the bay but stronger on the southwest side.

3.2. Pollock distribution and size structure

Adult pollock distributions during summer varied among years across the Bering Sea shelf (Fig. 7). In 2010, the pollock were found in high concentrations (>10,000 kg km^{-2}) in the outer shelf from the middle front to the shelf break (100–200 m bathymetry), and in patches north of Unimak Island in the south and outside of Anadyr Bay on the NW shelf (Fig. 7). In 2017 the adult pollock were more widespread across the shelf with high concentrations in western Anadyr Bay and north and west of St. Lawrence Island up to Bering Strait with smaller patches south of the island. In 2018, there was a low abundance of pollock on the SE shelf with small high density patches north of the Aleutians and near the Pribilof Islands; the highest concentrations were found on the northern outer shelf, and north and west of St. Lawrence Island to the Bering Strait, the northern limit of the available bottom trawl survey data. Acoustic data for the NW shelf in 2018 also indicate high densities of pollock south and west of St. Lawrence Island at the mouth of Anadyr Bay (Fig. 8). In 2019, the adults were found over most of the outer and middle shelf with high concentrations also south of Bering Strait. Since there was no 2019 survey in Anadyr Bay, concentrations in that region could not be evaluated.

The adult distributions appear to relate to the seasonal coverage of sea-ice and bottom temperature. In the high and moderate ice years of 2010 and 2017, respectively, the adults were located outside (west) of the 0 °C cold water region (Figs. 4 and 7; Fig. A3). Whereas, in the very low ice years (2018 and 2019) with almost no bottom water colder than 0 °C, the adults were more evenly distributed over the middle and outer shelf. However, these fish were not found in temperatures above 6 °C (Figs. 4 and 7; Fig. A3); thus, distributions in these years may have been constrained by high rather than low temperatures. A comparison of bottom temperature and depth range for adults in the eastern Bering Sea for 1987 to 2019, indicates that most adults are found at temperatures of 0–6 °C. On average only about 2.5% of adults were found below 0 °C and less than 1% above 6 °C (Table 2). Overall, cross-shelf distributions were

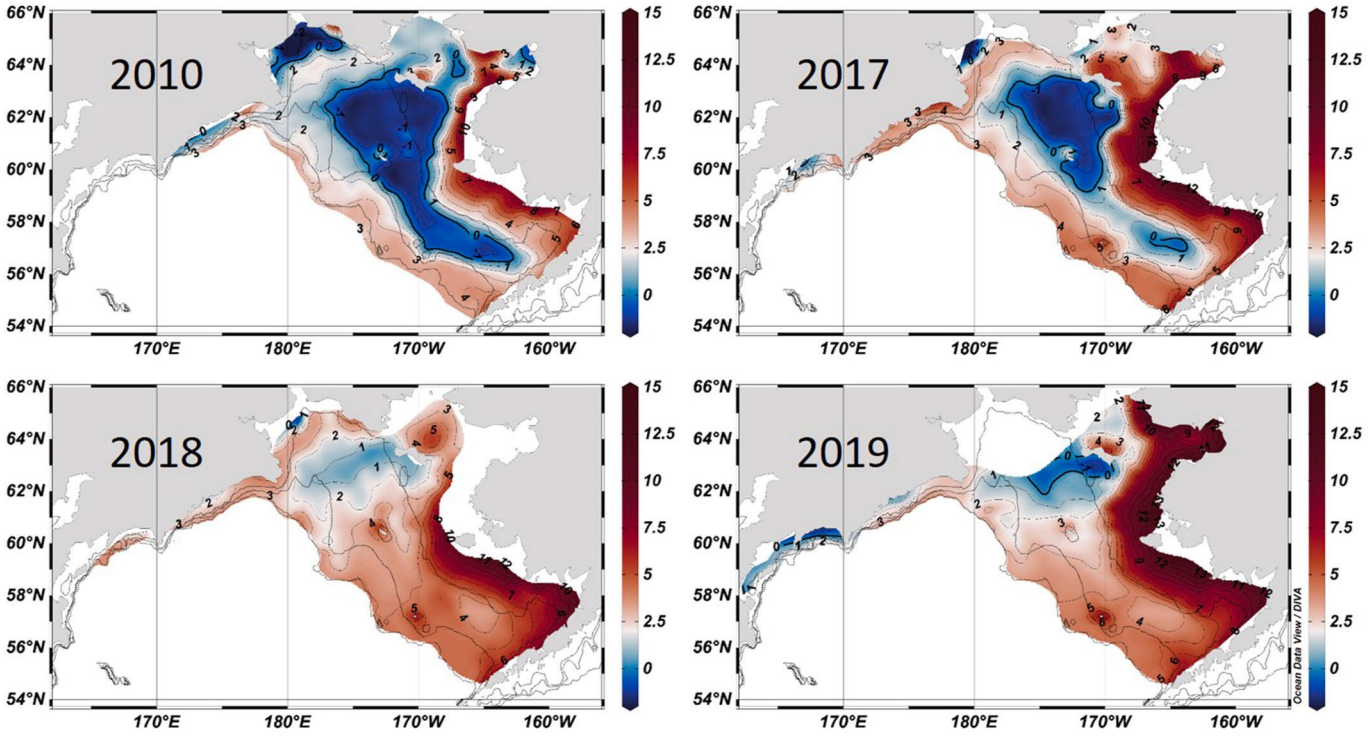

Fig. 4. Bottom temperatures from summer fisheries oceanography surveys for 2010, 2017, 2018, and 2019, normalized to July 15. The cold pool (<2°C) is designated by blue with the 0 °C contour designated by the bold line. (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

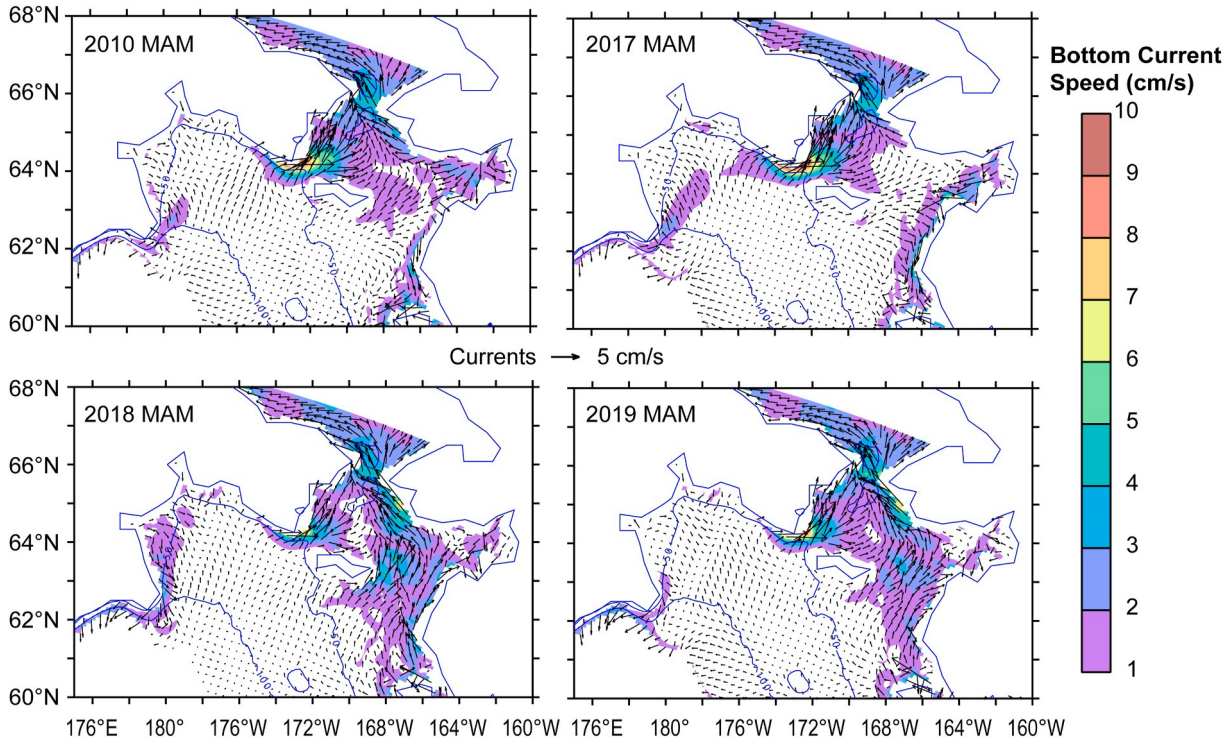

Fig. 5. Bottom currents averaged over March, April and May for 2010, 2017, 2018, and 2019 from the Bering10K model.

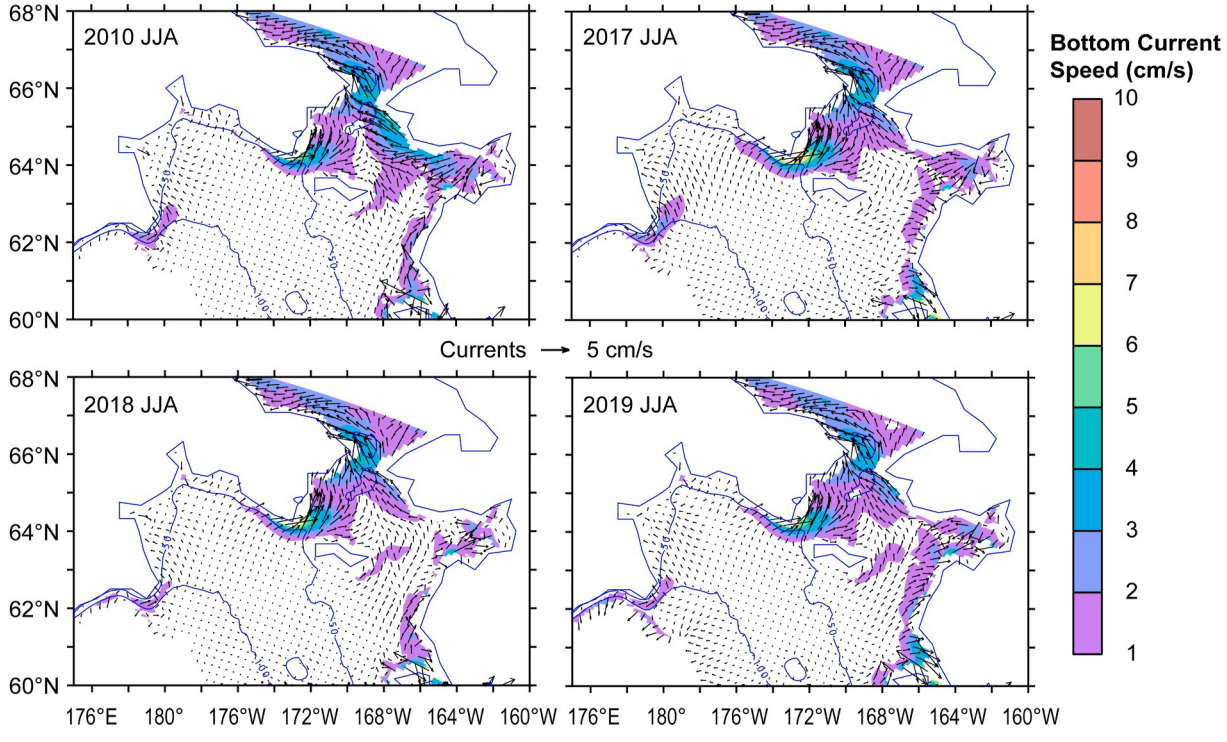

Fig. 6. Bottom currents averaged over June, July and August for 2010, 2017, 2018, and 2019 from the Bering10K model.

larger (extended over a greater depth range) in warm than in cold years. The high adult concentrations located north of St. Lawrence Island and in the NW region in 2017–2019 coincided with areas of higher bottom temperatures. Additionally, high concentrations of pollock were found on the northern middle shelf between St. Matthew and St. Lawrence islands in 2019.

