Recently, Zhao et al. (2021) used a three-dimensional ocean-sea ice-biogeochemical model to simulate nitrate flux through Bering Strait from 1998-2015 and found values of ~12 kmol s^{-1} during February-May, and ~8 kmol s^{-1} much of the remainder of the year. While that seasonality has loose qualitative agreement with monthly variability found here, their annual average of 9.63 kmol s^{-1} is significantly lower than our 16±5 kmol s^{-1}, and we find higher seasonality (~5-25 kmol s^{-1} versus ~8-12 kmol s^{-1}). A possible explanation for the discrepancy of the annual averages is that Zhao et al. (2020) found simulated nitrate concentrations upstream of Anadyr Strait that were significantly lower than in situ concentrations (~5 umol/kg), which may translate to lower nitrate fluxes through Bering Strait.

Deep water thermohaline and nutrient composition is fairly static (REF), however, the stability of the salinity-nutrient relationships over the multi-decadal period of record (1998-2018) is a central assumption, given these relationships are only estimated from the yearlong N2 mooring deployment (2017-2018). Though lacking in historical data directly at Anadyr Strait, the January-April salinity-nutrient measurements from N2 are near the mixing line between deep nutrient-rich and shallow nutrient-poor waters established

from hydrographic data collected (Fig. 2a) around a decade before the N2 deployment, providing some sign of long-term stability. Brine rejection from sea-ice formation is could also impact our estimates of nutrient flux, as it modifies salinity but not nutrients. However, the wintertime polynyas that are the strongest source of brine are upstream of Anadyr Strait (Danielson et al. 2006), and the pack-ice that is often present between the Anadyr and Bering straits has a weaker influence on salinity. Thus, while some influence of brine rejection is likely implicit in the salinity-nutrient relationships found at N2, these are unlikely to undergo drastic transformations in the wintertime transit time to Bering Strait.

Prominent discontinuities between estimated fluxes on either side of the summer season (May-August, Fig. 3b) mark the changeover between salinity-based nutrient estimates and *in situ* RUSALCA measurements used in calculating nutrient fluxes at Bering Strait. There are different uncertainties associated with each of the different methods, but the discontinuities may also reflect part of the seasonally varying nutrient uptake cycle. Brown et al. (2011) estimate that 54% of the regional annual net primary production occurs from May-July, so phytoplankton blooms during this interval are drawing down nutrient concentrations, thereby reducing the Arctic-bound nutrient flux. The Bering Sea has very high phytoplankton productivity, with 250-300 g C m-2 yr) (Sambrotto et al., 1984, Grebmeier et al. 1988, Springer, 1988, Walsh et al., 1989). Though biotic drawdown during the transit between Anadyr and Bering Strait is unknown, it is possible to construct a crude estimate assuming half the total production (~150 g C m-2) occurs evenly over the ~50 m deep shelf break from May-July. The expected draw down during the two week advective period from Anaydr to Bering Strait is ~ 6 umol N kg^{-1} (assuming a Redfield ratio of 16N:106C), and the remainder of the year is ~ 2 umol N kg^{-1}. Since our flux estimates only use the Anadyr salinity-nutrient relations from September-April, and nutrient concentrations during May-August are based on RUSALCA observations directly at Bering Strait, we expect the error from biotic drawdown in the Anadyr to Bering Strait advection period to be small.

As calculated in Section 3.2, the estimated nitrate, phosphate, and silicate flux in Anadyr Strait for the N2 mooring deployment period when salinity-nitrate relations hold (September, 2017 – April, 2018) was 17±4, 1.8±0.2, and 37±5 kmol s^{-1}, respectively. During the same period at Bering Strait, fluxes are estimated to be 24±8, 2.5±0.8, and 52±16 kmol s^{-1}. Though the uncertainty ranges overlap, it is possible that the larger mean values from Anadyr Strait are partially due to a branch of the Anadyr Current (presumably with the same salinity-nutreint relations) that flows around the southern shore of St. Lawrence Island (Danielson et al., 2006), but we presently lack the data to confirm this.

The estimates of volume transport through Bering Strait (Section 3.3) do not correct for influences from the ACC, which is an additional source of error. However, the fractional correction for the volume transport is ~10% (Woodgate, 2018), and ACC water is well known for being nutrient deplete (Danielson et al., 2017), so it is unlikely that the ACC contributes a significant fraction of the overall nutrient supply to the Arctic.

Woodgate (2018) described a multi-year trend of increasing transport along with a multi-year trend in declining salinity. For our calculation (which assumes a fixed relationship between nutrients and salinity) this introduces competing effects, as increased volume transport favors increased nutrient flux, while decreasing salinity under our parameterizations (Eqs. 1 and 2) translates to lower nutrient concentration and fluxes. Using the salinity-nutrient parameterizations established at N2, we find that silicate and phosphate

fluxes have likely increased significantly from 1998-2018, while nitrate, at best, has a weakly positive trend ($p=0.16$). Though nitrate, phosphate, and silicate are all very well correlated with salinity during non-summer months ($r \geq 0.89$), changes in salinity correspond to a larger fractional change in $NO3_{EST,BS}$ than either $PO4_{EST,BS}$ or $SiO4_{EST,BS}$ (Fig 2 b-d). Thus, the long term decrease in salinity at Bering Strait compensates for the increase in volume flux and $F_{NO3,BS}$ remains relatively steady. Salinity variability causes less fractional change in $PO4_{EST,BS}$ and $SO4_{EST,BS}$, such that the increased transport is the determining factor in long term changes of $F_{PO4,BS}$ and $F_{SiO4,BS}$ (also see Section 3.4).

Bering Strait is an important gateway for supply of Arctic nutrients, and this has major biological implications. Lowry et al. (2015) found that nutrient rich winter water advected north through Bering Strait was strongly associated with phytoplankton blooms in the Chukchi Sea. Torres-Valdes et al. (2013), even with their smaller total flux, found that that Bering Strait is a significant source of annual nutrient supply to the broader Arctic Ocean (21±4%, 35±6%, and 61±11%), for nitrate, phosphate, and silicate, respectively. If, as our analysis suggests, the true nutrient flux is higher than previously estimated, it implies that Bering Strait is an even more significant source of Arctic nutrients than previously appreciated. As temperatures in the Bering Sea rise, the timing of the spring breakup of sea ice shifts to earlier in the year (Danielson et al., 2020). Earlier spring blooms associated with the resulting increased light availability may lead to increased drawdown of the nutrients supplied by the Anadyr Current. By way of biotic consumption, this could reduce the nutrient supply to the Arctic through Bering Strait, although lateral particulate biomass fluxes may increase in turn. Thus, especially since our interannual estimate is calibrated only on one year of year-round data, an urgent requirement is for more year-round measurements of nutrients in the Anadyr Strait and indeed in the Bering Strait to better understand the full scope of Bering Strait region nutrient dynamics.

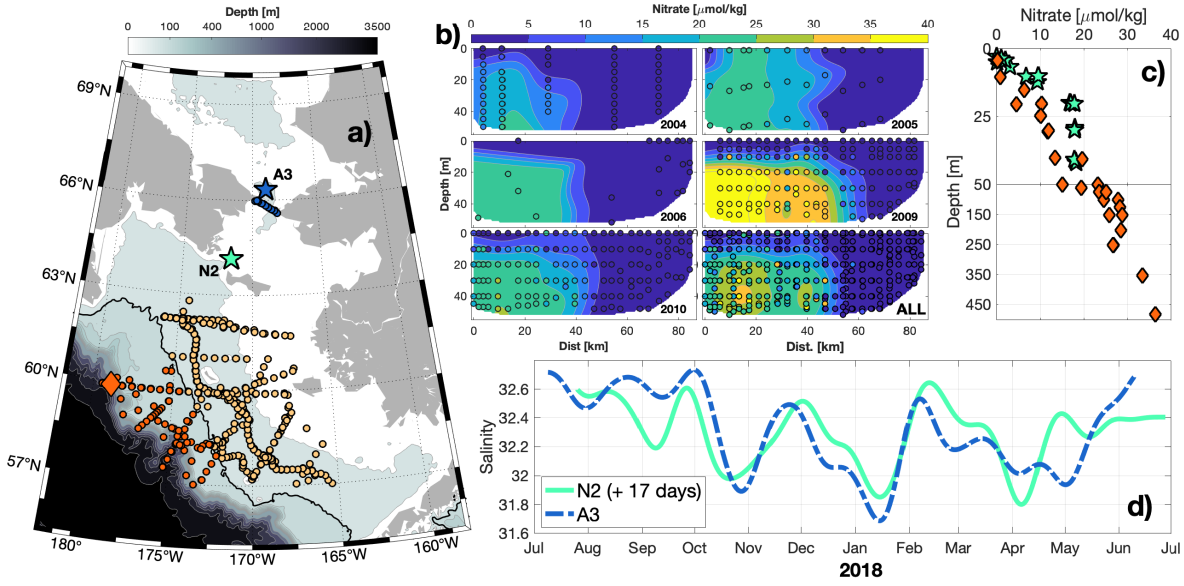

Figure 1: a) A regional map showing hydrography and mooring locations. Orange circles are sites of shipboard hydrography profiles collected mostly during summer from 2008-2018 (see Supplementary Table S2 for sources; dark markers are casts > 100 m), and blue circles mark Bering Strait RUSALCA stations. Stars mark mooring sites (N2,cyan; A3 blue). The dark depth contour is at 100 m. b) RUSALCA nutrient transects collected in August for years 2004, 2005, 2006, 2009 and 2010. Colored circles show measured nitrate values across Bering Strait (blue circles in panel (a)), and the contours are an objective map calculated from observations (smoothing length scales of 10 m and 10 km in the vertical and lateral dimensions, respectively). The lower right subpanel aggregates all years. c) Nitrate profiles collected at N2 (stars) and the Bering continental slope (diamonds). The location of continental slope observations is denoted by the orange diamond in (a). d) Low pass filtered (30 day cutoff period) salinity at N2 (cyan, lagged by 17 days) and A3 (blue).

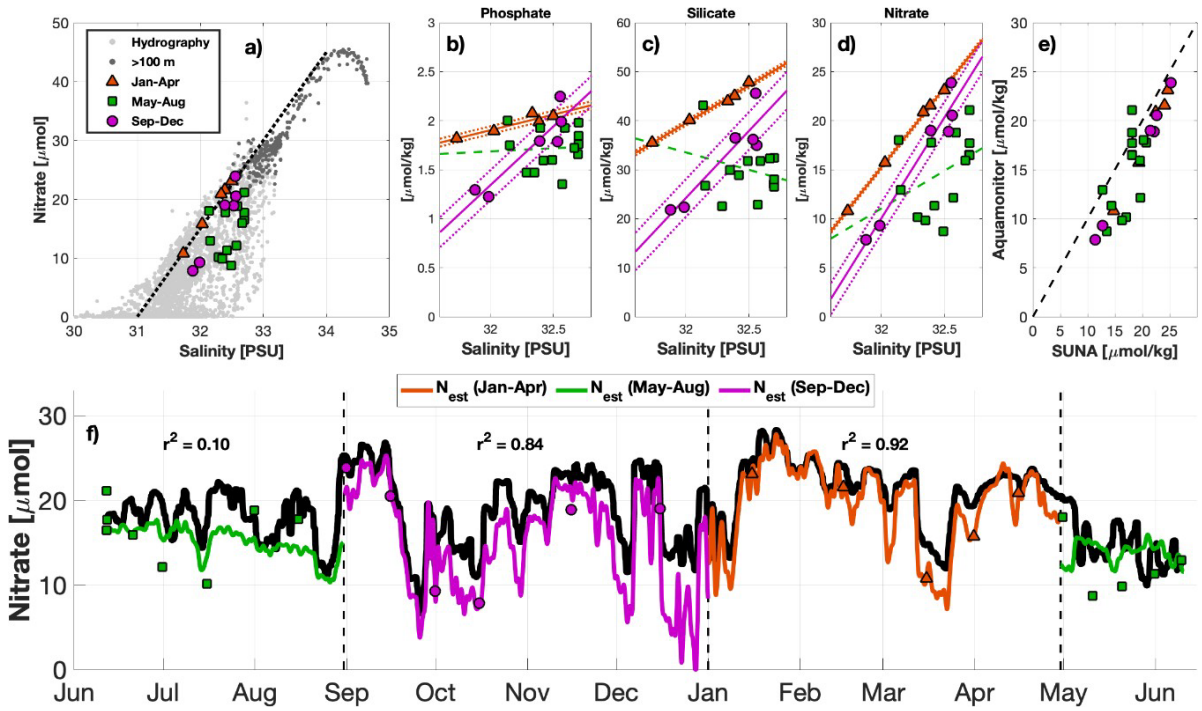

Figure 2 a) Hydrographic samples of nitrate and salinity across the Bering Sea in gray (see Fig. 1a). Darker markers indicate samples taken at > 100 m. Colored markers show 25 nitrate/salinity pairs taken by the Aqua Monitor and SBE at N2, where color corresponds to the seasons denoted in the legend. The dashed box shows the salinity and nitrate ranges plotted in (b). b) Small points show SUNA nitrate versus SBE 35 m salinity at mooring N2 during its 363 day deployment, while larger circles show Aqua Monitor nitrate versus SBE salinity. c) Aqua Monitor nitrate compared to SUNA nitrate (dashed line shows the 1:1 slope). d) SUNA nitrate (thick black) compared to $NO3_{est,N2}$ (colored lines). Colored circles show Aqua Monitor nitrate measurements and vertical dashed lines show delineations for the seasons (Jan-Apr, May-Aug, Sep-Dec). Seasonal color assignments in (b-d) are identical to those in (a).