General patterns of the adult distribution in the NW and NE regions may partially relate to the summer currents. In 2010, 2017 and 2018, high concentrations of adults were present in western Anadyr Bay potentially following the Navarin Current. Concentrations of adult pollock were also high to the west and north of St. Lawrence Island toward Bering Strait in 2017–2019, in the region of high currents. In the NE, adult pollock densities were much lower in 2010 compared to the 2017–2019, while in the NW there was not much difference in pollock

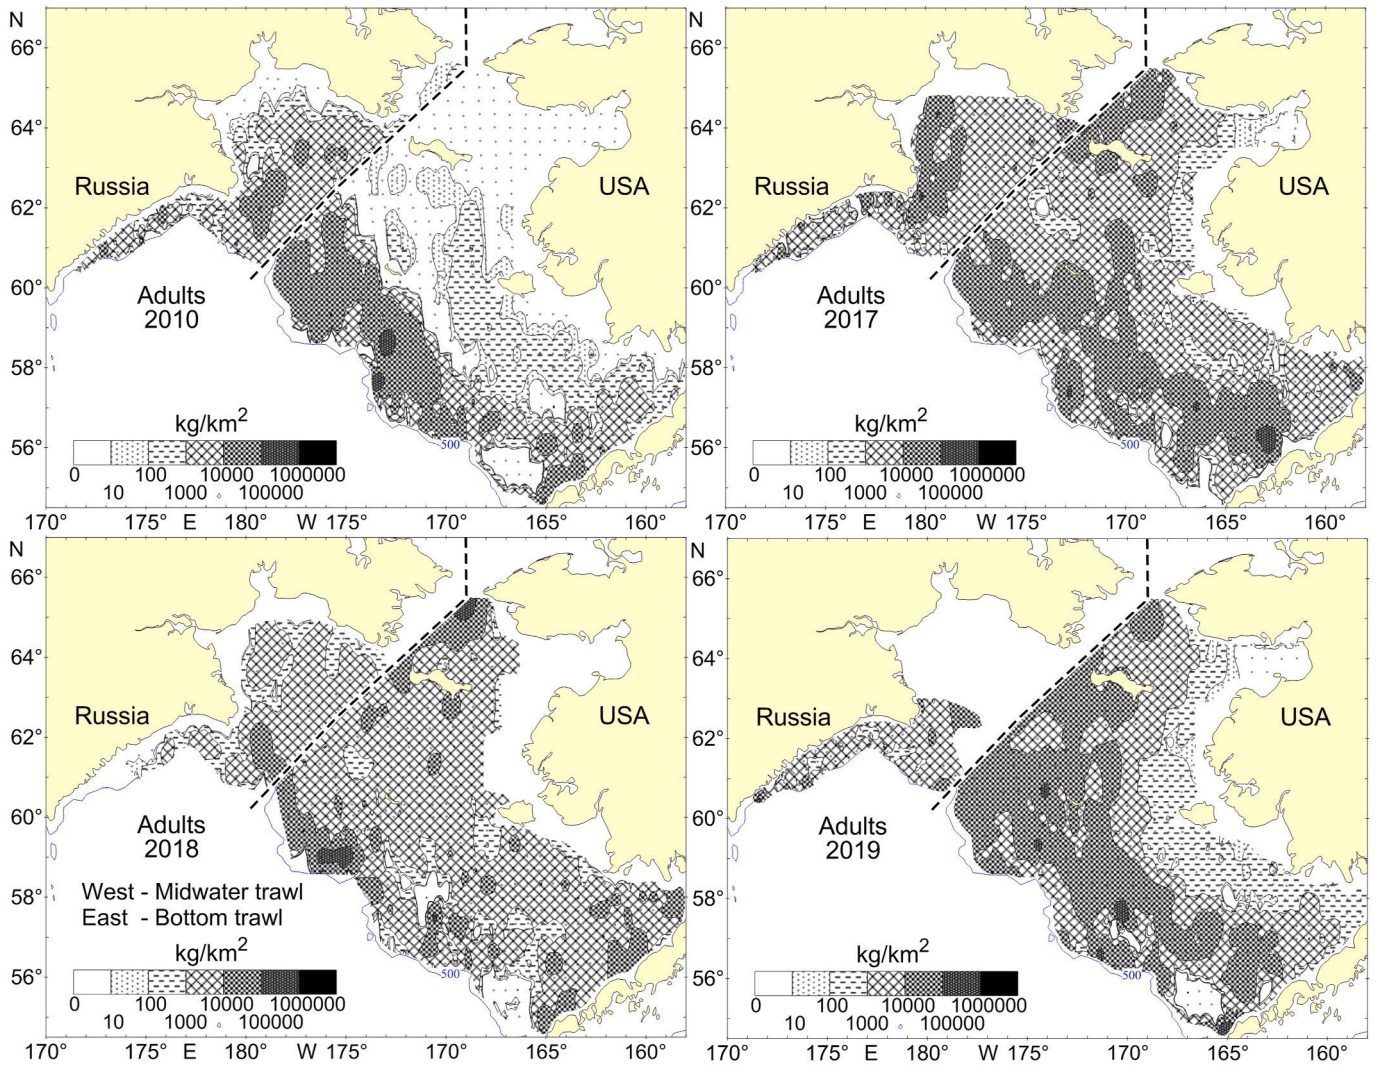

Fig. 7. Adult biomass distribution (kg km^{-2}) for pollock on the Bering Sea shelf from bottom trawls and pelagic (midwater) trawls (2018, NW area) in relatively cold conditions of 2010, intermediate conditions of 2017, and warm conditions of 2018 and 2019 during summer. See Table 1 for surveys dates by region and year. Fisheries sampling stations indicated by dots. US-Russia transboundary shown by dashed line.

densities between these periods.

Age-1 pollock tended to have a more northerly distribution than adults (Figs. 9 and 7). In 2010, age-1 pollock were generally in higher concentration (>1000 km^{-2}) in the outer shelf, but not as far offshore as adults, with smaller patches in the middle shelf, similar to adults, but also had high concentrations in Anadyr Bay (Fig. 9). In 2017, age-1 pollock were found in similar locations on the SE outer shelf and in Anadyr Bay, but were also located on the eastern inner shelf between Nunivak and St. Lawrence islands. In 2018 and 2019, age-1 pollock had a larger cross shelf distribution with the high concentrations located near the eastern inner shelf particularly in 2019 (large area with >10,000 pollock km^{-2}). Fewer age-1 pollock were observed in Anadyr Bay in 2018; there was no survey within Anadyr Bay in 2019, although there is an indication of high concentrations of age-1 pollock south of this area.

Age-1 pollock were found over a greater bottom temperature range than adults (Table 2, Fig. A4). Some age-1 fish were found in temperatures <0 °C, although the highest concentrations were found outside of the 0 °C cold pool. Age-1 pollock on the eastern inner shelf in 2018 and 2019 were found in warm (10 °C) water, much higher than the 6 °C temperature limit for adult distributions. On average age-1 pollock appear to be more widely distributed across bottom temperatures and depths, as indicated by an average 5.7% of age-1 pollock distributed in waters below 0 °C, and 6.7% in waters above 6 °C (Table 2). The high concentrations of age-1 pollock over the eastern inner shelf in 2018 and 2019, in particular, were located in an area with notable northward bottom currents (1–4 cm s^{-1}) south and east of St. Lawrence Island during spring (March–May) (Figs. 9 and 5). Age-1 pollock were not found in this eastern inner shelf area in 2010 when spring (and summer) northward bottom currents were low.

Pollock size structure data indicate differences in several year classes/age groups in the NW compared to SE and NE fish; this is particularly evident in 2010 and 2017 (Fig. 10). For example, in 2017 for NW pollock there were 5 distinct modes in length frequency histograms at ~13, 21, 28, 39, and 48 cm. Only modes similar to the first and last high modes for NW fish were seen in the NE fish at 15 and 49 cm, and in the SE fish at 15 and 45 cm. Age-1 pollock (~10–20 cm, Kotwicki et al., 2005) were found in all regions (NW, NE, and SE) in all years (2010, 2017, 2018, and 2019); the percentage of age-1 pollock were highest in 2010 in the NW and NE, and in 2019 in the NE. In 2010, the cold year, a 40 cm mode was observed both in the SE and NW. Each warm year (2017, 2018, and 2019) appeared to have a different pattern among regions in the size of the largest fish (>35 cm). In 2017, all 3 regions had main modes from 40 to 50 cm, but in the NW there was an additional mode at 39–40 cm. In 2018, the main mode in the NE was larger than in the SE (51 compared to 44 cm), and in 2019 all regions have similar size structure with the

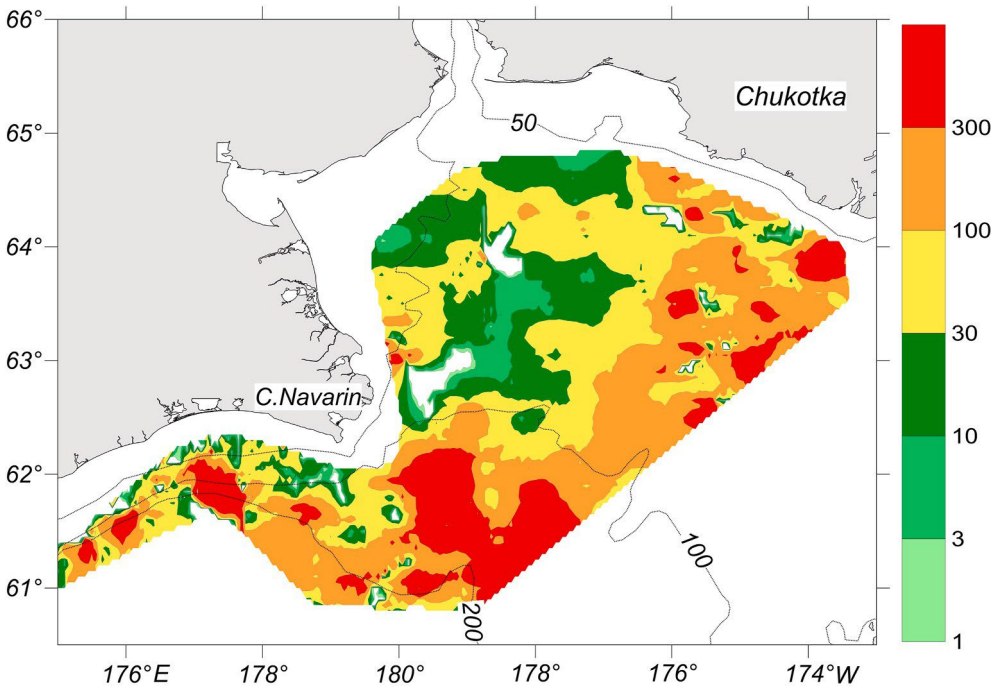

Fig. 8. Pollock distribution in the NW Bering Sea in August 2018 from the acoustic survey. Color bar indicates metric ton/nautical mile^2. The data are kindly presented by Dr. M.Y. Kuznetsov, TINRO. (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

main mode at 46–48 cm and minor modes at 23–25 cm. Spatial differences in size structure were observed even within areas. For example, the two modes for adult pollock in the NW in 2017 reflect the spatial inhomogeneity of size structure within this region. The relatively small fish with the dominant size 39–40 cm were numerous in the southern area (on Koryak shelf), whereas the fish > 50 cm strongly prevailed at the Chukotka coast in the northern Anadyr Bay. Possibly, these two peaks were formed by fish with the same age, but different origin. The same main size group of adults (age-4+ fish, last mode) is observed in all 3 areas in all years, with exception of the NE in 2010 where it was totally absent.