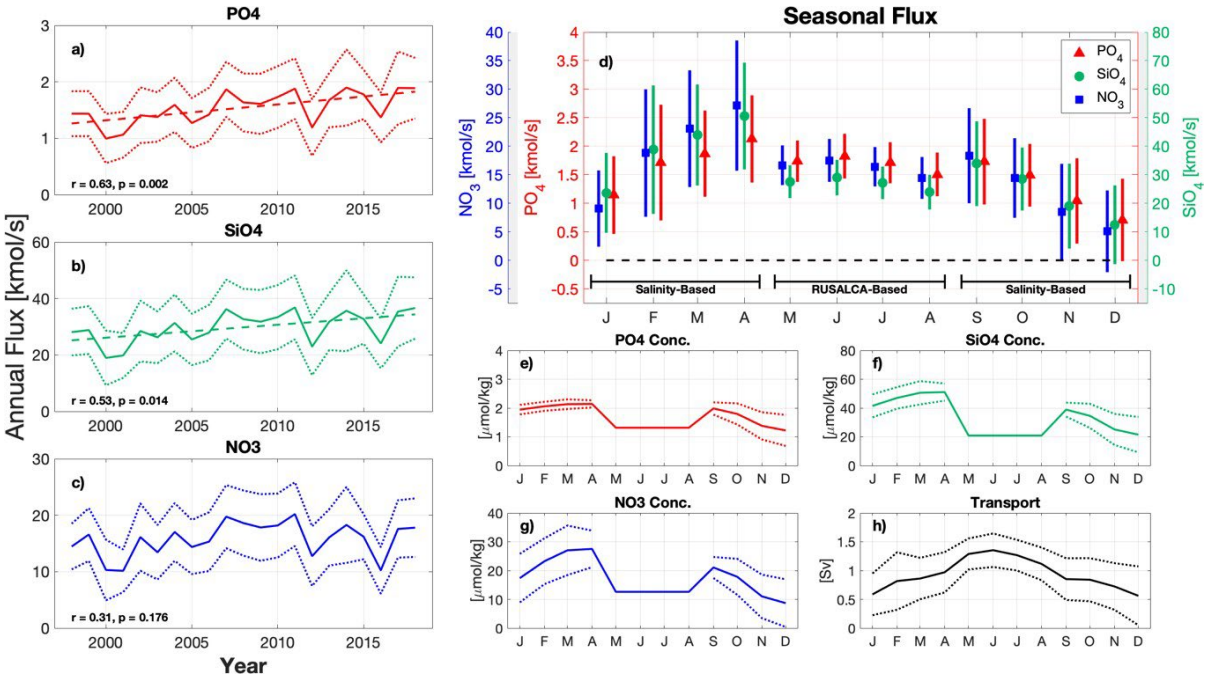

Figure 3: a-c) The annual-average nutrient flux through Bering Strait for each year. Positive values represent a poleward flux, dotted lines show the 95% CI, and dashed lines show the linear regression (if significant). d) The monthly average nutrient flux through Bering Strait spanning 1997-2018. Symbols are the mean and vertical lines show the standard deviation within each month. e-f) The monthly averages (solid line) and standard deviation (dashed lines) of nutrient concentrations and transport estimated at Bering Strait. There are no dashed lines from May-August to reflect the constant concentration assumed during that period.

Abstract

High latitude ecosystems are undergoing rapid ecological change. Pacific Arctic waters have experienced sea ice loss and increasing heat flux from the north Pacific Ocean into the Chukchi Sea. The zooplankton community has been shown to correspond to water mass types that are endemic to the Chukchi and Beaufort Seas as well as water masses that are advected from the Bering Sea. Here we examine the zooplankton community composition from a series of surveys in the Chukchi Sea from 2010-2019. The goal was to characterize the spatial variability of the zooplankton community in relation to variability in water masses and examine the temporal change in several key taxa that are critical forage for higher trophic levels. These key taxa include the calanoid copepod *Calanus glacialis*, the dominant large copepod, and *Pseudocalanus* spp., the dominant small copepod. The Chukchi Sea showed evidence of Bering Sea influence in each year as water masses with associated zooplankton communities were advected through Bering Strait. The amount of the Chukchi Sea influenced by these water masses was greatest during 2017 and 2019 when extremely high temperatures were observed. The high temperatures appeared to reduce overall *C. glacialis* abundance throughout the Chukchi Sea. Small copepods, in particular *Pseudocalanus* spp. increased in abundance in locations closer to the Bering Strait in association with warmer temperatures. These community changes agree with prior observations in the Chukchi Sea; however, the more recent surveys had abundances that were approximately an order of magnitude lower than in past years. This suggests that continued warming will result in an altered zooplankton community in the Chukchi that is dominated by smaller-sized copepods. The result would be a shift in trophic connectivity between higher trophic levels in the Chukchi Sea region.

Introduction

Zooplankton form a vital link between primary producers and energy that accumulates in the zooplankton standing stock is transferred to multiple higher trophic levels either directly or indirectly. This is the case along the Chuckchi Sea shelf where zooplankton are consumed by fish such as Arctic (*Boreogadus saida*) and Pacific herring (*Clupea pallasii*) (Eisner et al. 2013), seabirds (Gall et al. 2017), and marine mammals, including a key subsistence species the bowhead whale (*Balaena mysticetus*) (Heide-Jørgensen et al. 2013). Differences among the zooplankton community of the Chukchi Sea are related to differences in hydrography, in particular water masses defined by temperature and salinity characteristics (Eisner et al. 2013, Pinchuk and Eisner 2017). These correlations appear to be robust and have been tracked as water moves from the northern Bering Sea into the Chukchi Sea (Hopcroft et al. 2010, Ershova et al. 2015a, Kim et al. 2020). These zooplankton communities consist of both meroplanktonic larvae and holoplankton, with the latter dominated by copepods (Hopcroft et al. 2010, Questel et al. 2013, Ershova et al. 2015a).

Long-term changes in the zooplankton population in the Chukchi Sea appear to correlate with the amount of ice cover present. Matsuno et al. (2011) compared zooplankton communities in the Chukchi Sea during years with high ice cover (1991-1992) to years with low ice cover (2007-2008) and found a positive impact on zooplankton production in the low ice years due to advection of Pacific species into the Chukchi Sea, but at the expense of the local Arctic species. Other studies also suggest an increase in biomass of zooplankton in the western Chukchi Sea coincident with warming, again pointing to an increased role of Pacific species in general and *Calanus glacialis,* an important lipid-storing copepod, specifically (Ershova et al. 2015a, Ershova et al. 2015b). *Calanus glacialis* populations differ between the NBS and CS (Nelson et al. 2009, Spear et al. 2019, Spear et al. 2020) and may have recently begun to decline in the face of unprecedented warming (Huntington et al. 2020). As the Chukchi Sea experiences less ice with increased warming, the response of the zooplankton community will play an important role should the system become more pelagic.

In this study, we examine the long-term distribution of two dominant zooplankton species in the Chukchi Sea from 2010 to 2019. As the Arctic is already experiencing significant transformation in the face of warming (Huntington et al. 2020), the primary objective was to determine if recent variability in oceanography were correlated to shifts in the abundance of two dominant copepods, *C. glacialis* and *Pseudocalanus* spp. complex (Ershova et al. 2016, Questel et al. 2016). Both species are key members of the food web and affect trophic transfer to higher organisms. We compared the abundances of each species in relation to dominant water masses in the Chukchi Sea over time and determined if specific patterns related to oceanography may be used to make inferences about each species in the face of continued warming. Evidence of shifting populations may also be interpreted as an indicator of future shifts in the food web of the Chukchi Sea from a benthic dominated system to one that is more pelagic (Grebmeier 2012).

Methods

Study area

The Chukchi Sea has a broad, mostly shallow (<50 m) shelf situated between Alaska, USA and Siberia, Russia (Fig. 1). Survey transects varied among years, 2010–2019, depending on the scientific focus for the year, available ship time, and ice distribution. Surveys were primarily conducted in the later summer (August-October) with some variability among years in exact survey timing. Surveys were conducted as part of several different research projects including Arctic Whale Ecology Study (ArcWEST) (Brattström et al. 2019), Chukchi Acoustic Oceanography and Zooplankton Study (CHAOZ) (Berchok et al. 2015), the Distributed Biological Observatory (https://www.pmel.noaa.gov/dbo/), and the Arctic Integrated Ecosystem Research Program (https://www.nprb.org/arctic-program/about-the-program/).

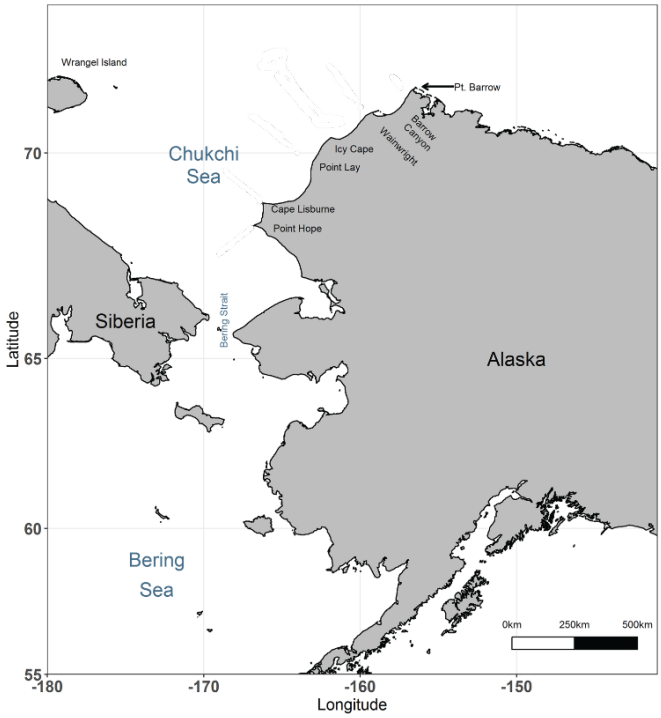

Figure 1.

Physical data

Water temperature (°C) and salinity data were calculated from conductivity temperature depth (CTD) measurements using a FastCat (Sea-bird SBE49) attached to the zooplankton tow cable. During 2019, the conducting winch failed during the second half of the research cruise, thus no FastCAT measurements were made for a portion of the sampling grid. As the zooplankton net samples the entire water column, the mean water column temperature and salinity were calculated over the maximum depth of the zooplankton tow. Based on these mean water temperatures and salinities, each station where a CTD measurement was taken was classified into a particular water mass based on (Danielson et al. 2020) (Table 1).

Table 1. Water mass designations from (Danielson et al. 2020).

Water mass	Abbreviations	Temperature range	Salinity range
Anadyr Water	AnW	$0 < T < 3$	$32.5 < S < 33.8$
Ice Melt Water/cool Coastal Water	IMW/cCW	$-2 < T < 3$	$22.0 < S < 30.8$
Cool Shelf Water	cSW	$0 < T < 3$	$30.8 < S < 32.5$

Warm Coastal Water	wCW	3 < T < 14	18.0 < S < 30.8
Warm Shelf Water	wSW	3 < T < 14	30.8 < S < 33.4
Modified Winter Water	MWW	-1 < T < 0	30.8 < S < 33.8
Winter Water	WW	-2 < T < -1	30.8 < S < 35.0
Atlantic Water	AtlW	-1 < T < 3	34.0 < S < 35.0
Bering Basin Water	BBW	3 < T < 5	33.8 < S < 35.0

Zooplankton data

Zooplankton were collected using multiple gear types over the sampling period. Zooplankton were collected primarily during daylight hours using a multiple-opening and closing 1 m^2 Tucker Sled trawl and sled-like runners at the bottom so that samples could be taken in close proximity to the bottom. A 505 µm (2013–2015) or a 333 µm (2010–2012) mesh net sampled while the sled was towed at a speed of 1.5–2.0 knots along the bottom for 2 min, then mechanically tripped to close and simultaneously open a second net to sample the entire water column from the bottom to the surface (wire retrieval rate 20 m min^{-1}). For smaller taxa, a 25 cm net with 150 µm mesh was suspended in the larger net that profiled the entire water column. Note that this setup is not ideal in cases where clogging in the 20- cm net occurs, thus the possibility of inaccurate volume filtered readings exist in this study. Samples that appeared questionable (e.g. low flowmeter readings, large jellyfish in the net) were excluded from the analysis. Taxa such as *C. glacialis* and *Pseudocalanus* spp. were enumerated in the water column only and not in the epibenthic samples. Both Tucker nets were equipped with a separate calibrated General Oceanics flow meter to estimate volume filtered. In other years, a paired bongo net (20 cm frame, 153 µm mesh for the smaller net and 60 cm frame, 505 µm mesh for the larger net) (Napp et al. 1996, Incze et al. 1997, Kimmel et al. 2018) from 2016-2019.Plankton captured by the nets were washed into the cod-ends, sieved through appropriately-sized wire mesh screens and preserved in glass jars with sodium borate-buffered 5% Formalin. Samples were inventoried at the end of the cruise and then sent to the Plankton Sorting and Identification Center in Szczecin, Poland, for processing. Subsampled taxa were enumerated and identified to lowest possible genera and life stage and returned to the Alaska Fisheries Science Center for verification. Ten percent of the returned samples were checked for quality assurance/quality control of species identification and enumeration.

Results

Water column mean water temperatures were warmer closer to the Alaska coast and in the southern portion of the Chukchi Sea over the study period (Fig. 2). The coldest temperatures were located near Point Barrow (see Fig 1). The warmest temperatures occurred during the latter portion of the study period, from 2017-2019 (Fig. 2). The coldest temperatures were observed in 2013 and 2016, though samples were restricted to northern locations during these years (Fig. 2). Salinity values were variable across the study region, showing no distinct spatial patterns that were repeated across years (Fig. 2). Overall salinity values also showed no temporal pattern (Fig. 2).

Figure 2. Mean water column temperature (°C) and salinity for zooplankton tows.

The predominant water mass (52% of all stations) observed was warm shelf water (wSW, see Table 1). This water mass was widespread during the latter three years of the study period (Fig. 3). The next two most commonly encountered water masses were ice melt water/cool coastal water (IMW, 23% of stations) and cool shelf water (cSW, 22% of stations). These water masses were found in the northern portion of the study region, near Point Barrow and Barrow Canyon (see Fig. 1).

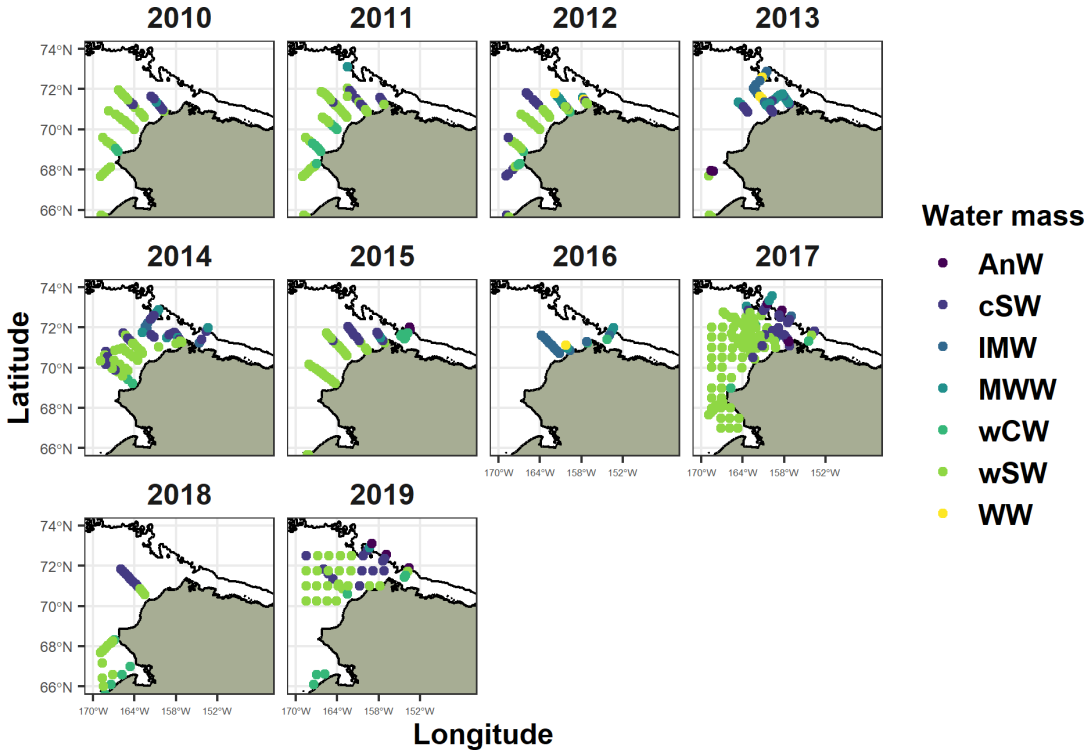

Figure 3. Distribution of water masses based on mean water column water temperature and salinity. Abbreviations for each water mass are defined in Table 1.

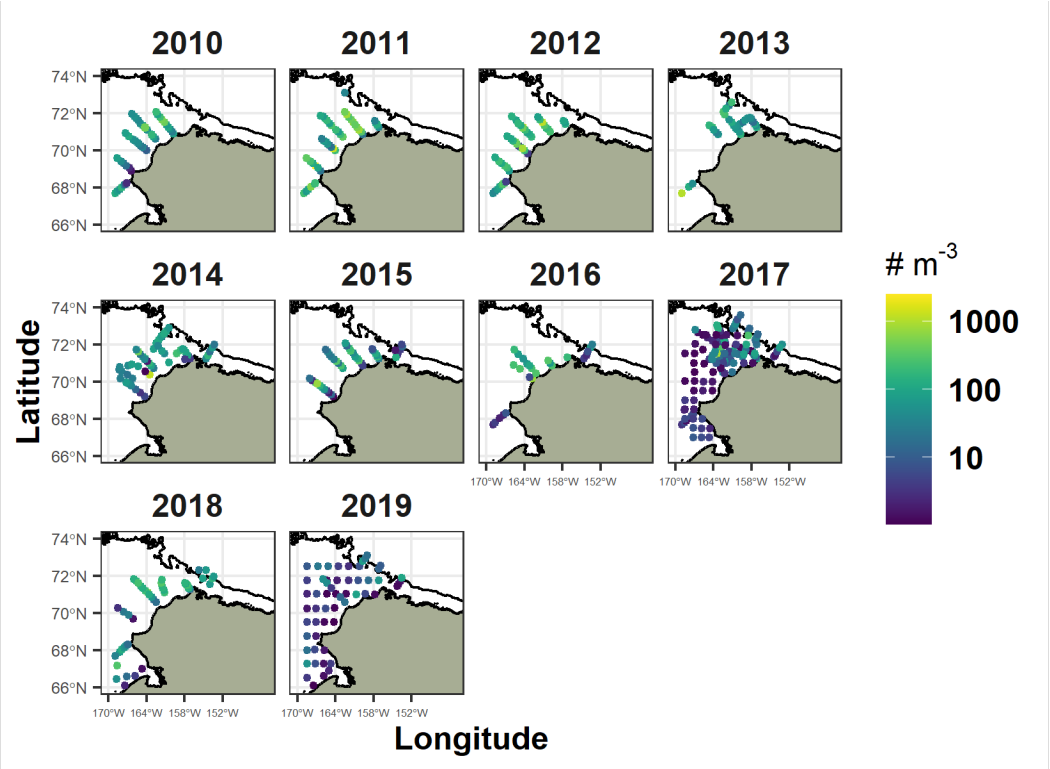
The two zooplankton species of interest showed differences in their distribution over the study period. *Calanus glacialis* was most abundant in the northern portion of the study region (Fig. 4). Abundances of *C. glacialis* peaked in 2011 and 2012, with numbers nearly three times as high as any other year (Fig. 4). Numbers for *C. glacialis* were lowest in 2019 (Fig. 4). *Pseudocalanus* spp. were most abundant in the southern portion of the study region, particularly in the latter three years (Fig. 5). *Pseudocalanus* spp. showed variability over time, peaking in 2014 and 2019 (Fig. 5). *C. glacialis* abundances were highest in cool shelf water, with abundances nearly 2.5 times greater than other

water masses (Table 2). In contrast, *Pseudocalanus* spp. was most abundant in warm shelf water and had very low abundances associated with Ice Melt Water (Table 2).



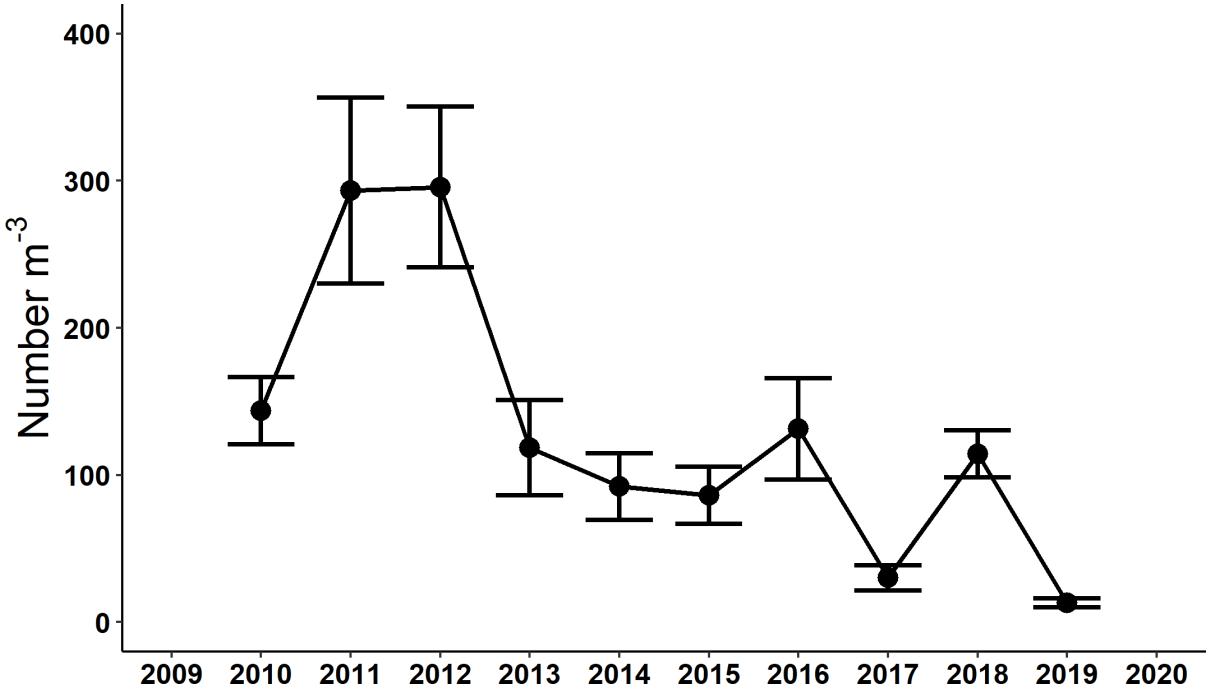


Figure 4. Spatial distribution of *Calanus glacialis* abundance (number m^{-3}) (top panel) and mean (± standard error) annual abundance (number m^{-3}) of *C. glacialis* abundance (bottom panel).