4. Discussion

4.1. Environmental factors related to changes in pollock distribution

Recent changes in adult and age-1 summer pollock distributions in the Bering Sea appear to be related to changes in climate including ice cover, water temperature, and oceanographic currents. Like others have reported earlier, our analyses of US collected data suggest that during cold years when ice is present and extensive, adult pollock are constrained to the outer Bering Sea shelf, limited by the presence of the frigid bottom waters of the 0 °C cold pool (Kotwicki et al., 2005). During warm years when ice is lacking and the cold pool is negligible or absent, pollock are unconstrained by cold bottom temperatures and they shift their distributions northward. However, unique to this study are the inclusion of northwestern Bering Sea (Russian) derived data that demonstrate that not only are pollock distributions north-shifted after ice-reduced winters, but there appears to be more intensive mixing between the Russian stock as it moves north and eastward, and the US stock as it moves north and westward. Specifically we show that pollock expanded their distribution to the area between St. Matthew and St. Lawrence islands in the US, and the area between St. Lawrence Island and Bering Strait in both US and Russian waters. Russia – US stock mixing could portend changes in stock diversity, which has important implications for pollock population resilience, rebuilding, and recovery in the face of climate shifts and anthropogenic pressures.

Several atmospheric and oceanographic factors acted in concert to prompt the spatial shifts described above. Changes in winds during winter impacted the ice and currents in 2017–2019. The seasonally averaged wind anomalies for 2014–2018, compared to 1979–2013, indicate that winds from the south (toward north) were much more prevalent in winter and fall in 2014–2018 (Danielson et al., 2020). These northward winds were correlated to northward water flow in Bering Strait (Danielson et al., 2020), and promoted northward movement of ice (Stabeno and Bell, 2019). In winter 2018, winds from the south occurred in November 2017, and again in February 2018, whereas in winter 2019, more typical winds from the north (and typical ice conditions) occurred in December–January, followed by the return of winds from the south in February 2019 (Stabeno and Bell, 2019). The ice responded to these wind patterns with more ice present in early winter in Anadyr Bay in winter 2019 than in winter 2018, although ice was low elsewhere in the Bering Sea in both winters.

We hypothesize that in 2017, the pollock moved north from their spawning locations over the SE shelf to the NE and NW shelf, stayed farther north than normally over winter due to the low ice conditions, particularly the lack of ice in Anadyr Bay, and remained there in summer 2018 leading to large numbers north of St. Lawrence Island and on the NW shelf, and exceptionally small numbers of pollock in the SE in 2018 (Ianelli et al., 2019). In autumn-winter 2018/2019, adults preferentially moved south as ice concentrations in Anadyr Bay returned to normal in early winter. This may have led to fewer adults north of St. Lawrence Island and more adults in the SE Bering Sea in 2019 compared to 2018 and 2017 (Ianelli et al., 2019). Bottom temperature was shown to be the most significant predictor of pollock distributions for the 1982–2018 time series in the eastern Bering Sea; variables tested included temperature (bottom, surface, minimum, maximum, and range), depth, stratification, substrate, latitude, and longitude. (Baker, in press). Baker (in press) also found that pollock were associated with a bottom temperature range of 0–4 °C.

The high temperature band along the eastern Bering Sea inner shelf in very warm years, 2019 in particular, may limit adults from moving inshore. The increase in metabolic rates at higher temperatures requires pollock to consume more food to avoid starvation and maintain feeding

Table 2

Mean proportions of pollock abundance (% of total weight) for a) adult (>age-2) and b) age-1 pollock, and c) number of successful tows by bottom temperature (°C) and bottom depth (nearest 20 m) from US groundfish bottom trawl surveys (SE and NE), 1987–2019. NA indicates the number of tows = 0. Top 95% of non-zero values are in bold. Darker shading indicates higher values.

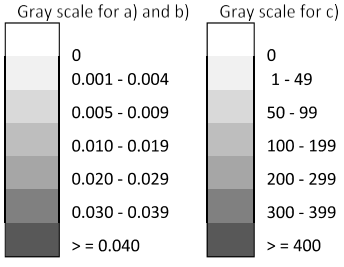

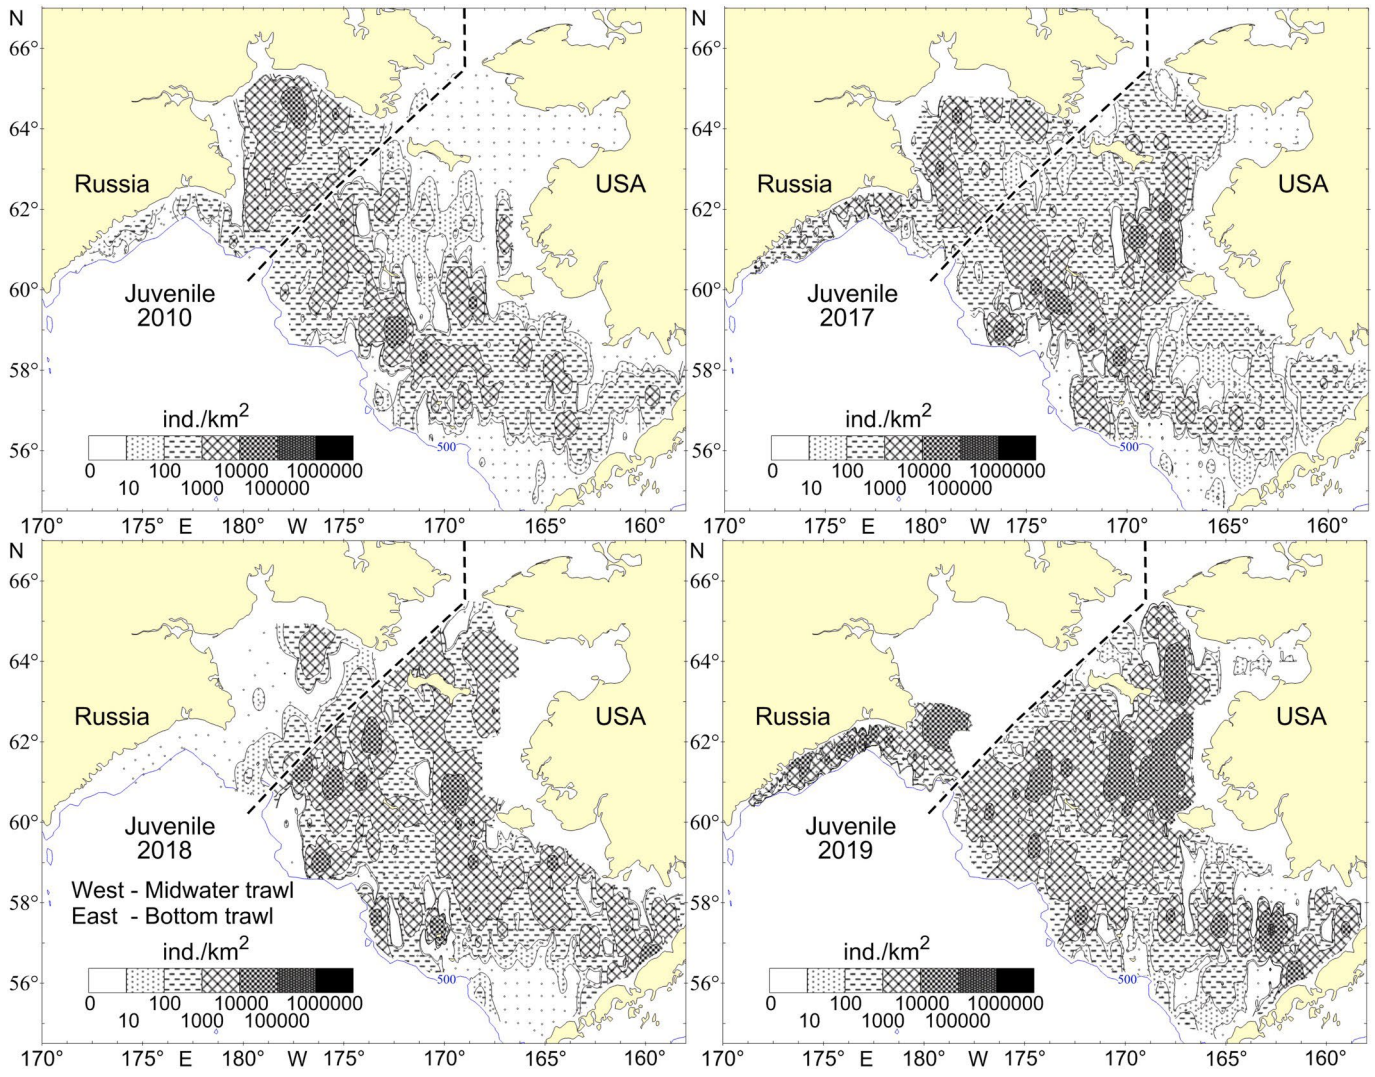

Fig. 9. Age-1 (juvenile) pollock abundance (number km^{-2}) for 2010, 2017, 2018, and 2019 from trawl surveys as described in Fig. 7.

and growth (Smith et al., 1988). The inner shelf varies from the middle and outer shelf ecosystems with differences in taxa and size of zooplankton and forage fish; for example, the inner shelf has smaller-sized and fewer lipid-rich zooplankton taxa (Eisner et al., 2014) and younger/smaller stages of forage fish such as Pacific herring (*Clupea pallasii*) (Andrews et al., 2016). Therefore, adult pollock may avoid or not survive on the inner shelf due to temperature limitation, low prey/food availability or a combination of these or other factors. The presence of age-1 pollock on the inner shelf may reflect the ability of juveniles to tolerate a larger temperature range than adults, as well as differences in preferred prey for adults and juveniles (Buckley et al., 2016). Pollock in the eastern Bering Sea have been shown to move from nearshore to offshore habitats as they progress from juvenile to adult stages (Baker, in press; Barbeaux and Hollowed, 2018; Hollowed et al., 2007).

We also hypothesize that heightened air and sea surface temperature in the northwestern Bering Sea in winter 2018 prevented the water column temperature from becoming cold enough to form a dense lens of water (cold pool) at the shelf bottom. In addition, the stratification was weak in the spring due to the lack of fresh water from ice melt, so the surface warmth could mix deeper, eroding whatever cold pool had formed over the winter(Stabeno and Bell, 2019). As a result, the Navarin Current, usually a strong northeastward flowing current in summer (Favorite et al., 1976; Luchin and Menovshchikov, 1999; Stabeno et al., 2016), was weaker compared to other warm years or sometimes absent. Instead, a northward stream developed that flowed along the eastern shelf and passed east of St. Lawrence Island (Fig. 5). This circulation change likely resulted in a change in pollock summer migration patterns by assisting them to move toward the Chukotka coast using both the Navarin Current and this along-shelf northward stream, as indicated by observations of dense aggregations of pollock in the southern and northern parts of Anadyr Bay (Fig. 8). Accordingly, dense feeding aggregations of pollock were observed at bottom depths throughout Anadyr Bay in 2017–2018 (bottom trawl survey data for 2017 and acoustic survey data for 2018), though their density in the midwater was still lower in the northern part.

4.2. Indications of movement of pollock among regions based on size structure

Size structure data can be used to estimate similarity (and potential mixing) of populations among the SE, NE and NW regions over our 4 study years. In general, the NE and NW have similar modes (first mode indicative of age-1 fish and last mode indicative of age-4+ fish) for all years. General size structure in the Russian sector (NW) is not similar to that in the US sector (SE and NE) in 2010, because of additional minor modes observed in the NW. This suggests that the pollock present in the northeastern part of the Russian EEZ in summer were a mixture of

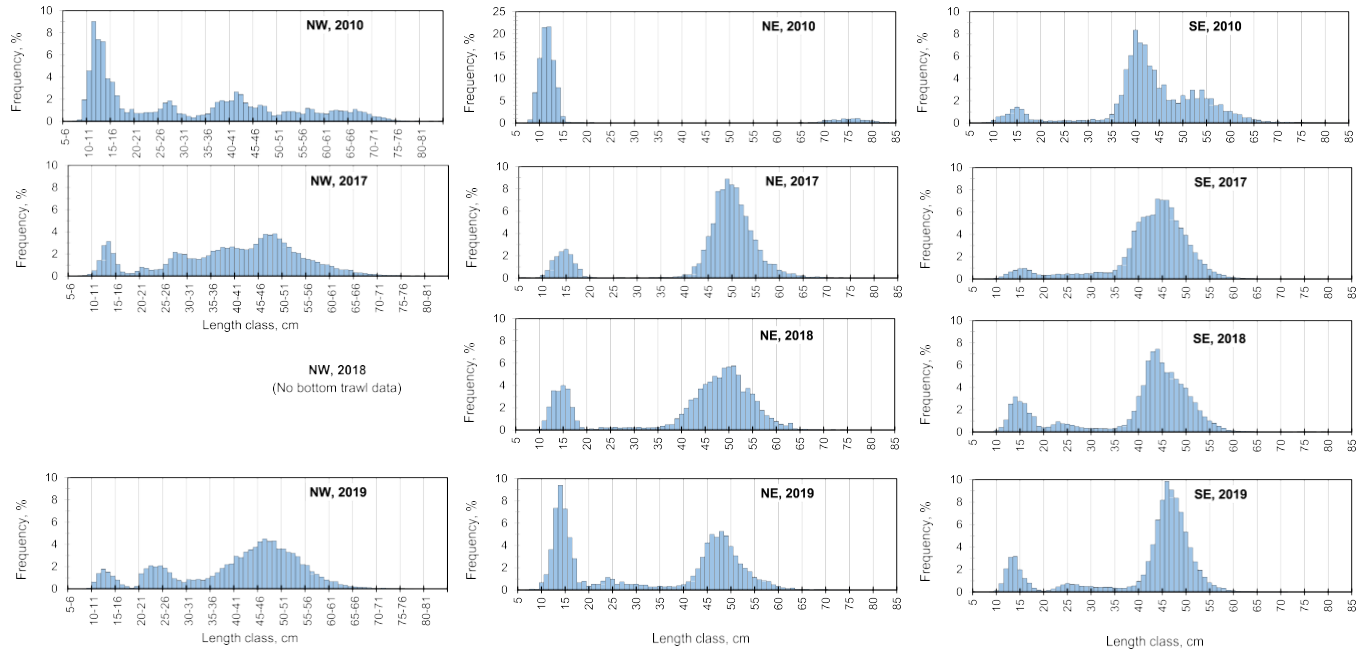

Fig. 10. Size structure of pollock in Russian region (NW) and in US regions (NE, SE). Regions are shown in Fig. 1. Note scale change for NE in 2010. Frequency are % of total individuals. Length data not shown for the NW in 2018 (midwater trawl data).

several stocks that originated from the eastern and western spawning grounds. Kotwicki et al. (2005) hypothesized that timing of feeding migrations is earlier in warm years compared to cold years, which can result in summer distributions that are farther north in warm years compared to cold years. If this is the case, in warm years in the NW and NE we may observe pollock stocks that are more mixed compared to the cold years. Additionally, larger fish can move faster (Kotwicki et al., 2005), leading to slightly larger fish in the north than south. An interesting feature of the pollock length data is a broader size distribution for modal groups for the NW shelf. The US bottom trawl surveys typically only capture age-1 and small numbers of very old and large fish in the 0 °C cold pool. Therefore, the size structure shown in the NE in 2010, where pollock in this region were almost entirely observed within the 0 °C cold pool, is not unusual. Without the cold pool present, pollock distribution demographics may be similar across the international border as suggested by the similar size structure in all regions in 2019. Some of the differences between the NE and NW in the presence or absence of the modes for 2 and 3 year old pollock likely arise from low selectivity of the US bottom trawl survey for these ages (Ianelli et al., 2014). The US bottom trawl survey does not consistently capture age-2 and age-3 pollock because these pollock are often located above the depth of the bottom trawl headrope as demonstrated by higher relative catches of age-2 and age-3 pollock on acoustic surveys (Honkalehto et al., 2013). Differences in the trawl gear (e.g., bottom trawls on Russian surveys have a 3.6 m vertical opening compared to 2.7 m for US surveys) or differences in the depth distribution of the age-2 and age-3 populations can confound interpretation of the size structure data between US and Russian surveys.

4.3. Spawning and feeding migrations

It is unknown whether population-level movement of Bering Sea pollock in response to changing temperatures and ice are temporary shifts that may be reversed if cold stanzas return to the Bering Sea shelf, or whether they are indicative of broader, enduring range alternations that include colonization of higher latitude areas. Pollock are known for their ability to change spawning locations depending on environmental conditions. For example, within the eastern Bering Sea, during warm springs, pollock spawning occurs more to the east (on the middle shelf) while during cold years it is to the west (outer shelf) (Smart et al., 2012). Also, connectivity between spawning and nursery areas is higher during warm years, maximizing dispersal potential (Petrik et al., 2016). Evidence of colonization would include indication of gonad development in adult fishes (spawning condition), and multi-year collections of eggs and early-stage larvae (yolk sac). At present there are comparatively few records of early-stage pollock larvae being collected in the northern Bering and Chukchi seas so it seems unlikely that northern colonization on a large scale has occurred. However, a historic paucity of field sampling during the spawning months (~March–June) in the northerly reaches of the shelf precludes a conclusive assessment. Of those larvae that have been collected, it seems most likely that they were transported from known (Unimak, Bogoslof, or Pribilof islands; Bacheler et al., 2010) or purported (Zhemchug or Navarin canyons) spawning areas rather than being locally produced. Theoretical biophysical transport modeling efforts have demonstrated that pollock larvae spawned from the northern-most known spawning areas in the eastern Bering Sea connect significantly with nursery habitats over the middle and outer shelves in the northern Bering Sea (Petrik et al., 2016), though connectivity from known spawning regions to the Chukchi Sea has not been shown. Connectivity of older early life stages (age-0 juveniles) to northerly regions is also theoretically possible; a combination of favorable currents and directional swimming could enable age-0 pollock to reach northerly regions of the Bering Sea in as little as 4–6 weeks (Duffy-Anderson et al., 2017). Pollock early life stages (<age-2) are unique from adult stages in that, because they have wide thermal tolerance ranges, they are capable of withstanding the frigid (−1.0 – 0 °C; Laurel et al., 2015; Laurel et al., 2018) cold pool temperatures that adults avoid, making young capable of moving northward even during years when a sizable cold pool is present. However, extensive population level migration such as that presented here requires a thermal corridor that permits the large-scale exchange of multiple age classes of pollock, suggesting it can only occur during periods that are warm, ice-free, and cold pool minimal over multiple years.

Movement of fish not only requires appropriate environmental conditions, but also the right biological conditions as well. Of course, spatial scale is a critical issue in these considerations, with biotic

controls exerting sizable influence over smaller scales and abiotic controls exerting influence over larger scales. One significant exception to this general observation is the large-scale seasonal migration (Kotwicki et al., 2005) that pollock undertake post-spawning (spring) to forage areas (summer) and then to overwintering grounds (fall/winter) which is likely motivated by both biotic (reproduction, feeding) and abiotic (temperature) controls. Nevertheless, all life history stages of pollock are able to modify their behavior to exploit food resources that maximize energy intake and growth, and minimize predation risk. While not examined in the present study, the ability of prey (zooplankton) and predators (arrowtooth flounder (*Atheresthes stomias*), seabirds such as murres, and northern fur seals (*Callorhinus ursinus*) to also modify their behavior in response to changing oceanographic conditions is a reasonable assumption. Pollock are zooplanktivores and preferentially prey on euphausiids and large, lipid-rich zooplankton species. Juvenile pollock have been previously demonstrated to shift their vertical distribution (Olla and Davis, 1990; Schabetsberger et al., 2003) in response to shifting prey availabilities, and adults shift horizontal distributions in response to zooplankton occurrence (Barbeaux and Hollowed, 2018). Spatial shifts in pollock as related to predator avoidance have also been documented (Bailey, 1989; Ciannelli et al., 2002), as are shifts in response to presence of competitors (Sturdevant et al., 2001).

4.4. Value of evaluating data across E and W Bering Sea

The inclusion of data from both the eastern and western Bering Sea shelf, across the US–Russia transboundary line is imperative for understanding the movement of pollock and the underlying climatic, environmental and biological drivers for these distribution changes. This is especially relevant in recent warm years (with likely greater movements across international borders, as suggested by the similarity in size structures in 2019). The dramatic northward movement in 2017–2019 and range shifts in pollock also complicate evaluations of stock abundance and provide challenges for management of this large commercial fishery (Baker, in press). It is vitally important for researchers across the Bering Sea shelf to work together to address these recent and future variations in pollock distributions. Moreover, cross border issues are not limited to pollock, but also to other species such as Pacific cod, and flatfish (e.g. Alaska plaice (*Pleuronectes quadrituberculatus*); O'Leary et al., in review). Due to the differences in the survey and density estimation methodology between US and Russian surveys our comparisons of densities on both sides of the border are more qualitative than quantitative. However in the future it is important to improve on these estimates by improving cooperation between Russia and the US to focus not only on data sharing but also on comparisons of catchability and selectivity of survey gears used on both sides of the border. The precision and accuracy of across border fish movement estimates will depend on the ability to estimate accurate selectivity ratios between survey gears (Kotwicki et al., 2017). However, selectivity ratios can only be estimated from experimental paired sampling or by using nearest neighbor techniques (e.g. O'Leary et al., in review). Both of these methods require closer cooperation between US and Russian survey scientists. Good examples of such cooperation existed in the 1980s and 1990s, when it was common for Russian surveys to sample in the eastern Bering Sea; however this sampling has not occurred in the last two decades. Other examples of dedicated international survey efforts include the Russian-American Long-term Census of the Arctic (RUSALCA; Crane and Ostrovskiy, 2015) in the Chukchi Sea and the current Year of the Salmon surveys in the Gulf of Alaska. Continuation of long term monitoring efforts and increased cooperation between monitoring programs for groundfish and habitat variables (e.g., water temperature) by US NOAA and Russian TINRO scientists, will allow researchers to better monitor and understand impacts of climate change on the Bering Sea fisheries and ecosystems.