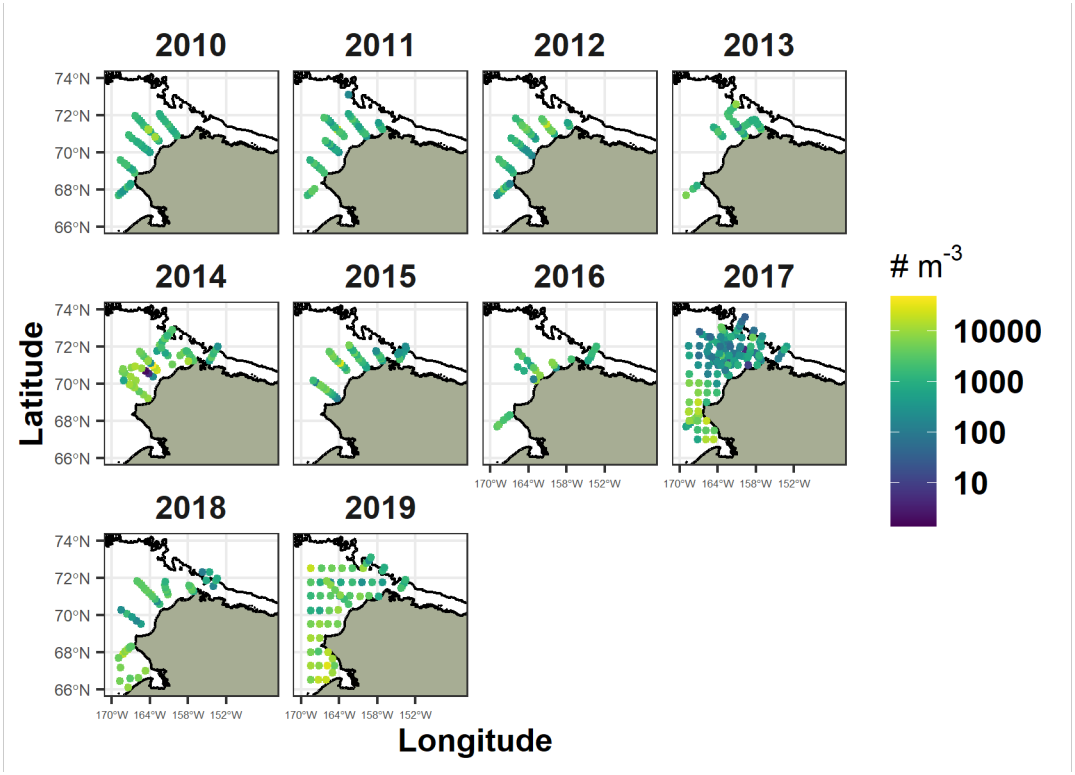

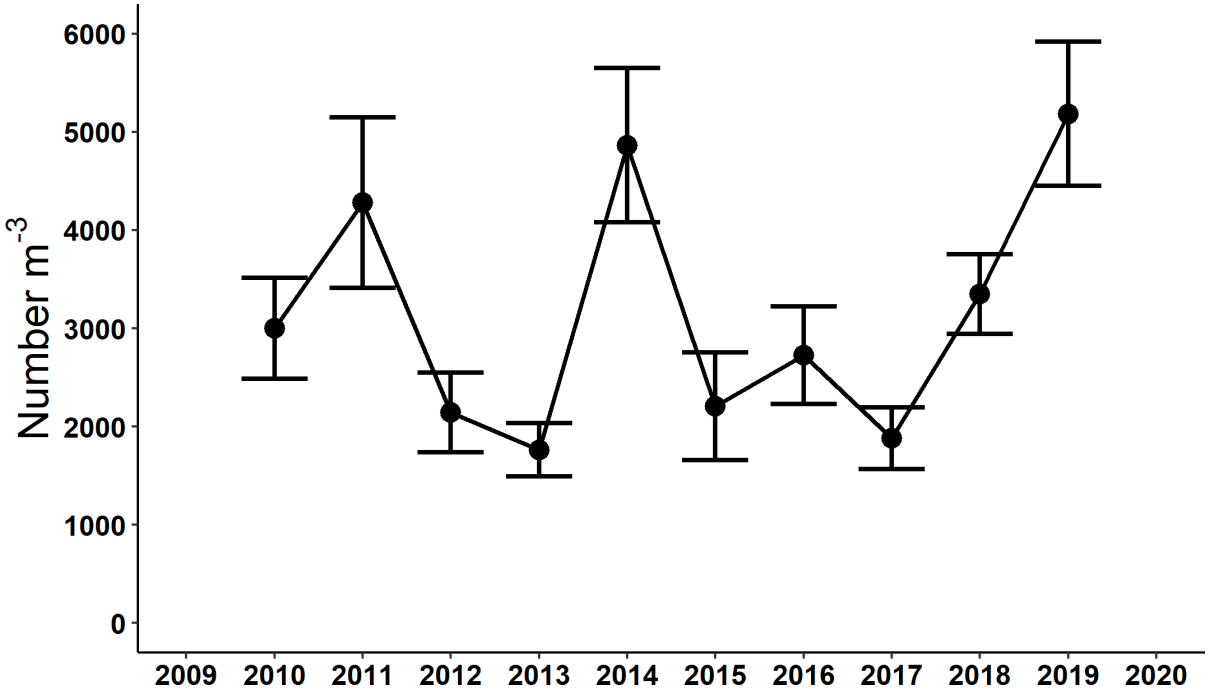

Figure 5. Spatial distribution of *Pseudocalanus* spp. abundance (number m^{-3}) (top panel) and mean (± standard error) annual abundance (number m^{-3}) of *Pseudocalanus* spp. abundance (bottom panel).

Table 2. Mean abundance (± standard deviation) of *C. glacialis* and *Pseudocalanus* spp. for each dominant water mass type

Water mass	Abbreviations	*C. glacialis*	*Pseudocalanus* spp.
Ice Melt Water/cool Coastal Water	IMW/cCW	100.45 (91.33)	1252.32 (1248.65)
Cool Shelf Water	cSW	267.92 (207.34)	5970.26 (4616.67)
Warm Shelf Water	wSW	88.59 (167.35)	6906.64 (7947.72)

Discussion

The two copepod species appeared to respond differently over the 10 year period of observation in the Chukchi Sea. The variability in intrusion of Bering Sea water over time relates strongly to the zooplankton community composition observed (Pinchuk and Eisner 2017, Kim et al. 2020, Spear et al. 2020) and both species were no exception. The copepod *Calanus glacialis* was associated with cold/cooler water and was more abundant during years that featured greater coverage of these water masses. The dominant smaller copepod, *Pseudocalanus* spp., was found in high abundance in both cool shelf water and warm shelf water. The response of both species appears to be related not only to water mass distribution, but also to population structure and species composition. The most striking response over the time-period was the widespread warm conditions in the latter half of the study period, resulting in a steady rise in the abundance of *Pseudocalanus* spp. beginning in 2017 in the southern Chukchi Sea and these species became widespread in 2019. This coincided with a precipitous decline in *C. glacialis* abundance during 2019. This unprecedented event comes after steady warming of the Chukchi Sea (Danielson et al. 2020), recent periods of low ice in the Bering Sea (Stabeno and Bell 2019), and unprecedented influx of heat into the Chukchi Sea (Huntington et al. 2020). Hereafter we attempt to provide context to this observation and present potential implications of a shift in these two species.

The copepod *C. glacialis* is known to be widespread in the shallow shelf of the Chukchi Sea (Hopcroft et al. 2010, Ershova et al. 2015b). Its annual life cycle appears to be related to ice formation and retreat (Søreide et al. 2010) in Arctic waters. However, more complex population dynamics appear to be occurring in the Chukchi Sea as it has been suggested that two distinct populations exist, a northern endemic population and once that is routinely advected from the northern Bering (Pinchuk and Eisner 2017, Spear et al. 2019). This is also supported by genetics (Nelson et al. 2009; Ashjian et al. 2017). Any differences in ecology between these two populations remain unknown; however, differences in temperature sensitivity may be expected as Arctic *Calanus* species have longer life cycles more adapted to longer periods of ice cover (Ji et al. 2012). This difference in temperature sensitivity may impact the number of annual cohorts, diapause timing, and lipid storage dynamics (Banas et al.

2016, Renaud et al. 2018). Therefore, the increasing influx of Bering Sea water (Woodgate 2018) resulting in increased population into the Arctic may result in food web changes related to different life-history behavior of the *C. glacialis* Bering Sea population.

The copepod *Pseudocalanus* spp. is complex of up to four species, two of which are temperate (*P. mimus* and *P. newmani*) and two are Arctic (*P. acuspes* and *P. minutus*) (Ershova et al. 2016, Questel et al. 2016). These species are difficult to distinguish morphologically, but using genetics Ershova et al. (2016) determined that *P. acuspes* is likely the dominant genus in the Chukchi Sea with *P. newmani* occurring as well, though significant variability over time was observed. Only *P. mimus* did not contribute significantly to overall biomass in the Chukchi Sea (Ershova et al. 2016). The presence of multiple species may explain the similar abundance of *Pseudocalanus* spp. in both cool and warm water masses as *P. acuspes/P. minutus* may have been the primary taxa in cooler waters whereas *P. newmani* may have been the representative taxa during the warming event in the latter half of the record. Such differences have important implications for the food web as *P. acuspes* has higher rates of estimated secondary production on average (Ershova et al. 2016), is larger and stores more lipids relative to temperature species (McLaren et al. 1989). Thus, the relative shift to smaller bodied zooplankton predicted for boreal regions may be complicated by differing ecology of these species and *Pseudocalanus* spp. is a prime example.

As the Arctic continues to warm at a rapid pace, changes in the biogeography of the Chukchi Sea should be expected (Sigler et al. 2017). The connectivity between the northern Bering Sea and the Chukchi will increase (Woodgate 2018) with longer periods of reduced ice cover being predicted (Overland and Wang 2007). We reach similar conclusions to others that Pacific species endemic to the Bering Sea will become increasingly prevalent in the Chukchi Sea food web (Matsuno et al. 2011, Sigler et al. 2011, Ershova et al. 2015b, Kim et al. 2020). Such a change will impact the relative timing of zooplankton availability in general and these species specifically. A reduction in overall lipid availability may be one consequence of population shifts, though it has been suggested that species that do not store lipids will fare poorly in Arctic waters (Ershova et al. 2016) or that other mechanisms will compensate for lower lipid occurrence (Renaud et al. 2018). Here we focused only on two key copepod species; however, we aim to examine the community as a whole to elucidate further patterns related to oceanography.

Chapter 15: Detection of high levels of paralytic shellfish toxins in Northern Alaskan food webs and estimated toxin doses to Pacific walruses and Bowhead whales

Lefebvre, K., et al., NOAA Fisheries, kathi.lefebvre@noaa.gov

Lefebvre, K. et al. (in preparation) ***Paralytic shellfish toxins (PSTs) in Arctic food webs in 2019 during anomalously warm ocean conditions and estimated toxin doses to Pacific walruses and bowhead whales***

Introduction: Climate change-related ocean warming and reduction in Arctic sea-ice extent, duration and thickness increase the risk of cyst germination and toxic blooms of the dinoflagellate, Alexandrium catenella. This algal species produces neurotoxins that impact marine wildlife health and cause the human illness known as Paralytic Shellfish Poisoning (PSP).

Methods: This study reports Paralytic Shellfish Toxin (PST) concentrations quantified in Arctic food web samples which include phytoplankton, zooplankton, benthic clams, benthic worms, and pelagic fish collected in summer 2019 during anomalously warm ocean conditions.

Results and Discussion: PSTs were detected in all trophic levels with the highest concentrations in benthic clams collected offshore on the continental shelf in the Beaufort, Chukchi, and Bering Seas. Most notably, toxic benthic clams (*Macoma calcarea)* were found north of Saint Lawrence Island where Pacific walruses (*Odobenus rosmarus*) are known to forage for a variety of benthic species, including *Macoma*. Fecal samples collected from 13 walruses harvested for subsistence purposes near Saint Lawrence Island during March to May 2019, all contained detectable levels of STX. In contrast, only 64% of fecal samples from zooplankton-feeding bowhead whales (n = 9) harvested between March and September 2019 in coastal waters of the Beaufort Sea near Utqiaġvik (formerly Barrow) and Kaktovik were toxin-positive. This was consistent with the lower concentrations of PSTs found in regional zooplankton prey. These findings raise concerns regarding potential increases in PST/STX exposure risks and health impacts to Arctic marine mammals as ocean warming and sea ice reduction continue.

Key words: Phytoplankton, Bering Sea, Chukchi Sea, Synechococcus

Intended Journal: Oceans

Abstract: Size structure of phytoplankton populations has been shown to be an important determinant of the flow of carbon and energy to higher trophic levels in Arctic ecosystems. Phytoplankton populations dominated by small (<10um) pico- and nanophytoplankton cells are generally dominated by eukaryotic flagellates that are tightly grazed by microzooplankton leading to increases in trophic length. General dogma suggests that the picocyanobacteria *Synechococcus* is detectable but comprises a negligible fraction of phytoplankton carbon in Arctic ecosystems. As part of the Arctic IERP sampling program, we quantified the abundance of the *Synechococcus*, and other picophytoplankton, during the spring to fall period between 2017-2019 in the Northern Bering and Chukchi Seas. *Synechococcus* abundances increased from <500 cells/ml in spring to >50,000 cells/ml in the fall around Kotzebue Sound. Furthermore, the spatial extent of regions with elevated *Synecococcus* abundances in late summer/fall, as well as the absolute abundances, increased from 2017 to 2019, coincident with increasing late summer/fall water temperatures. When integrated over the euphotic zone, *Synechococcus* contributed up to 40% of estimated total phytoplankton carbon during late summer/fall in Kotzebue sound and the region near Icy Cape. These observations support an increased importance of a previously marginal phytoplankton group during a warming period in the Chukchi Sea. The full implications of these changes in the phytoplankton community remain to be resolved.

Introduction: Arctic and subarctic seas are facing many stressors that may lead to significant changes in its function in the future (IPCC 2021). An important change is sea ice loss that when coupled with intensification of the hydrological cycle (Peterson et al., 202; Serreze et al., 2006) will likely lead to increases in stratification in near shore shelf systems, a key controlling factor of the productivity, through negative impacts on nutrient inputs, and structure of marine ecosystems of the Arctic Ocean (Carmack et al., 2006, Carmack 2007). The impact(s) of these

changes on phytoplankton at the base of marine food chains is not completely resolved, particularly changes in phytoplankton community size structure (Tremblay and Gagnon, 2009).