Coordinated efforts through international organizations (e.g., the North Pacific Marine Science Organization (PICES), the Pacific Arctic Group (PAG), and the North Pacific Anadromous Fisheries Commission (NPAFC)) are also crucial for ongoing communication, data synthesis and the sharing of research ideas and hypotheses. PICES efforts include the North Pacific Ecosystem Status Report, plenary presentations in Vladivostok, Russia in 2017 by Zuenko et al. and Kivva et al. and two workshops on international interdisciplinary efforts to understand the role of the North Bering Sea in modulating arctic environments (Eisner et al., 2017; Baker et al., 2018). Communication has been greatly strengthened by publication of collaborative research, such as Panteleev et al. (2011) on topography, Baker et al. (2020) and Danielson et al. (2020) on oceanography, Beamish et al. (1999) on pelagic fishes, Aydin et al. (2002) on food webs, and O'Leary et al. (in review) on groundfish spatiotemporal variations, in addition to the current manuscript.

4.5. Future considerations

Data presented here on warm-year shifts in pollock distribution between the southern and northern Bering Sea present several important points for consideration. First, are the observed changes presented here harbingers of the future? Ocean heating has already altered the southern Bering Sea shelf such that ice-free winters are now common (2001–2019) and associated warm-year cascading fisheries population and demographic shifts are expected; will the same be true of the northern Bering Sea? Our data show that Russian–US stock mixing over multiple years may be occurring, which can affect the demographic make-up of both populations. Moreover, thermally-mediated differences in age-specific survivorship also could be occurring, given age-selective processes previously described for pollock in the southern Bering Sea during warm stanzas (Heintz et al., 2013).

Stock shifts and stock mixing could pose other problems, as well. Homogenization and loss of diversity (portfolio effects) is known to decrease the ability of a population to adapt to changing conditions, heightening the risk of volatility and exacerbating the potential for failure. Likewise, local population extinctions in areas depleted by northward moving stocks are another topic of concern. Ecologically, local depletions increase the risk of imbalance in food web dynamics, with changes in energy transfer, and potential loss of other co-dependent species. Economically, local depletions of commercial stocks like pollock will require fishers to travel farther to harvest fish, with cascading consequences on cost, time, and resources (Haynie and Huntington, 2016).

Spatial analysis of pollock distributions over the 1982–2018 time series indicated that the highest variance in abundance was outside core habitat areas, suggesting that pollock are able to expand their ranges and utilize areas of more marginal habitat (Baker, in press). In 2018, 2019 adult and juvenile pollock have been observed in high densities in the southern Chukchi Sea on fisheries oceanography surveys, both in the US and Russian sectors (E. Farley, A. Savin, pers. comm.; Orlov et al., 2020). This suggests that pollock have the potential to move northward from the north Bering Sea into the Chukchi Sea as the climate warms and ice diminishes. Whether it will be possible for pollock to colonize these Arctic regions remains an open question that depends, in part, on the magnitude of the climate change in the future, but also on the pollock temperature tolerance, prey resources, reproductive requirements, and predation pressure. Enhanced collaboration among US and Russian researchers is essential for successful evaluation of distribution changes and management of key Bering Sea fisheries in the face of a rapidly changing climate.

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Acknowledgements

We thank the captains, crew, and scientific staff who participated on the many Bering Sea fisheries surveys conducted by NOAA AFSC (US) and TINRO (Russia). Funding for surveys and data analysis was provided by NOAA Fisheries, NOAA PMEL, and TINRO. This is PMEL contribution #5082. This is EcoFOCI contribution number EcoFOCI-N957. We greatly appreciate the suggestions from two anonymous reviewers, and we thank Libby Logerwell and Ed Farley for reviews on earlier drafts of the manuscript. We are grateful to PICES for encouraging the international collaborations that led to the production of this manuscript.

Abstract

Pacific halibut (*Hippoglossus stenolepis*) is managed as a single stock throughout the Gulf of Alaska (GOA) and eastern Bering Sea (BS), but biogeographical barriers and the potential for differential impacts of climate change may alter habitat use and distributions, and restrict connectivity between these ecosystems. To improve our understanding of larval dispersal pathways and migrations of young fish within and between GOA and BS, we (1) examined potential pelagic larval dispersal and connectivity between the two basins using an individual-based biophysical model (IBM) focusing on years with contrasting climatic conditions, and (2) tracked movement of fish up to age-6 years using annual age-based distributions and a spatio-temporal modeling approach. IBM results suggest that the Aleutian Islands constrain connectivity between GOA and BS, but that large island passes serve as pathways between these ecosystems. The degree of connectivity between GOA and BS is influenced by spawning location such that an estimated 47-58% of simulated larvae from the westernmost GOA spawning location arrived in the BS, with progressive reductions in connectivity from spawning grounds further east. From the results of spatial modeling of 2-6 year old fish, we can infer ontogenetic migration from the inshore settlement areas of eastern BS towards Unimak Pass and GOA. The pattern of larval dispersal from GOA to BS, and subsequent post-settlement migrations back from BS toward GOA, provides evidence of circular, multiple life-stage, connectivity between these ecosystems, regardless of climatic variability or year class strength.

Introduction

The Pacific halibut (*Hippoglossus stenolepis*) population in North American waters of the Pacific Ocean and Bering Sea supports vibrant commercial, recreational, subsistence, and tribal fisheries. The management strategy in Alaskan waters encompasses both the Gulf of Alaska (GOA) and the Bering Sea (BS) and uses stock assessment models of spawning biomass combined with agreed management approaches (Stewart & Hicks, 2018) to manage the species as a single, panmictic population, although the International Pacific Halibut Commission (IPHC) also uses current stock distribution to inform harvest distribution. Despite this cross-ecosystem management strategy, the Aleutian Islands are a permeable barrier between the North Pacific and BS ecosystems (Seitz et al., 2011; Spies, 2012; Parada et al., 2016), and there is evidence of differential impacts of climate change across these marine ecosystems such as loss of sea ice in the BS, warm and cold temperature stanzas in the BS (Duffy-Anderson et al., 2017), and warming events in the GOA (Cavole et al., 2016). Such ecosystem discontinuities have the potential to impact species that rely on large geographic domains and multiple habitats throughout their life cycles (Norcross et al., 1999; Mumby et al., 2004; Rochette et al., 2010). For Pacific halibut, fluctuations in year class strength may be determined by conditions during the early life stages that influence growth, survival, and transport to suitable habitats (Bailey et al., 2005). Population age composition of Pacific halibut indicates that a single large year class can dominate the fishery for several years (Stewart & Hicks, 2018), implying that environmental conditions that influence year class strength can have lasting impacts on fishery yield.

Pacific halibut have a complex life-cycle with passive dispersal and active migration stages, and there is evidence to suggest that connectivity between the GOA and BS may occur across multiple life stages. Adults spawn during winter in the deep water of the outer continental shelf and slope throughout the GOA and BS (Thompson & Van Cleve, 1936; Skud, 1977; Sohn et al., 2016). Dispersal occurs during the

pelagic egg and larval stages, and after ~5-7 months, once metamorphosis into the asymmetrical adult form is complete, the juvenile settles to inshore shallow nursery areas (St. Pierre, 1989; Thompson & Van Cleve, 1936). Oceanographically-driven connectivity between the GOA and BS is primarily unidirectional, and fish that are spawned in the GOA may be exported into the BS through Aleutian Island passes (Best, 1977; Skud, 1977; Hinckley et al., 2019). However, mark-recapture studies show that some Pacific halibut during the juvenile and adult life stages migrate from the BS into the GOA (Dunlop et al., 1964; Webster et al., 2013), counteracting the assumed prevailing direction of larval transport. This potential circular transport and migration pathway suggests cross-ecosystem dependence and reliance on habitats in both the GOA and the BS during different life-stages.

Ecosystem changes such as shifts in oceanography (Stabeno et al., 2012), warm and cold climate stanzas, loss of sea ice, and declines in high quality food in the BS (Kimmel, 2018; Duffy-Anderson et al., 2017; Duffy-Anderson et al., 2019) can create survival bottlenecks for species that transition between ecosystems. For example, egg and larval distributions are influenced by the strength and direction of ocean currents that vary among temperature regimes (Stabeno et al., 2012) and seasons (Stabeno et al., 2002; 2016a; 2016b). Shifts in oceanographic currents can profoundly influence the survival of eggs and larvae through favorable transport to hospitable habitats that support growth and survival (Goldstein et al. 2020; Bailey & Picquelle, 2002; Atwood et al., 2010; Napp et al., 2000; Petitgas et al., 2013). Movement by young juveniles, however, is not dictated by oceanographic currents to the same degree as larval dispersal, and there is evidence for counter-current migrations of Pacific halibut (Skud, 1977; St. Pierre, 1989; Clark & Hare, 1998; Webster et al., 2013). Thus, a multiple life-stage approach is required to assess the degree of connectivity between the GOA and the BS and the reliance of Pacific halibut populations on both ocean basins.

Identifying population connectivity across marine ecosystems that incorporates both larval dispersal and active migration could aid in the development of holistic management strategies that reflect habitat requirements across life stages as well as factors that contribute to year class strength. To better understand the geographic continuity of Pacific halibut populations and the vulnerabilities of Pacific halibut to environmental change, we assess life stage-specific distributions and connectivity between the GOA and the BS during years of warm and cold temperature stanzas and opposing year class strength using, (1) empirical larval distributions, (2) an individual-based biophysical larval dispersal model, and (3) spatio-temporal modeling of age-specific data. Incorporating larval dispersal and subsequent ontogenetic migration will provide a holistic understanding of population connectivity, multi-life stage habitat use, and potential vulnerabilities of the Pacific halibut fishery to ecosystem change.

Materials and Methods

Geographic area

The geographic area for this analysis includes the GOA and BS (Figure 1). Within the GOA, the westward flowing Alaskan Stream is the primary water source for flow through multiple Aleutian Island passes connecting the GOA and BS ecosystems (Royer, 1981; Reed & Schumacher, 1986; Stabeno et al., 1995). Originating in the central GOA is the Alaska Coastal Current (ACC) which flows westward along the continental shelf (Stabeno et al., 1999) and is the primary source for flow through Unimak Pass which is the first major pass encountered by the westward flowing current and also the only major connection point between the BS and GOA continental shelves. Based on drifter trajectories, after entering the BS via Unimak Pass, water then flows along the 50-m, 100-m, and 200-m isobaths to the west and north in the BS (Stabeno et al., 2002).–

Catch data

Larval catch and effort data were obtained from the National Oceanic and Atmospheric Administration (NOAA) Alaska Fishery Science Center Ichthyoplankton Information System database (https://access.afsc.noaa.gov/ichthyo/; NOAA 2019). Gear used for data collection most often included a MARMAP (Marine Resources Monitoring, Assessment and Prediction program) type bongo sampler (Posgay & Marak, 1980) with an inside diameter of 60 cm and a 0.333 or 0.505-mm mesh net. Tucker trawl gear was used less often and was composed of cone-shaped fine-mesh nets. Bongo and Tucker gear were determined to fish the same population (Boeing & Duffy-Anderson, 2008) and standardized catches are therefore considered comparable for analysis. Pacific halibut larvae were identified and catches for both gears were standardized to number of individuals caught under 10 m^2 of sea surface area (Smith & Richardson, 1977).

For juvenile and adult fish analyses, catch and effort data from the NOAA Alaska Fisheries Science Center summer bottom trawl survey (NOAA 2020), were coupled with individual fish information, including ages derived from otoliths collected during the surveys (age data available upon request https://www.iphc.int/form/data-request). The NOAA BS bottom trawl survey was conducted annually with stations located on a 20 nautical mile square grid extending from inner Bristol Bay in the eastern Bering Sea within the 200-m depth contour (Figure 1). The standard survey trawl gear and survey design are described in Stauffer (2004) and Clark et al. (1997). The GOA bottom trawl survey was conducted biennially and consisted of a stratified random sampling design based on data from previous surveys (Stauffer, 2004; Clark et al., 1997). Gear for this survey is described in Stauffer (2004). Net mensuration systems recorded net performance, and electronic data loggers recorded temperature and depth during both surveys. Area-swept catch per unit effort was calculated from the distance towed and

net width (Clark et al., 1997). Once settled, Pacific halibut are not routinely monitored until they are captured during the NOAA[A1] Alaska Fisheries Science Center summer bottom trawl surveys at 2 years of age. From various studies it has been observed that age-0 and age-1 Pacific halibut reside in bays and inshore waters from Dixon Entrance to Unimak Pass in the GOA and along the Alaska Peninsula and Bristol Bay in the BS (Best & Hardman, 1982; Norcross et al., 1997; Best, 1977; Stoner & Abookire, 2002). Occasionally, age-1 fish have been caught in the bottom trawl survey, but that number is small, and those in the aging sample and confirmed as age-1 fish, totaled just 57 individuals from 2000-2018 according to the IPHC database. Due to the low numbers of these age-0 and age-1 fish, and lack of standardized monitoring, estimates of relative abundance and modeling of distribution begin at age 2. Thus, catch data from the 2007-2015 bottom trawl surveys were used to examine 2-6 year old fish.

Age data

Age in whole years (2-6 year olds) for demersal juveniles was established using right sagittal otoliths collected during the NOAA Alaska Fisheries Science Center summer bottom trawl surveys. In younger fish (< 5 years), otoliths were surface-aged, i.e. annuli counted on the surface using dissecting microscopes. In older fish or if annuli were indistinct, the break and bake method of aging (described in Forsberg, 2001) was used. While not all trawl stations have Pacific halibut age data collected, the spatial coverage of aged fish was generally comprehensive for the cohorts examined here, particularly in the Bering Sea. Although coverage in the biennial gulf of Alaska survey had some gaps, these were not sufficient to affect our interpretation of the overall distributional patterns.

Cohorts studied

The 2005 and 2009 Pacific halibut year classes were selected as focal cohorts for analysis based on the following rationale: (1) they represent cohorts spawned during distinct BS environmental stanzas (i.e. warm and cold, respectively) (Stabeno et al., 2012), (2) they represent relatively strong and weak year classes, respectively (Stewart & Hicks, 2018), and, 3) the sampling coverage at both the pelagic and settled phases for the two selected cohorts was robust and comparable. The supplemental year classes of 2003, 2004, 2010, and 2011 were added to the larval dispersal modeling and to the subsequent spatio-temporal modeling of older life stages to contrast patterns and strengthen comparisons of advection and migration during warm and cold years. For analytical purposes involving annual cohort analyses, one hatch date (January 1) is assigned per spawning season, regardless of actual spawn date to assign year classes. For example, the 2005 year class includes those larvae spawned from Autumn 2004 through Spring 2005.

Individual-based biophysical model

Larval dispersal, transport, and connectivity were determined using a three dimensional individual based biophysical model (IBM) coupled with daily-averaged output from a hydrodynamic model (ROMS, https://www.myroms.org/). The IBM was developed using the Dispersal Model for Early Life Stages (DisMELS) IBM framework (Stockhausen et al. 2019a) to track transport and dispersal of the pelagic egg and larval stages of marine organisms through earlier life stages from spawning to settlement. Briefly, DisMELS incorporates a Lagrangian particle tracking algorithm and species-specific traits, allowing the model to be parameterized for multiple species (Stockhausen et al., 2019b; Duffy-Anderson et al., 2013; Cooper et al., 2013; Sohn, 2016). The hydrographic ROMS model is a primitive equation, three dimensional ocean circulation model driven by atmospheric forcing (details are available at: myroms.org, Shchepetkin & McWilliams, 2005; Haidvogel et al., 2008). The ocean model used for the present study was the regional Northeast Pacific ROMS model (NEP 6) with ~10 km resolution that spans the GOA and the BS. NEP 6 incorporates sea ice and tidal dynamics that are important for circulation within the study

region (Danielson et al., 2011; Hermann et al., 2013) and has previously been utilized for larval dispersal models in the Bering Sea (Petrik et al., 2016). Output from the ROMS model was saved in daily increments. For the IBM, ROMS daily output was spatially interpolated using bilinear interpolation in order to obtain the physical variables associated with each modeled larvae. Larval locations (latitude, longitude, and depth) were determined using a fourth-order predictor-corrector algorithm that incorporated swimming, buoyancy, and vertical and horizontal random walks for diffusive motion (Stockhausen et al., 2019b). Larval movement was primarily passive (no orientation or directed swimming behavior) except for vertical movement to maintain larvae within preferred depth ranges (Table 1). Larval locations as well as age, size, and development stage were based on 20-minute time steps and saved at daily time steps.

Pacific halibut larval release locations for the IBM were based on known spawning locations (St. Pierre, 1989) that were manually-digitized to create spatial polygons that contained point locations with a 1-km resolution grid for simulated larval release (ESRI ArcMap version 10.6; Figure 2), and were the same for all modelled years. A total of 200 individuals were released from each grid cell. Pacific halibut typically spawn from October-April; however, the exact monthly spawn dates are unknown. Therefore, larvae were released from October-April during each study year from the 25th-28th of each month at midnight to capture the general monthly dispersal patterns. Larval early life history traits generally followed those described in Sohn (2016) and larval mortality was not included in the model. Based on limited nursery habitat information throughout the study domain, all model simulations were terminated once a larvae reached the newly-settled juvenile stage after a pelagic larval duration of 180 days (Table 1). This time- and stage-based model termination limits conclusions that can be made regarding settlement success and post-settlement survival, but provides insight regarding dispersal distance.

Spatio-temporal model

Spatial modeling of trawl survey data allows for a more expansive (but less direct) assessment of cohort movement patterns than is possible using common wire tagging mark-recapture methods. Modeling the 2005 and 2009 year classes provides a look at the similarities and differences between relatively strong and weak cohorts that were spawned during warm and cold environmental stanzas, respectively. Data from other cohorts of intermediate strength (2003-04 and 2010-11 year classes) were also modeled, with results available in supplementary material.

All Pacific halibut caught during the trawl surveys were measured to obtain length data, but spatial coverage for age sampling was often less extensive. To overcome these data limitations, a spatio-temporal modeling approach was utilized (Webster et al., 2020) in order to leverage information about spatial and temporal dependence from observed data to make predictions of abundance within habitat that is unsampled in a given year, as well as improve the quality of estimation elsewhere. For each spatial location (i.e., trawl survey station), the catch-per-unit-effort (CPUE) was computed by dividing catch weight for fish with known age by survey station effort (net width times tow distance), and then adjusting for the sampling fraction in cases where less than 100% of fish were aged. For each aged cohort at each survey station in each year:

$$\text{CPUE} = \frac{W}{E} * \left(\frac{1}{f}\right) \quad (1)$$

where W=catch weight of fish, E=effort (net width x distance) and f=sampling fraction of halibut (proportion aged).

In summary, let $c(s,t)$ be the trawl CPUE value of a given cohort at location s and year t, where s represents the spatial locations of the fished survey stations, taking values $s_1, \ldots, s_n$ and $t = t_1, \ldots, t_T$, corresponding to ages 2 to (T+ 1). In this model, $s_i \hat{I} S^2$, the set of points on the surface of a sphere, and therefore coordinates in longitude and latitude format are converted to Cartesian coordinates on a

sphere for modeling. Data from the trawl surveys contain observations of zero CPUE, due to stations in low-density areas catching no Pacific halibut. The probability that $c(s,t)=0$ is accounted for by using a semi-continuous model, which models the data as a combination of zero and non-zero processes. Two new variables are defined, $x(s,t)$ for presence or absence of Pacific halibut in the catch, and $y(s,t)$ for the CPUE value when Pacific halibut are present:

$$x(s,t)=\begin{cases}0, c(s,t)=0\\ 1, c(s,t)>0\end{cases} \quad (2)$$

$$y(s,t)=\begin{cases}NA, c(s,t)=0\\ c(s,t), c(s,t)>0\end{cases} \quad (3)$$

The *NA* indicates that $y(s,t)$ is a random variable that can only take non-zero values, and is therefore undefined when $c(s,t) = 0$. The variable $x(s,t)$ has a Bernoulli distribution, $x(s,t) \sim \text{Bern}(p(s,t))$, while a gamma distribution is used for the $y(s,t)$, $y(s,t) \sim \text{gamma}(a(s,t), b(s,t))$, which has mean $\mu(s,t) = a(s,t)/b(s,t)$. Only the gamma mean is allowed to vary: the variance, $= a(s,t)/b^2(s,t)$, is assumed invariant over space and time.

Next let the $e(s,t)$ be a Gaussian Field which is shared by both component random variables in the following way:

$$u(s,t) = \text{logit}(p(s,t)) = \beta_x + e(s,t) \quad (4)$$

$$v(s,t) = \log(\mu(s,t)) = \beta_y + \beta_e e(s,t) \quad (5)$$

where β_x and β_y are intercept parameters (which could be generalized to a covariate model) and the parameter β_e is a scaling parameter on the shared random effect. Temporal dependence is introduced through a simple autoregressive model of order 1 (AR(1)), as described in Cameletti et al. (2013), as follows,

$$\varepsilon(s, t) = \rho\varepsilon(s, t - 1) + \eta(s, t) \quad (6)$$

where ρ denotes the temporal correlation parameter and $|\rho| < 1$. For a given year, t, the spatial random field (SRF), $\eta(s, t)$, is assumed to be a Gaussian field with mean zero and covariance matrix Σ. We assume a stationary Matérn model (Cressie, 1993) for the spatial covariance model, which specifies how the dependence between observations at two locations decreases with increasing distance. Models were fitted in R using the R-INLA package (Lindgren & Rue, 2015), which uses a computationally efficient Bayesian approach to fitting spatial and spatio-temporal models. Further details are available in Webster et al. (2020).