Globally picophytoplankton (<2um) are well known and dominate in the major oligotrophic ocean gyres, but dogma is that they are not quantitatively important in the sub/arctic systems (Buitenhuis et al. 2011, Flombaum et al. 2013). In contrast, numerous measurements of size-fractionated chlorophyll have shown that the picoplankton size fraction can dominate phytoplankton biomass in sub/arctic systems during oligotrophic periods (e.g., summer) and regions (e.g., off-shelf) (e.g., Booth and Horner, 1997; Brugel et al., 2009; Legendre et al., 1993; Li et al., 2009; Odate, 1996). Given that picophytoplankton have a much higher carbon to chlorophyll ratio than microphytoplankton, it is likely that their importance to both carbon cycling and quality as a food source has been further underestimated (Lee et al., 2013). Within the picophytoplankton size class there is a wide diversity of both eukaryotic (e.g., prasinophytes and cryptophytes, Lovejoy et al., 2007; Sergeeva et al., 2010) and prokaryotic (e.g., Cottrell and Kirchman, 2009; Not et al., 2005) organisms. More recent studies have used flow cytometry as a more efficient tool to numerically quantify these <2um cells into operational categories (i.e., pico- and nanophytoplankton; Laney and Sosik, 2014), although some organisms do contain unique pigment signatures that allow them to be distinguished from other similar cells. For example, *Synechoccocus* and cryptophytes both contain the orange pigment phytoerythrin, and thus can be identified as specific groups within the pico- and nanophytoplankton.

In the region between the eastern Beaufort Sea and Baffin Bay picophytoplankton numerically dominate in deeper water stations off shelf, and particularly in the SCM (e.g., Ardyna et al., 2011, Schlooss et al. 2008). In the Chukchi and western Beaufort Seas, it has also been shown that small prasinophytes, other flagellates (e.g., cryptophytes) and non-colonial phaeocystis (<5um) dominated in the deeper basin sites during summer and fall, while diatoms dominated on the shallow shelf (Gosselin et al 1997, Booth and Horner, 1997; Hill et al., 2005; Sergeeva et al., 2010; Sherr et al., 2003). Based upon a few stations in the southern Bering Sea, Liu et al. (2002) observed that picophytoplankton abundance, both *Synechococcus* and eukaryotes decreased from the basin to the shelf. Some eukaryotic picophytoplankton strains have been shown to persist through the winter maintaining growth rates that exceed grazing losses, and have been suggested to represent unique temperature controlled biogeographical clades (Lovejoy et al., 2007). Representatives of this eukaryotic psycrophillic clade are pan-Arctic, with some representatives having maximum growth temperatures of ~12.5◦C, so there may be problems in the future, and could cause disruptions in the food web. In contrast, the picocyanobacteria *Synechococcus,* has been found to be associated with slightly warmer and saltier water than eukaryotic picoplankton (Cottrell and Kirchman, 2009; Not et al., 2005; Tremblay and Gagnon, 2009, Waleron et al., 2007, Gradinger and Lenz 1989). Interestingly, Waleron et al. (2007), using eDNA analysis, identified 6 OTUs similar to *Synechoococcus* from the Mackenzie River system. These OTUs were linked to freshwater *Synechococcus* and it was concluded that they flushed into the system and implied they survived but were not actively growing.

The distributions of picophytoplankton around the sub/Arctic are important to understand, in particularly their contributions to total biomass (not just numbers), as well as the environmental variables that they correlate with to understand the niches that they currently occupy and when

those niche boundaries might be exceeded. In this study we address the following questions. 1) what are the large spatial (i.e., cross shelf) and seasonal patterns of *Synechococcus* abundance and biomass in the Northern Bering and Chukchi Seas; 2) what are the environmental parameters associated with patterns in *Synecococcus* biomass; and 3) is there evidence of long term trends in *Synechococcus* biomass.

Methods: *Sample collection:* Physical, chemical and biological measurements were made as part of the Arctic Integrated Ecosystem Research Program (AIERP, 4 cruises, and one cruise of opportunity) within the Northern Bering and Chukchi Sea region (Table 1, Figure 1). Samples were collected in clean Niskin bottle at roughly 10m spacing throughout the water column. At each station and depth a range of discrete phytoplankton samples were collected including size-fractionated chlorophyll a (Chl-a), picoplankton and nanoplankton counts by quantitative flow cytometry (e.g., Lomas et al., 2010), microplankton counts by inverted microscopy and FlowCAM, and seston particulate organic carbon (POC). Only flow cytometry data data are reported in this study.

Phytoplankton cell counts and carbon biomass estimates: Samples for picoplankton enumeration were generally collected at four to seven depths throughout and just below the euphotic zone, fixed with paraformaldehyde (0.5% final concentration), stored at ~4°C for 1-2 h, before long-term storage at -80°C. Samples were analyzed on a Becton Dickinson (formerly Cytopeia Inc.) Influx or Jazz cytometer using a 488 nm blue excitation laser, appropriate Chl-*a* (692 ± 20 nm) and phycoerythrin (580 ± 15 nm) bandpass filters, and was calibrated daily with 0.53-µm and 3.0-µm fluorescent microbeads (Spherotech Inc. Libertyville, Illinois, USA). Each sample was run for 4-6 min (~0.3-0.5 mL total volume analyzed), with log-amplified Chl-*a* and phycoerythrin fluorescence, and forward and right-angle scatter signals recorded. Data files were analyzed from two-dimensional scatter plots based on Chl.-*a* or phycoerythrin fluorescence and characteristic light scattering properties (e.g., DuRand and Olson, 1996) using FCS Express 3.0 (DeNovo Software Inc. Los Angeles, California, USA) or SortWare (Becton Dickenson, East Rutherford, New Jersey, USA). Picophytoplankton, operationally defined as cells <3.0-um, were identified as *Synechococcus* cells based upon cell size and the presence of phycoerythrin. Based upon these gating criteria, the number of cells in each identified population was enumerated and converted to cell abundances by the volume-analyzed method (Sieracki et al., 1993). Precision of triplicate samples was <10% for cell concentrations >200 cells mL^{-1}. Carbon per cell was estimated for flow cytometrically identified phytoplankton using a calibration curve that related cellular particulate organic carbon (POC) to normalized geometric mean cellular forward scatter (proxy for cell size) (e.g., DuRand et al., 2001, Casey et al. 2013, data specific to the flow cytometer used in this study). Carbon content of each identified population was estimated by multiplying volumetric cell abundance and POC per cell derived from the calibration curve.

Table 1. Summary details associated with cruises included in this analysis.

Cruise ID	Dates	Latitude (°N)	Longitude (°W)
		(min-max)	(min-max)
SKQ-2017-09S	5th June – 26th June 2017	56.4 to 69	-172.6 to -169
OS-1701	6th Aug – 27th Sept 2017	67.0 to 72.5	-169.0 to -152.3
SKQ-2018-13S	7th June – 23rd June 2018	63.3 to 69	-171.5 to -164.4
HLY-1801	8th Aug – 23rd Aug 2018	64.7 to 71.8	-170.0 to -153.8
OS-1901	1st Aug – 2nd Oct. 2019	63.3 to 72.5	-171.5 to -154.2

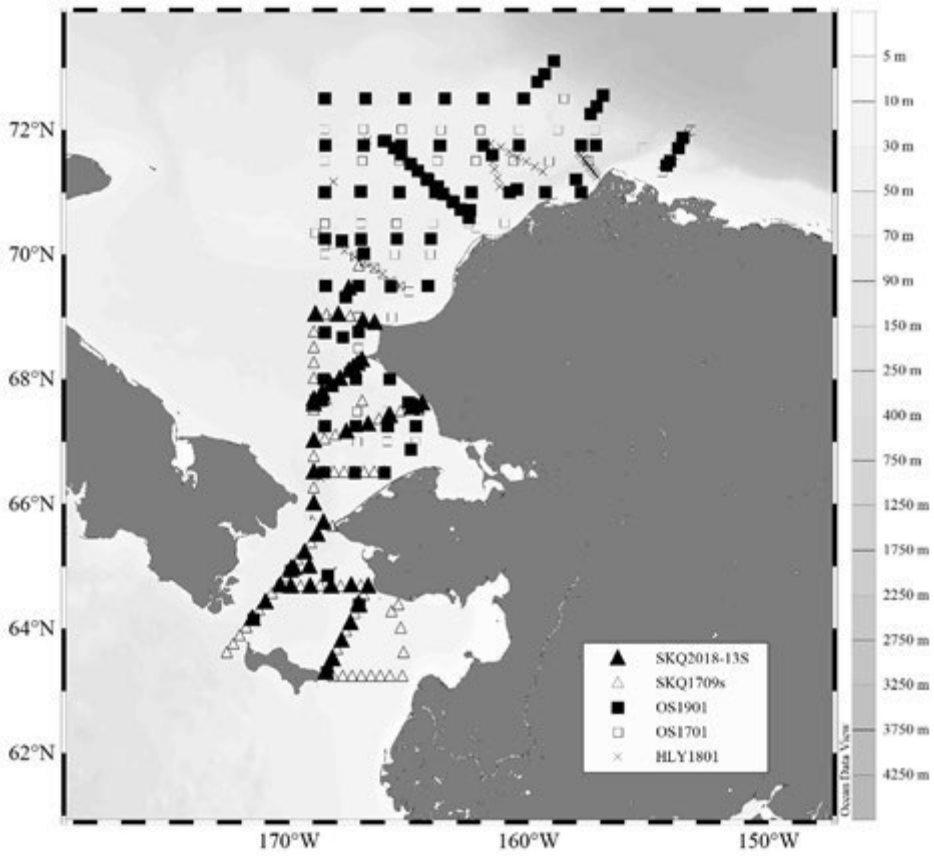

Figure 1. Map of station locations included in this analysis. There are a total of 494 discrete stations, although some are sampled multiple times over multiple cruises within the same program.

Chlorophyll: Sample volumes varied depending upon the cruise, but ranged from 0.1 - 1L, and in all cases were gently vacuum filtered (≤5 mm Hg) for total chlorophyll (Chl-a) analysis onto Whatman GFF (or equivalent) filters (nominal 0.7 µm pore size). At selected stations, size-fractionated chlorophyll concentrations were estimated by filtered paired samples sequentially through a 5 µm Whatman Track Etch polycarbonate filters and then a Whatman GFF filter. After filtration, samples were stored frozen at -80◦C until extraction and analysis. For analysis, samples were extracted in 5 ml of 90% acetone for 24 h at -20◦C. Samples were analyzed on a calibrated fluorometer, either Turner Designs TD-700 or 10-AU, with day-to-day performance of the fluorometer tracked using a commercially available solid standard. Fluorescence readings were taken before and after the addition of 75 µl of 1.2M HCl and concentrations calculated using standard equations (Parsons et al., 1984).

Dissolved nutrients: Samples for nutrient analysis were collected at the same depths as Chl-a and rate process incubation samples. Samples were syringe filtered using 0.45µm cellulose acetate membranes, and collected in 30ml acid washed, high-density polyetehnyel bottles after three rinses. On the BASIS and EcoFOCI cruises, samples were stored frozen at -80◦C and analyzed later at the shore-based facility, while samples from the BEST cruises were stored at 4◦C until analysis at sea, usually within 12 hrs of collection. Phosphate, nitrate, nitrite, and ammonium

concentrations were determined using a combination of analytical components from Alpkem, Perstorp and Technicon. WOCE-JGOFS standardization and analysis procedures (Gordon et al., 1993) were closely followed including reagent preparation, calibration of lab glassware, preparation of primary and secondary standards, and corrections for blanks and refractive index. Nutrient data from the Bering Sea program cruises were accessed from the Bering Sea Project Data Archive (Stabeno et al., 2013a, b), and data from the BASIS and EcoFOCI cruises were provided by co-author CWM.

POC analysis: [to be written]

Data analysis: [to be written]

Results: *Spatial and temporal distribution of* Synechococcus. *Synechococcus* cell abundance showed a clear seasonal variation in each major region (Figure 2). Cell abundance in the spring period were generally low (<1000 cells/ml), with the highest concentrations in the Northern Bering Sea/Bering Strait region. In stark contrast, in late summer/early fall, cell abundances could exceed 100,000 cells/ml. In summer/fall periods highest abundances were in Kotzebue Sound, although between years in the study the spatial extent of high cell abundances increased substantially.

Synechococcus abundances were found to have a seasonal vertical distribution pattern (Figure 3). During spring periods (e.g., June 2018), *Synechococcus* abundances were greater at depth, whereas in late summer/early fall (e.g., Aug/Sept. 2019), greatest *Synechococcus* abundances were restricted to the upper 20m of the water column over the broader spatial range where they were observed.

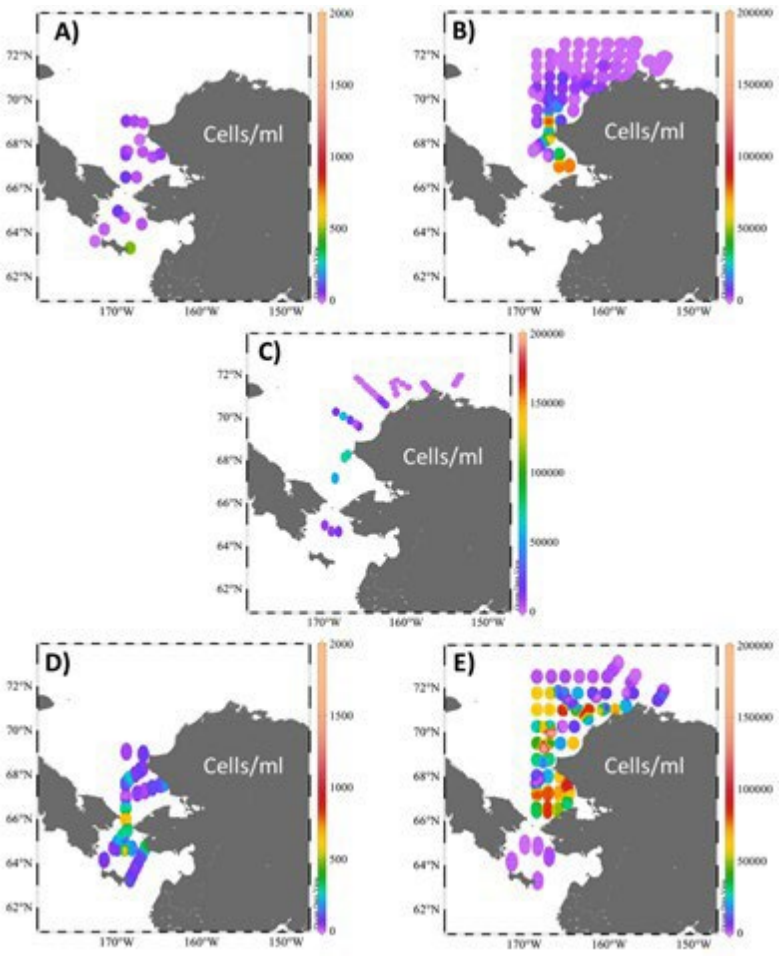

Figure 2. Seasonal patterns of Synechococcus abundance in the Northern Bering and Chukchi Seas. A) spring 2017 (SKQ-2017-09S), B) late summer/early fall 2017 (OS1701), C) summer 2018 (HLY1801), D) spring 2018 (SKQ-2018-13S), and E) late summer/early fall 2019 (OS1901). Note the 100x different in scales between the spring and late summer/early fall cruises.

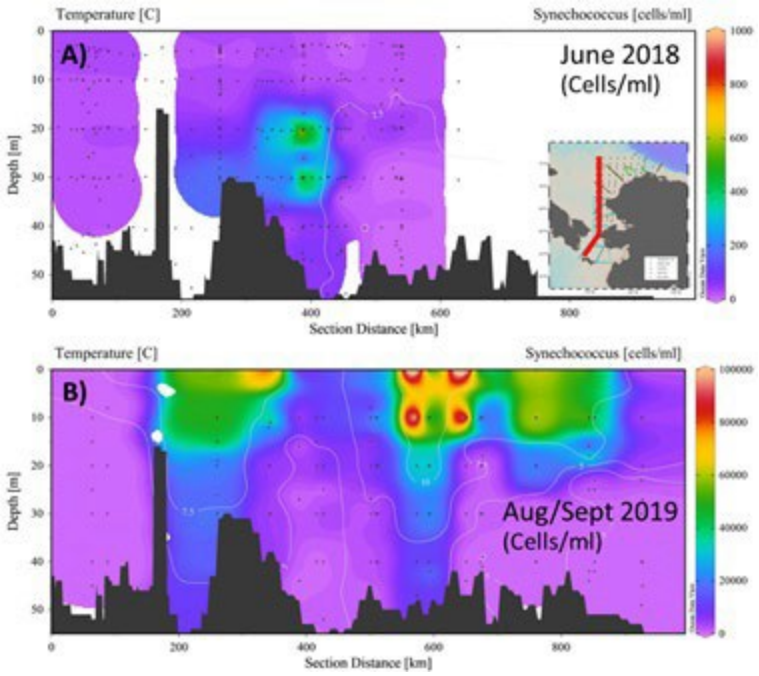

Figure 3. Latitudinal section plot of Synechococcus abundance through the study region.

Relationships to environmental parameters. Synechococcus cell abundances were highest in waters with temperatures >7oC and salinities <30.5 (Figure 4a). The T/S region where *Synechococcus* cell abundances were highest is classified as the warm coastal water (Danielson et al. 2020), although elevated abundances can also be found in the warmer/fresher regions of the warm shelf water. These waters are also depleted in inorganic nitrogen concentrations (Figure 4b).

Multiple linear regression (Model 2) analysis suggests that the only environmental variable that is significantly related to *Synechococcus* cell abundance is Temperature (Table 2). Interestingly there are two other nanophytoplankton populations, size-defined nanoeukaryotes, and the specific nanoeukaryote group of the cryptophytes, that are significantly related to *Synechococcus*.

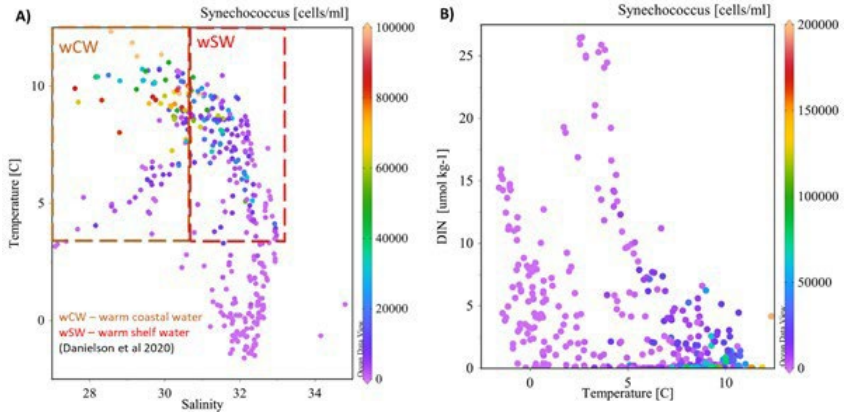

Figure 4. Relationships between Synechococcus abundance and environmental variables. A) temperature/salinity plot. Dashed lines bound the warm coastal water (orange) and warm shelf water (red) domain as defined by Danielson et al. 2020. B) temperature/ dissolved inorganic nitrogen (DIN) plot. DIN is defined as the sum of NO3, NO2 and NH4.

Table 2. Results of multiple linear regression (Model 2) analysis between *Synechococcus* abundance and environmental and biological variables. Variables significantly related to *Synechococcus* abundance are shown in italic font.

Parameter	**Coefficient**	**Std. Error**	**t-statistic**	**P-value**

Contributions to total biomass. Cell abundances were converted to carbon biomass values using the relationship between normalized forward light scatter and cellular carbon (Casey et al., 2013). Total phytoplankton carbon was estimated by multiplying total chlorophyll-a by the slope of the particulate organic carbon to chlorophyll-a ratio. *Synechococcus* carbon, as a percentage of total phytoplankton carbon, increased as total phytoplankton carbon decreased, reaching values as high as 40% of total phytoplankton carbon (Figure 5). At chlorophyll-a concentrations $\leq$2ug/L, a value commonly used to denote a 'bloom', *Synechococcus* could contributed >20% of total phytoplankton carbon and increased to >40% at <1ug/L chlorophyll. Samples from the shallowest depths and warmest temperatures consistently contributed higher fractions of total phytoplankton biomass.

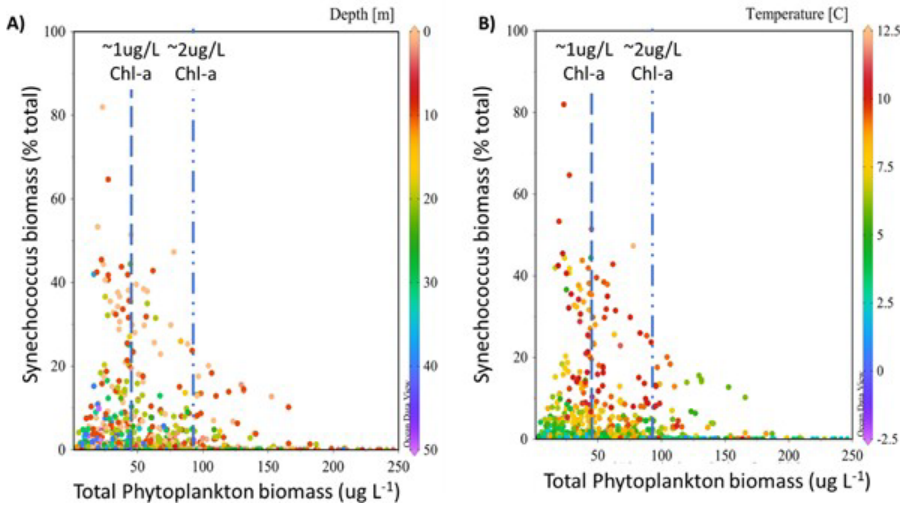

Figure 5. Contributions of Synechococcus to total phytoplankton carbon as function of A) depth and B) temperature. Dashed lines denote phytoplankton carbon associated with 1ug/L and 2ug/L chlorophyll.

Discussion

Highly productive systems like the Bering and Chukchi Seas are generally characterized by strong seasonal blooms of large phytoplanktonic diatoms that are rich in fatty acids and serve as an important food source for higher trophic levels. Seasonality of phytoplankton blooms, in particular the 'fall bloom' are gaining increasing recognition as being important in the trophic transfer of carbon and energy (Sigler et al., 2014). In the eastern Bering Sea shelf system, while *Synechococcus* has been observed (e.g., Liu et al., 2002; Moran et al., 2012) their abundances are generally low and represent a minor contribution to total phytoplankton carbon. The data presented in this study suggest that in the Chukchi Sea there is a very different pattern, with a much stronger seasonal amplitude in the abundance of *Synechococcus* and contribution to total phytoplankton carbon. Given the niche that *Synechococcus* fills globally (Flombaum et al., 2013; Visintini et al., 2021), our observations are consistent with *Synechococcus* growing into waters that are warm and nutrient deplete. In other ocean regions, *Synechococcus* abundances are tightly controlled by grazing (e.g., Worden and Binder, 2003), unfortunately there are not *Synechococcus*-specific grazing rates in the Northern Bering and Chukchi Seas. In the Northern Bering and Chukchi Seas, the picoplankton size fraction is tightly controlled by grazers, however, observations were at a time when *Synechococcus* abundances were low (Krause et al., 2021). The extensive net growth of *Synechococcus* during the late summer/fall period suggests a potential disruption to in this grazing control. The ecological impact of the observed increase in *Synechococcus* abundance remains to be fully understood.

Increasing Synechococcus *in a warming Arctic.* As *Synechococcus* has generally been considered a trivial component of the Arctic phytoplankton community, there are relatively few studies that have quantified their abundance and from which carbon biomass can be estimated. *Synechococcus* biomass increased over the past decade in the region of Kotzebue Sound and north (Cottrell and Kirchman, 2009; Laney and Sosik, 2014, this study; Figure

6a). During this time, water temperatures in this same region increased significantly (Cottrell and Kirchman, 2009; Laney and Sosik, 2014; Lee et al., 2013, this study; Figure 6b). This observation is consistent with our environmental analysis from this study where temperature was the only variable that was significantly related to *Synechococcus* abundance. Zhuang et al. (2021) observed that pigments associated with picoplankton, and potentially cyanobacteria, increased from 2008-2016 on a transect in the Chukchi Sea along Icy Cape, consistent with our observations.