Results

Pacific halibut larvae were found during the NOAA ichthyoplankton survey in 2005 east of Kodiak Island, but there was no sampling at those stations in 2009 (Figure 3). Larvae were found in both study years in and around Unimak Pass, and in Bering Canyon. In 2005, larvae were present on the north side of the Alaska Peninsula in the BS and over Bering Canyon, but in 2009, larvae were absent along the north side of the Alaska Peninsula east of the 200 m isobath. Pacific halibut larvae were not found after May in either year. Empirical larval distributions from the supplemental study years were similar to the two focus years (Supplemental Figure 1; Supplemental Table 1).

When comparing larval characteristics of the two primary study years, the month of May was selected because of similar sampling coverage between the two years, and the assumption that spawn timing did not differ substantially between years such that larvae that were present in the water column during a particular month were roughly the same age between years. The catch weighted mean length in 2009 (15.38 mm ± 5.03) was ~87% that of 2005 (17.62 mm ± 6.79) for both the BS and GOA combined, and the average standardized catch of larvae/10 m^2 in 2009 (0.4 larvae/10m^2 ± 2.1) was only 20% that of the 2005 catch (2.0 larvae/10m^2 ± 6.6) (Table 2). When those two annual cohorts were sampled two years later during the NOAA groundfish trawl surveys, the estimated abundance of the 2005 year class was ~53% higher than that of the 2009 year class for the BS and GOA combined, but the average fork length was significantly less for the 2005 cohort than for 2009 both in the GOA and BS (*t*-test *p*-value-0.0027).

Larval dispersal pathways

IBM results from focal study years, 2005 and 2009, and representative spawn locations throughout the GOA and BS showed that, generally, larvae were advected westward away from the spawning subregions in the GOA, and were transported northwest in the BS along the continental slope (ex: 200 m isobath; Figs. 1, 4-6). Larvae spawned in the BS (Spawn Region 1, Figure 2) remained north of the Aleutian Islands throughout their pelagic larval stage (Figure 4) and were transported along the continental slope to arrive at the Pacific coast of Asia within ~3 months. Within 6 months post-release, simulated larvae had the potential for widespread dispersal along the Asiatic coastline and north through the Bering Strait in both the focal and supplemental modeled years (Figure 4; Supplemental Figure 2). In 2005 (Figure 4a), larval dispersal to the western BS was greater than in 2009 (Figure 4b). A portion of the larvae that were spawned in the western GOA (Spawn Region 2; Figure 2) arrived to the

BS from the GOA within 1-3 months and were primarily transported through island passes, including high larval densities near Unimak Pass, in all study years (Figure 5; Supplemental Figure 3). Transport to the northwest in the BS appeared greater in 2005 (a warm year; Figure 5a) compared with 2009 (a cold year; Figure 5b), especially for larvae that were spawned in the earlier months. Larvae that were not transported to the BS were either retained in the western GOA or advected to the eastern Aleutian Islands. A similar pattern of dispersal to the west and through Aleutian Island passes was observed for Spawn Region 3, but there was higher retention of larvae in the GOA and reductions in dispersal to the BS compared with Spawn Region 2 (Figure 2; Supplemental Figure. 4). Dispersal from the GOA to the BS from the easternmost spawn regions was minimal, but dispersal within the GOA was widespread along the GOA coastline (Spawn Regions 4 and 5; Figures 2 and 6; Supplemental Figures 5 and 6). Larvae that originated from Spawn Region 4 arrived to the BS within 4-5 months, but the majority of larvae were retained in the GOA in the vicinity of Unimak Pass and were not transported westward along the Aleutian Islands (Supplemental Figure 5). The easternmost Spawn Region (Spawn Region 5; Figure 2) showed minimal connectivity between GOA and the BS, with indications that only late stage larvae had the potential to traverse the GOA and arrive in the BS after ~6 month pelagic larval duration (Figure 6). A large proportion of the larvae from Spawn Region 5 were retained in the eastern GOA and some were transported southward along the coast as well as offshore (Supplemental Figure 6). Connectivity with the western GOA was greatest in the earlier spawn months and there did not appear to be notable differences between the two primary study years of 2005 and 2009 (Figure 6).

Comparisons among warm (2003-2005) and cold (2009-2011) stanza years showed generally consistent sub-regional patterns in connectivity and transport according to the larval transport model (Table 3). Larvae that originated in the BS (Spawn Region 1), remained within the BS ecosystem throughout their trajectories (Supplemental Figure 2). The highest degree of connectivity as well as the greatest interannual variability in connectivity from GOA spawn locations to the BS occurred from

Spawn Region 2 where 47-58% of the larvae had the potential to be advected into the BS depending on year (Table 3; Supplemental Figure 3). The majority of simulated larvae from Spawn Region 3 remained in the GOA, but ~15-21% had the potential to be advected into the BS (Table 3; Supplemental Figure 4). This contrasted with Spawn Regions 4 and 5 where very few modeled larvae arrived to the BS (<10% and <2%, respectively; Table 3, Supplemental Figures 5 and 6). From Spawn Region 1, there was potential in every modeled year for arrival to north Pacific Asiatic coastal regions and in some years, the Arctic (Supplemental Figure 2). The model also showed that there was potential for the arrival of larvae to the north Pacific Asiatic coast from Spawn Regions 2 and 3 in some years (Supplemental Figures 3 and 4). Larvae from Spawn Regions 4 and 5 were not likely to reach the north Pacific Asiatic coast, but were dispersed throughout the GOA (Supplemental Figures 5 and 6).

Empirical larval observations and IBM trajectories both show concentrations of larvae around island passes and dispersed through the western GOA and eastern Bering Sea along the 200-m isobath (Figures 3-6; Supplemental Figures 1-6). In contrast with empirical larval observations that showed larvae to the east of Unimak Pass in 2005 (Figure 3), almost no IBM trajectories crossed the isobaths along the continental slope to arrive on the continental shelf in the BS (Figures 4- 6; Table 3; Supplemental Figures 2-6). In addition, IBM results did not show larval transport to the western Aleutian Islands where there is a known population of Pacific halibut (Seitz et al. 2008). Large-scale qualitative comparisons are possible as described here, but detailed quantitative comparisons between empirical presence and modelled trajectories are difficult, given that the larval surveys are limited in scope in any given year both spatially and temporally, and Pacific halibut larvae that are caught are not aged so there is no method available to estimate probable origination or settlement locations.

Ontogenetic migration

The spatial model output suggests that as 2 year olds, the 2005 cohort was concentrated in Bristol Bay in the BS and around Kodiak Island in the GOA, and the BS component appears to have stayed aggregated as they began to emerge from Bristol Bay, with distributional centers that moved west and south along the Alaska Peninsula in the immediate subsequent years (Figure 7; Supplemental Figure 7). By age 4, young Pacific halibut were clustered on both sides of Unimak Pass in contrast to younger fish that were concentrated inshore in the southeast BS. Age-5 and age-6 fish appeared less aggregated and were dispersed over a wider range and to deeper depths than younger fish. These patterns in distributional changes over time were generally consistent in other large cohorts from 2003 and 2004 (Supplemental Figures 8 and 9), with apparent dispersal outwards from inside shallow waters of Bristol Bay and south of Nunivak Island (ages 3-4 years), and subsequent aggregation around Unimak Pass (ages 4-6 years).

Model output suggests that the 2009 cohort was more evenly dispersed overall compared to the 2005 cohort at comparable ages (Figure 8; Supplemental Figure 10), lacking the obvious high-density concentrations of the earlier cohort (note the different scales on the two figures). A primary difference from 2005 was that, in addition to a part of the population leaving Bristol Bay and migrating southward along the Alaska Peninsula as seen with the 2005 cohort, a portion of the 2009 year class also continued to occupy the Bristol Bay area as they aged and were not migrating outward to other parts of the BS to the same degree at the 2005 cohort. There was some indication that there were aggregations around Unimak Pass, but there were no obvious aggregations in the GOA. Overall average abundance (Table 2) and sample sizes (Table 4) were relatively low, making it difficult to observe small scale density changes in this cohort. However, according to the model, distributional changes with age were generally similar for other low-density cohorts from 2010 and 2011 (Supplemental Figures 11 and 12; Supplemental Table 2), although with some differences in timing and dispersal (e.g., the 2010 and 2011 cohorts both showed a stronger clustering south of Nunivak Island in 2015).

Discussion

Developing an understanding of cross-ecosystem population connectivity can inform management strategies for Pacific halibut by providing information about dispersal, migration, and habitat use across multiple life stages. Model results suggest consistent and substantial larval connectivity between the western GOA and the BS. Pacific halibut larvae that originated in the western GOA have the potential to be transported to the BS, and those larvae that originated from populations in the BS are likely transported northwest along the isobaths in the BS. In addition to larval dispersal, age-specific distributions of Pacific halibut showed ontogenetic range expansions, suggesting that juveniles radiate from their settlement areas in the BS to regions throughout the continental shelf, and potentially reach the Aleutian Islands and the GOA. Spawning in the GOA may provide access to important settlement habitats in the BS, and the potential reverse migration from the BS to the GOA may be important for access to suitable habitats for older life stages, or for maintaining source populations that facilitate access to juvenile settlement habitats.

Biophysical modeling results suggest that the Aleutian Islands constrain larval connectivity between the GOA and the BS, but that island passes are corridors that connect the two ecosystems. Several studies have highlighted oceanographic connectivity between the GOA and the BS through large island passes (Royer, 1981; Reed & Schumacher, 1986; Stabeno et al., 1995;) with estimates of ~30% of the Alaska Coastal Current (Aagaard et al., 2006) transported from the GOA to the BS through Unimak Pass (Stabeno et al., 2016a). For pelagic larvae, island passes could facilitate connectivity between the GOA and the BS. IBM results suggest a link between the two basins via large island passes in the eastern Aleutian Islands where an estimated average of 35% of larvae that originated in the western GOA (Spawn Regions 2 and 3) were transported into the BS.

The majority of larval dispersal modeling studies in the North Pacific to date have focused on the GOA or the BS in isolation; however, some studies hypothesize that larvae that were spawned in the western GOA and subsequently exited the study area were potentially transported further west to the Aleutian Islands or into the BS (e.g. Gibson et al., 2019). One study to provide evidence of basin connectivity was that of Parada et al. (2016) that modeled walleye pollock (*Gadus chalcogrammus*) larval transport and found evidence for basin connectivity. Coinciding with our results, several studies have highlighted east-west connectivity in the GOA, particularly between spawning grounds in the eastern GOA and nursery areas in the central GOA for sablefish (*Anoplopoma fimbria*) (Gibson et al., 2019), Pacific cod (*Gadus microcephalus*) (Hinckley et al., 2019), arrowtooth flounder (*Atheresthes stomias*) (Stockhausen et al., 2019a), and Pacific ocean perch (*Sebastes alutus*) (Stockhausen et al., 2019b). Dispersal patterns in the BS were typically south to north, coinciding with other modeling studies for walleye pollock (Petrik et al. 2016), northern rock sole (Cooper et al. 2013), and Greenland halibut (Duffy-Anderson et al. 2013). Simulated Pacific halibut larvae in the BS were primarily transported along the continental slope, with some larvae reaching the north Pacific Asiatic coastline or transitioning through the Bering Strait.