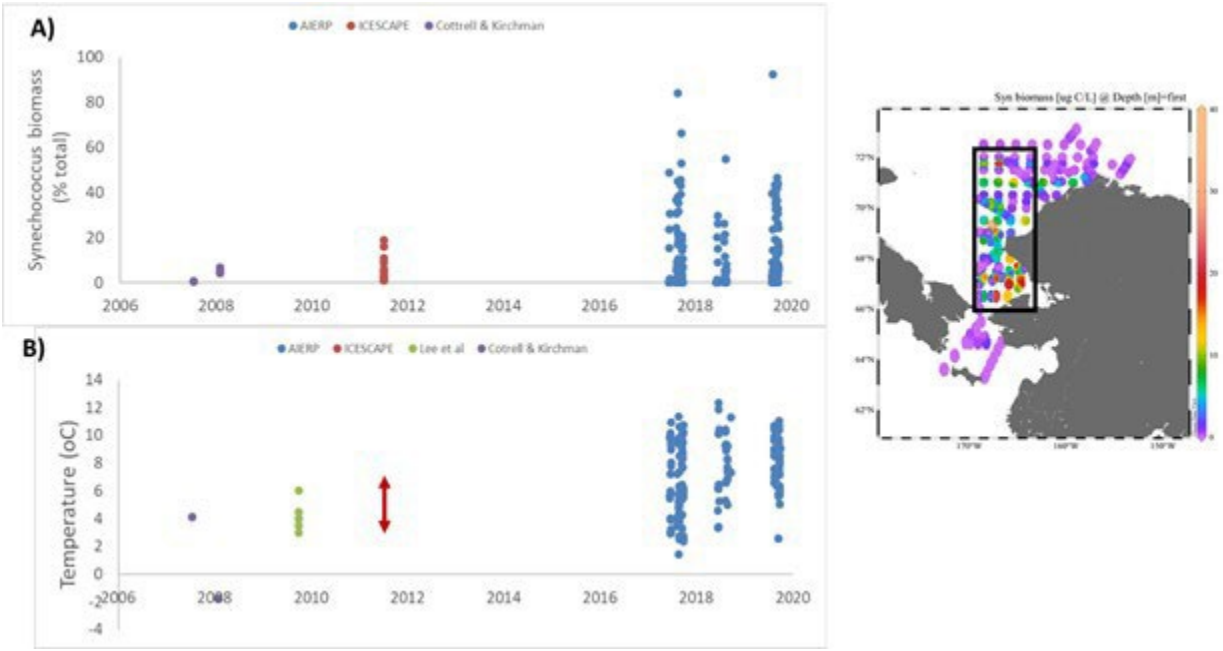

Figure 6. Changes in A) Synechococcus biomass and B) sample water temperature from published studies over time. Map inset shows the bounding box (black line) from which our data and those of previously published studies are used for this analysis.

Chapter 17: Estimates of heat transport through the Chukchi Sea to the Beaufort Sea from a decade of in situ observations

McCabe, R.M., NOAA Pacific Marine Environmental Laboratory, ryan.mccabe@noaa.gov
Stabeno, P.J.

McCabe, R. M., P. J. Stabeno, et al. (in preparation) Estimates of heat transport through the Chukchi Sea to the Beaufort Sea from a decade of *in situ* observations

Introduction: An increasing trend in northward volume transport through Bering Strait and into the Chukchi Sea is well established. Analyses of historical water property profiles have similarly quantified a multi-decade warming trend in the Chukchi Sea, with higher rates of increase in recent years. The water column heat content transported across the Chukchi shelf ultimately empties into the Canada Basin where it contributes to an observed accumulation of heat, likely with far reaching consequences. To better understand the amount of, and variations in, heat that gets delivered to the Canada Basin, we use *in situ* observations to construct a decade-long direct estimate of heat transport over the Chukchi Sea continental shelf.

Methods: Water column velocity and near-bottom temperature observations from three mooring sites spanning the eastern Chukchi Sea continental shelf are used to construct a time series of the along-shelf transport of heat from the Chukchi Sea into the Beaufort Sea via Barrow Canyon. In winter months, observations suggest the water column is well mixed such that near-bottom temperature records are sufficient for constructing the heat transport estimates. During ice-free seasons, data from the three primary mooring locations are supplemented with sea surface temperature from satellites, ship-based water property profiles, and from short duration moorings having shallower records.

Results and Discussion: The resulting transport of heat out of Barrow Canyon and into the Beaufort Sea changes seasonally with essentially no northward heat transport in winter months. Variability in monthly heat transport is primarily a result of changes in water column heat content with a smaller contribution from changes in volume transport. Interannual differences in the heat transport are also discussed. On an annual basis, there is enough heat exiting the Chukchi shelf through Barrow Canyon to warm the upper 100 m of the Beaufort Sea by approximately 0.5 °C.

Chapter 18: Surface versus advective heat fluxes on the shallow Chukchi Sea continental shelf

McCabe, R.M., NOAA Pacific Marine Environmental Laboratory, ryan.mccabe@noaa.gov
Stabeno, P.J., Mordy, C.W.

McCabe, R. M., P. J. Stabeno, C.W. Mordy, et al. (in preparation) Surface versus advective heat fluxes on the shallow Chukchi Sea continental shelf

Introduction: The goal of this project was to analyze in situ moored observations of water column temperature and associated atmospheric variables (shortwave and longwave irradiance, wind velocity, air temperature, relative humidity) within the context of a heat budget for the central Chukchi Sea shelf. Ultimately we seek to better understand the relative contributions of heat resulting from two sources: local surface fluxes and oceanic advection of heat from remote locations.

Methods: Bulk algorithms were used to make estimates of the net surface heat flux and its primary components (shortwave, longwave, sensible, and latent) over a roughly two-month period during summer 2015. Satellite sea surface temperature and available shipboard data are used to estimate spatial temperature gradients. When these records are combined with nearby moored velocity records, an advective component of the heat flux can be estimated.

Results and Discussion: Over the first month of the deployment, the cumulative net surface heat flux increased at a nearly constant rate. After mid August, net shortwave irradiance decreased and both the sensible and latent heat fluxes generally increased in magnitude, acting to remove heat from the ocean surface. During this latter half of the record, no additional accumulation of heat was observed. A low-pressure storm system moved into the region in late August, efficiently mixing heat throughout the water column. Analyses of the advective component of the heat flux are ongoing, but, at present, it appears that surface and advective fluxes contribute more or less equivalently to the total heat flux.

Chapter 19: Interannual variability of salts and nutrients at the Distributed Biological Observatory Site DBO 1

Mordy, C.W., CICOES, University of Washington, mordy@uw.edu

Stabeno, P.J., Hristova, H.

Mordy, C.W., P. Stabeno, H. Hristova (in preparation). Interannual variability of salts and nutrients at the Distributed Biological Observatory Site DBO1

Introduction: In winter, nutrient replenishment in the eastern Chukchi Sea is primarily the result of transport of nutrients from the Bering Sea shelf and slope. Along the Ice Cape line in the Chukchi Sea, pre-bloom concentrations of nitrate, a limiting nutrient, were found to vary by ~40%. This variability is driven by interannual differences in both winter transport and the concentration of inorganic nitrogen (nitrate and ammonium) in the Bering Sea source water. Variability in winter transport in the Chukchi Sea is driven by northerly (weakens transport) and southerly (strengthens transport) wind events, with a recent increase in southerly wind events. Unknown are the drivers of nutrient variability in the Bering Sea. The goal of this study is to unravel physical drivers of nutrient variability on the northern Bering Sea shelf.

Method: To study the physical drivers of this variability, we examined surface geostrophic currents from altimetry (anomaly from 1993-2012 mean), velocity data from the M8 and M5 moorings, and the relationship between salinity and DIN (nitrate and ammonium) along the slope to determine variability in the contribution of slope water versus middle shelf water to DBO1.

Results and Discussion: There is considerable spatiotemporal variability in nitrate and ammonium concentrations across the northern Bering Sea. The inner shelf (<50 m) is well-mixed and nutrient poor. The middle shelf (50-100 m) is stratified in summer with nutrient depleted surface water and higher nutrients in the bottom layer. However, in the bottom layer. ~30% of the nitrate typically found in source waters along the slope have been lost to the ecosystem through denitrification. The outer shelf (100-200 m) is more frequently flushed with slope water, and has higher nutrient content and a weaker denitrification signal. Therefore, the relative contributions of slope and shelf water largely determine interannual variability of nutrient content in Bering Sea source water that flows through central Bering Strait. Interannual variability of salinity and DIN were highly correlated, and the salinity at M8 was dependent upon northward transport that includes on-shelf flow of slope water. Since 2005, DIN concentrations around the M8 mooring were lowest in 2016 (11.3 μM) and greatest in 2019 (24 μM). Hence, year-to-year differences in the amount of DIN in source waters that are transported to the eastern Chukchi Sea vary by ~50%, and suggest that net community production over the eastern Chukchi Sea may have varied between ~30 and 70 g C m^{-2} during this time.

KEYWORDS: Fatty acid analysis, Arctic, Chukchi Sea, northern Bering Sea, phytoplankton

ABSTRACT

Arctic and subarctic ecosystems are transitioning due to ocean warming, resulting in conditions that will lead to shifts in phytoplankton communities, their nutritional compositions, and production of fatty acids (FA). FA biomarkers are useful indicators of changing phytoplankton community composition and provide insight into basal resource quality for higher trophic level consumers such as zooplankton, fish, birds and marine mammals, yet phytoplankton FA information is largely lacking from the Bering and Chukchi Sea region. Therefore, we analyzed suspended particulate matter (seston) fatty acids (FA), chlorophyll-a (Chl-a) and environmental data collected from four surveys in the North Bering and Chukchi Seas, two during June of 2017 and 2018 and two during August and September of 2017 and 2019. Our objectives were to determine 1) whether, seston FA composition was correlated with phytoplankton taxonomic composition analyzed using imaging microscope (FlowCAM) techniques, 2) seasonal differences in seston FA concentrations, and 3) how FA concentrations vary with environmental parameters. We found significant seasonal differences in seston FA compositions, with diatom biomarkers more prevalent in spring, followed by a community shift to dinoflagellate and small flagellate FA biomarkers in late fall. These results were overall confirmed by FlowCAM analyses. FA seston concentrations were correlated with total and large size-fractioned Chl-a concentrations, nitrogen concentration and temperature. Lastly, we used a model framework to predict availability of the diatom-associated essential FA, eicosapentaenoic acid (EPA, 20:5n-3). Combined our analysis provide new information on FA phytoplankton dynamics and the important nutritional role of phytoplankton for higher trophic level consumers in the Northern Bering and Chukchi Sea regions.

1. INTRODUCTION

The Bering and Chukchi Seas are some of the most productive areas of the Arctic (Hill et al., 2018). A pronounced diatom spring bloom commonly associated with the timing of ice breakup (Fujiwara et al., 2016; Laney and Sosik, 2014) fuels pelagic and benthic secondary production (Grebmeier et al., 2006; Sigler et al., 2014). Later in the season, once the ocean stratifies, a majority of the large size-fractioned phytoplankton biomass is often present in subsurface water layers (Martini et al., 2016) while smaller sized plankton occur in the surface waters (Giesbrecht et al., 2019). Arctic and subarctic ecosystems, including the Bering and Chukchi Seas are transitioning (Huntington et al., 2020) due to rapid ocean warming. This scenario is projected to continue in the coming decades (Hermann et al., 2019) with changes already affecting sea ice phenology, spring bloom timing and phytoplankton production (Clement Kinney et al., 2020; Song et al., 2021). These changes also influence the production of fatty acids (FA) synthesized by phytoplankton which play a key nutritional role for the growth and functioning of marine consumers. More baseline data on phytoplankton nutrition, including their FA compositions is needed for tracking potential short and long-term changes in the quality and quantity of basal resources in the Bering and Chukchi Sea food webs.

Phytoplankton play a crucial nutritional role in marine ecosystems due to their ability to synthesize dietary FA required by higher trophic level organisms (Budge et al., 2014; Dalsgaard et al., 2003). Marine consumers generally lack the ability to synthesize several essential FA at a sufficient rate to meet their metabolic demand (Helenius et al., 2020), and therefore require FA preformed in their diets (Bell and Tocher, 2009). Several essential polyunsaturated FA (PUFA), including eicosapentaenoic acid (EPA, 20:5n3) and docosahexaenoic acid, (DHA, 22:6n3), are central compounds that regulate cell membrane fluidity, neurological functioning, localized

47 hormones and growth (Bell and Tocher, 2009; Helenius et al., 2019; Tocher et al., 2019). Dietary
48 limitation of essential PUFA directly influence zooplankton fecundity and growth rates (Leiknes
49 et al., 2016; Pond et al., 1996), survival of larval (Copeman and Laurel, 2010) and juvenile fishes
50 (Bell et al., 1995), and lower overall ecosystem productivity (Litzow et al., 2006).
51 The relative amounts of specific FA vary among phytoplankton taxa (Cañavate, 2019;
52 Parrish, 2013), thus changes in phytoplankton community compositions induce shifts in the
53 dietary FA pool available for consuming organisms (Galloway and Winder, 2015). The
54 association between specific FA and certain taxonomic groups also make FA useful biomarkers
55 (Dalsgaard et al., 2003). Yet, the utility of FA biomarkers to partition phytoplankton taxa is
56 known primarily from monoculture experiments (Cañavate, 2019; Dunstan et al., 1993;
57 Jónasdóttir, 2019). Using FA biomarkers to distinguish phytoplankton taxa in field samples is
58 more challenging (Reuss and Poulsen, 2002), variable and less studied (Galloway and Budge,
59 2020; Marmillot et al., 2020). Nonetheless, field studies in other high latitude systems, such as
60 the Beaufort Sea (Connelly et al., 2016; Marmillot et al., 2020), West Greenland Sea (Reuss and
61 Poulsen, 2002), and Barents Sea (Falk-Petersen et al., 1998) have highlighted that changes in
62 phytoplankton compositions, including seasonal shifts from diatoms to flagellates, can be visible
63 in the seston FA pools. Beyond the primary association with a specified phytoplankton
64 taxonomic group, individual FA biomarkers vary with environmental conditions (Sushchik et al.,
65 2004). Although FA provide valuable information about food quality, they are often not
66 diagnostic or species-specific but should rather be viewed as indicative of dominance from broad
67 taxonomic groups (i.e., predominance of diatoms versus flagellates; (Jónasdóttir, 2019),
68 particularly when analysis field data. Therefore, additional species information from microscopy

imaging techniques are also beneficial to validate observed FA biomarker patterns (Marmillot et al., 2020).