The prevailing east to west modelled larval transport in the GOA and the south to north trajectories in the BS along the 50-200 m isobaths agree with the prevailing currents in each respective ecosystem (Stabeno et al., 2002; 2004), and with empirical data showing larval concentrations near island passes. However, smaller-scale comparisons with empirical data suggest that model limitations likely impacted finer scale connectivity patterns and transport trajectories. The absence of simulated larval transport to inshore regions of the BS conflicts with the empirical larval distributions during 2005 where larvae were found north of Unimak Pass along the Alaska Peninsula. In addition, according to catch data from the NOAA Fisheries bottom trawl surveys, young demersal stage Pacific halibut are consistently found in high abundance near shore in the southeastern BS. Together, these empirical data suggest that larval transport to the southeastern BS may be much greater than portrayed in the advection modeling. Thus,

At N2, $NO3_{EST,N2}$ closely tracks both the synoptic and longer period signals captured by the SUNA nitrate sensor ($NO3_{SUNA,N2}$) during the January-April and September-December time frames (Fig. 2d). Although offsets between $NO3_{SUNA,N2}$ and $NO3_{EST,N2}$ are not uniform from September to May (largest in December with instances of 10 μmol differences), the average is 2.5 μmol/kg, which is comparable to the errors and biases discussed in Section 2.1.1.

As with nitrate, correlations with salinity are also significant ($p<0.02$) for Aqua Monitor-measured phosphate and silicate for both January-April and September-December time frames, but neither are significantly correlated during the May-August period. For January-April, May-August, and September-December, the correlation coefficient (r) between SBE salinity and phosphate is 0.89, 0.37, and 0.92, respectively. For salinity and silicate, the correlation coefficients during the same time period are 0.98, 0.12, and 0.91, respectively. Salinity-based estimates of phosphate ($PO4_{EST,N2}$) and silicate ($SiO4_{EST,N2}$) are calculated in identical fashion to $NO3_{EST,N2}$ (Eq. 1).

3.3 Nutrient Fluxes through Anadyr Strait

Using velocity data from the N2 ADCP and the salinity-nutrient regressions described above, we estimate nutrient fluxes through Anadyr Strait by assuming a homogenous flow field through the strait. The homogeneous flow field has been applied to the Bering Strait throughflow with good success by Woodgate and Peralta-Ferriz (2021), despite the presence of the Alaska Coastal Current (ACC) in Bering Strait, which is arguably more problematic than the weaker lateral gradients found in Anadyr Strait. Based on the ADCP current measurements on the N2 mooring, we further assume that the water column is unstratified over November through April such that the salinity and nitrate measurements at 35 m depth are representative of the full water column. For May through October, we assume that the water column is stratified and that the upper 10 m of the water column is nitrate-deplete.

Anadyr Strait is 73 km wide, has a mean depth of ~ 35 m, and is approximately 2.7×10^6 m^2 in cross-sectional area. The major axis of the principal ellipse of the sub-tidal barotropic currents (from the ADCP on N2) is roughly normal to Anadyr Strait (i.e. oriented with the through-flow). If treated as representative for the whole Anadyr Strait, currents along this axis can be used to calculate the volume transport through the strait (T_{AS}). The average speed of the currents along the major axis current is 39 cm s^{-1} for the year-long deployment, which translates to a volume transport of 1.1 Sv to the northeast and is similar to the estimated transport at Bering Strait (1.3±0.3 Sv), based on A3 measurements.

To estimate the nutrient flux through Anadyr Strait, we combine the monthly salinity-based estimates of nutrient concentration at N2 (Section 3.1) with the volume transport through the strait (T_{AS}). Nitrate flux ($F_{NO3,AS}$), for example, is assessed as:

$$F_{NO3,AS} = T_{AS} NO3_{est,N2} \rho_0 \qquad \text{Eq. 2}$$

where ρ_0 is the nominal density of seawater in the region (1025 kg m^{-3}). Fluxes for phosphate and silicate ($F_{PO4,AS}$ and $F_{SiO4,AS}$, respectively) are calculated similarly. From September, 2017 to April 2018 (when salinity nutrient regressions are significant), average nitrate, phosphate, and silicate fluxes are 17±4, 1.8±0.4, and 36±9 kmol s^{-1}. Uncertainty estimates include error from the regressions as well a ±20% assumed error on our transport estimates, as we do not have sufficient in situ data to fully constrain transport

through Anadyr Strait. Changing the assumed transport uncertainty by ±10% modifies flux transport errors by about 2, 0.2, and 3 kmol/s for nitrate, phosphate and silicate, respectively. Using a summertime nutrient depletion depth of 20 m (assumed 10 m here) would reduce these flux estimates by < 10%.

3.4 Nutrient fluxes through Bering Strait

Anadyr and Bering straits are highly covariable. At a 17 day lag, the low-passed (30 day cutoff period) salinity measured at N2 and A3 (both near 35 m) have a correlation coefficient of 0.70 and both time series have similar means and dynamic ranges (Fig. 1d). Given the dominance of the Anadyr Strait-sourced waters in the Bering Strait and the strong co-variability in salinities, we employ the methods of Section 3.3 to estimate the nutrient flux into the Arctic. The foundations of our nutrient flux calculations are estimates of Bering Strait salinity and transport based on observations from the A3 mooring (See Fig. 1a and Section 2.1.2). Although monthly estimates of transport (T_{A3}) and salinity (S_{A3}) begin in 1990, the early data record has gaps so here we focus on the continuous period of the record, starting in fall 1997.

Thus, we apply the monthly salinity measured at A3 (S_{A3}) to Equation 1 to estimate monthly concentrations for nitrate, phosphate, and silicate ($NO3_{EST,BS}$, $PO4_{EST,BS}$, and $SiO4_{EST,BS}$, respectively). Using T_{A3} and these salinity-estimated nutrient concentrations, we employ Eq. 2 to calculate monthly nutrient fluxes through Bering Strait ($F_{NO3,BS}$, $F_{PO4,BS}$, $F_{SiO4,BS}$), Since salinity and nutrients are not significantly correlated at N2 from May-August, we do not use the salinity parameterization (Eq. 1) during these months. Instead, we turn to *in situ* observations from the Russian-American Long-Term Census of the Arctic Program (RUSALCA) program (REF???)to estimate the average nutrient concentrations within the strait. From a set of five separate cruises spanning 2004 to 2010 (all during the month of August), we select stations that are in close proximity to the strait (Fig. 1a). Station locations are transformed to an along-strait coordinate system, and we use objective mapping to estimate the average nutrient section along Bering Strait for each year (See Fig. 1b for nitrate). For all nutrients, objective maps show both subsurface and western enhancement of concentrations, revealing the nutrient depletion near the surface across the whole Strait, nutrient rich subsurface waters from Anadyr Strait in the west, and the nutrient poor waters of the ACC in the east. We compute the mean concentration of each parameter over the entirety of aggregated (all years) objective maps (both in depth and transect distance) and find averages of 12.6, 1.3, and 20.9 μmol/kg for nitrate ($NO3_{RUS,BS}$), phosphate ($PO4_{RUS,BS}$), and silicate ($SiO4_{RUS,BS}$), respectively, which are treated as representative average concentrations for Bering Strait from May to August. While these estimates lack *in situ* data from May to July, SUNA data from N2 suggests that this season is typically the least temporally variable (Fig. 2d), so averages from August should serve as a serviceable but conservative representation for the May-August time frame. Thus, our monthly nutrient fluxes in summer (May-August) combine the variable transport estimate from A3 with a constant nutrient value (rather than the variable nutrients used from January-April and September-December). By combining the RUSALCA-based (May-August) and salinity-based (all other months) we construct a continuous monthly record of nutrient flux through Bering Strait from August 1997-August 2019. The period-of-record mean for nitrate, phosphate, and silicate fluxes are 16±5, 1.5 ± 0.5, and 30 ± 10 kmol s^{-1}, respectively.

Interannual variability is found to be relatively strong with ranges (including error) of approximately 5-25, 0.5-2.5, and 10-50 kmol s^{-1} for nitrate, phosphate, and silicate, respectively (Fig. 3a). There are statistically significant ($p<0.05$) long term temporal trends for annually averaged phosphate ($p<0.01$) and silicate ($p<0.02$), but not for nitrate ($p=0.16$). Sensitivity analysis, where transport (T) and nutrient concentrations

(C) are split into mean and anomaly terms ($T = \overline{T} + T'$, $C = \overline{C} + C'$, and nutrient flux is $T \cdot C$), shows that increasing transport is responsible for the increase in flux for phosphate and silicate ($|T' \cdot \overline{C}| > |\overline{T} \cdot C'|$), while for nitrate decreased nutrient concentrations offset the increased transport ($|T' \cdot \overline{C}| \approx |\overline{T} \cdot C'|$). There is also considerable seasonal variability (Fig. 3b). Monthly average fluxes range between about 5±7 to 27±11, 0.7±0.7 to 2.1±0.7, and 12±13 to 50±18 kmol s^{-1} for nitrate, phosphate, and silicate respectively (± values are standard deviations of monthly fluxes), with maxima in April and minima in December. This timing coincides with the months of maximum and minimum salinity, which is consistent with our salinity-based parameterizations (Eq. 1, and Fig. 2b).

4. Discussion

From 1998 to 2018 we estimate the average poleward flux of nitrate, phosphate, and silicate through Bering Strait is 16±5, 1.6±0.5, and 30±10 kmol s^{-1}, respectively. MacDonald et al. (2010) estimated that 12.4 kmol s^{-1} of nitrogen is needed to support the annual 50 g C m^{-2} y^{-1} of new production in the Chukchi Sea alone, and that the total flux of dissolved inorganic nitrogen was 16.5 kmol s^{-1}, within the uncertainty range the 16±5 kmol s^{-1} of nitrate that we estimate. The wintertime nitrate flux estimates at Bering Strait presented in this work are in relatively good agreement with those found downstream at Icy Cape by Mordy et al. (2020), after accounting for the ~40% of Bering Strait transport that flows by the mooring array used (e.g. 6±2 kmol/s compared to 18±10 kmol/s found here during February). However, our nutrient fluxes are significantly higher than those estimated by Torres-Valdes et al. (2013), ranging between ~25-75% greater. The majority of the discrepancy is rooted in methodological differences, with our single year, but year round time series of nitrate observations providing the basis of our annually-resolved approach. Torres-Valdes et al. (2013) in contrast use temporally static nutrient concentrations along with seasonally changing transport estimates, whereas we use nutrient concentrations that vary over January-April and September-December (only static from May-August). The average nitrate concentration was approximately 10 μmol/kg across Bering Strait during the August, 2005 RUSALCA cruise used in Torres-Valdes et al. (2013), compared to the annually averaged 15.6 μmol/kg estimated here between the years of 1997-2018, which is roughly the same fractional difference between the their nitrate flux estimate and that found here.