Here we use FA biomarkers as indicators of changing phytoplankton community compositions, and of basal resource quality for higher trophic level consumers. We analyzed suspended particulate matter (seston) FA, chlorophyll-a (Chl-a), phytoplankton taxonomic data, and environmental data from four surveys spanning the northern Bering-Chukchi Sea region, two during spring (June) in 2017 and 2018 and two during late summer (August/September) in 2017 and 2019. More specifically, we examine:

1) Seasonal and annual patterns in both absolute FA concentrations and percent FA composition;

2) the relationship between phytoplankton taxonomic data (dinoflagellates and diatoms) determined from imaging microscope analyses (FlowCAM) compared to specific FA biomarkers;

3) the relationship between individual FA biomarkers and physical, chemical, and biological variables; and

4) show how a simple model framework to predict concentrations of the diatom-sourced essential fatty acid, EPA, can provide a measure of consumer nutritional quality at an increased spatial resolution.

2. METHODS

2.1. Data collection

Four surveys were conducted in northern Bering-Chukchi Sea region as part of the Arctic Integrated Ecosystem Research Program (AIERP), during June of 2017 and 2018 (Arctic Shelf

Growth, Advection, Respiration, and Deposition Rate Experiments [ASGARD]) and during August and September (hereafter Aug/Sep) of 2017 and 2019 (Arctic Integrated Ecosystem Survey; Fig. 1). All data are publicly available in the DataONE repository (https://doi.org/10.24431/rw1k5a0). Water samples were collected from 5-12 L Niskin bottles attached to the CTD rosette. At every sampling station, total and size-fractioned (<5, 5-20, >20 μm) Chl-a (mg m^{-3}) samples were collected. Total Chl-a samples were collected at 10 m intervals (~5-6 depths) and filtered through 25 mm Whatman GF/F filters (nominal pore size 0.7 μm). Size-fractionated samples were collected at 2-3 depths using a stacked filtration unit, using 47 mm Whatman GF/F filters for <5 μm, and 47 mm polycarbonate filters with a pore size of 5 and 20 μm, to sample the 5-20 and >20 μm large size fractions. Filters were stored frozen (−80 °C) and analyzed within 6 months with a bench top fluorometer following standard methods (Parsons, 1984). Samples for dissolved inorganic nutrients (nitrate, nitrite, ammonium, phosphate, and silicic acid; μmol kg^{-1}) were collected from each Niskin bottle, filtered through 0.45 cellulose acetate filters, and frozen. Samples were analyzed on a Seal AA3 or Seal AA500 continuous segmented flow analyzer following methods in (Gordon et al., 1993). Ammonium was analyzed using the OPA method (Holmes et al., 1999). At every other station, seston was sampled at 1-2 depths for FA analysis (n =167). Vertical profiles of temperature and salinity were collected from surface to near-bottom at each station using a Sea-Bird Electronics (SBE) 9+ CTD, data processed and averaged into 1-m bins.

Phytoplankton community samples were analyzed for cell abundance using Fluid Imaging Technologies VS Series benchtop FlowCAM (hereafter referred to as FlowCAM) using a 10× objective and 200 μm flow cell in autoimage mode (Álvarez et al., 2014). Samples were counted from surveys in June 2017 and Aug/Sep 2017. Images were grouped into diatoms or

115 dinoflagellates. Diatoms were imaged in both June and Aug/Sep 2017, while dinoflagellates
116 were imaged only in Aug/Sep 2017. Biovolumes of cells were estimated from images using the
117 biovolume estimation function (cylindrical shape) in the VisualSpreadsheet (Scarborough, ME)
118 software provided with the instrument. These estimates compared well with manual estimates of
119 biovolume using standardized shapes and appropriate geometric equations (Menden-Deuer and
120 Lessard, 2000). FlowCAM biovolumes of diatoms and dinoflagellates were compared to
121 concentrations of the FA biomarkers of diatoms and dinoflagellates, and the ratio of DHA: EPA.
122
123 2.2. Fatty acid analyses
124 We collected FA seston samples, which comprise all living and non-living material
125 between 0.7-200 μm, such as phytoplankton, heterotrophic protists, bacteria, mesozooplankton
126 eggs and nauplii, and detritus. During sampling in June and Aug/Sep, phytoplankton commonly
127 constitute the majority of the seston material (Connelly et al., 2016; Hama, 1999) and thus the
128 majority of the seston FA can be attributed to phytoplankton FA. Water samples ranging in
129 volume from 2 L to 6 L were collected for seston fatty acid analysis on each of the four Arctic
130 surveys. Samples were collected from the surface, Chl-a maximum, or at near-bottom depths.
131 Seawater was prescreened through a 200 μm Nitex mesh into 2L sample bottles (1-3 bottles per
132 sample). Each bottle was filtered onto a pre-combusted Whatman 47 mm GF/F filter (0.7 μm
133 nominal pore size), and sample filters were stored aboard the ship at -80°C. Samples were
134 shipped frozen on dry ice to the Hatfield Marine Science Center (HMSC) in Newport, Oregon,
135 and analyzed at the Marine Lipid Ecology Laboratory. To obtain sufficient material, some filters
136 were combined for each sampling depth (1-3 filters), placed into lipid-clean glass tubes and
137 stored in chloroform under nitrogen for less than 3 months prior to extraction. Lipids were

138 extracted using a modified Folch procedure (Folch et al., 1957) using 2:1 chloroform: methanol
139 as described by Parrish et al. (1999). A total of 167 seston samples were processed for FA
140 analyses. An internal standard (23:0 methyl ester) was added to all samples at approximately
141 10% of the total FA concentration, and total lipid extracts were derivatized into their fatty acid
142 methyl esters (FAMEs) using sulphuric acid-catalyzed transesterification (Budge et al., 2006).
143 Resulting FAMEs were analyzed on an HP 7890 GC FID equipped with an autosampler
144 and a DB wax+ GC column (Agilent Technologies, Inc., U.S.A.). The column was 30 m in
145 length, with an internal diameter of 0.25 mm and film thickness of 0.25 µm. The column
146 temperature began at 65 °C and held this temperature for 0.5 min. Temperature was increased to
147 195 °C (@ 40 °C min^{-1}), held for 15 min then increased again (@ 2 °C min^{-1}) to a final
148 temperature of 220 °C, where it was held for 1 min. The carrier gas was hydrogen, flowing at a
149 rate of 2 ml min^{-1}. Injector temperature was set at 250 °C and the detector temperature was
150 constant at 250 °C. Peaks were identified using retention times based upon standards purchased
151 from Supelco (37 component FAME, BAME, PUFA 1, PUFA 3) and in consultation with
152 retention index maps performed under similar chromatographic conditions as our GC-FID
153 (Wasta and Mjøs, 2013). Column function was checked by comparing chromatographic peak
154 areas to empirical response areas using a quantitative FA mixed standard, GLC 487 (NuCheck
155 Prep). Chromatograms were integrated using Chem Station (version A.01.02, Agilent). Select
156 samples were run in triplicate and the coefficient of variation for peaks >1% of the sample, were
157 less than one.
158
159 2.3. Statistical and data analyses

Absolute FA concentrations, the amount of seston FA per volume seawater (reported as mg m^{-3}), were used to infer overall availability of FA as basal resources for consumers. FA data were calculated as percent of total fatty acids, which is a useful metric for quantifying phytoplankton compositional changes in the seston. FA were classified as C:Bn-P, where C is the number of carbon atoms, B the number of double bonds and P the position of the first double bond from the methyl group end (Budge et al., 2006). We considered two aspects of phytoplankton FA composition. Firstly, we focused on phytoplankton biomarkers, such as those indicative of diatoms: 16:1n-7, 16:4n-1, EPA (20:5n-3) and a composite diatom biomarker based on the ratio of 16:1n-7/16:0 (Budge and Parrish, 1998; Dalsgaard et al., 2003). Flagellates are a diverse group, including small autotrophic flagellates, heterotrophic flagellates and dinoflagellates. Therefore, we refer to the biomarkers 18:4n-3, 18:5n-3 and DHA (22:6n-3) as a combination of flagellate and dinoflagellate (dino+flag) FA biomarkers, due to the difficulty in partitioning among these groups using FA biomarkers alone. Secondly, we focused on long-chain PUFA (C_{20+22}) such as EPA and DHA, that are essential in the diet of secondary consumers. In addition, we assessed the ratio of DHA to EPA to denote relative dino+flag: diatom biomarkers in the samples, and a bacterial biomarker, here the sum of all odd carbon FA and branched FAs (Kaneda, 1991).

Type II regressions using $\log_{10}$-transformation were used to assess pairwise relationships between FA seston concentrations, and biological and physical variables including temperature, salinity, nutrients, and total and size-fractioned Chl-a concentrations. One-way Analysis of Variance (ANOVA) with associated post-hoc Tukey Honestly Significant Difference (HSD) was used for group comparisons, such as between seasons, years, depth category (above, below or in the mixed layer) and water mass designations (warm shelf water, cool shelf water, Anadyr water,

183 modified winter water and warm coastal water, Danielson et al., 2020). ANOVA models were
184 assessed for normality and homogeneity of variances of the residuals and variables were log_{10}-
185 transformed when necessary. Non-metric multidimensional scaling (nMDS) using Bray-Curtis
186 distances was used to assess multivariate patterns of the FA percent data, using all FA that
187 constituted more than 1% of the total FA, and the groups saturated FA (SFA), monounsaturated
188 FA (MUFA), PUFA and Bacterial FA.

189 Linear mixed effects models (Zuur et al., 2009) were used to assess how multiple
190 physical and biological parameters influence the FA composition of seston samples, and then to
191 develop a simple model framework that allows prediction of water column (0-50 m) integrated
192 EPA (mg m^{-2}) concentrations over broader spatial or temporal scales. For each FA biomarker a
193 full linear mixed effects model included the following predictor variables: total Chl-a,
194 temperature, nitrogen (sum of nitrate and ammonium), salinity and depth (a categorical variable
195 as described earlier) parameters that are all known to influence FA compositions (Budge et al.,
196 2014; Galloway and Winder, 2015). The different surveys were included as a random effect
197 because we expected that relationships between FA and environmental variables were likely to
198 be independent among years and season. For all models, inspections of residual plots did not
199 reveal obvious deviances from normality or homoscedasticity after log-transformation of
200 variables. In cases of multicollinearity (variance inflation factor (VIF) > 5), we retained only one
201 of those values in the final analysis.

202 Mixed effects models were performed for the following biomarkers: the ratio of DHA:
203 EPA, the ratio of PUFA: SFA, and FA percentage data for diatom biomarkers 16:4n-1 and EPA,
204 and dino+flag biomarkers 18:5n-3 and DHA. We followed the recommendations in (Zuur et al.,
205 2009) for fitting FA mixed effects models. First, the optimal random effect structure (which

206 could be no random effect) was fitted for the full model using restricted maximum likelihood
207 estimation. Second, we used maximum likelihood estimation to determine the most parsimonious
208 fixed effect model structure, with the optimal random structure as determined in step one.
209 Finally, the most parsimonious model for each FA, which included the optimal random and fixed
210 effect structures, was re-fitted with restricted maximum likelihood estimation. Determination of
211 the most parsimonious model in each step was decided using Akaike Information Criterion
212 corrected for small sample sizes (AICc, Burnham and Anderson, 2002). In the instances where
213 more than one model had similar AICc scores (<1 AICc), we chose the model with the lower
214 number of explanatory variables. For simplicity, we report only the final parsimonious model for
215 each FA biomarker in the results.

216 To predict integrated EPA (mg m^{-2}) concentrations, we used a mixed effects model to the
217 EPA concentration data. Because the biological, chemical and physical survey data was sampled
218 at a higher vertical and spatial sampling resolution compared to the FA sampling, these models
219 allowed for predicting integrated water column EPA concentrations for all survey stations.
220 Predictive models were computed using natural log-transformed data, thus a correction was
221 applied to re-convert predicted FA concentrations (Duan, 1983). All analyses were done using R
222 version 3.6 (R Core Team, 2018). Mixed effects models were fitted using the "*nlme*" package
223 (Pinheiro et al., 2017), AICc using the "*AICcmodavg*" package (Mazerolle and Mazerolle, 2019),
224 and type II regressions were computed using the "*smatr*" package (Warton et al., 2012).
225

226 **3. RESULTS**

227 3.1. Spatial patterns of Chl-a and FA concentrations.

228 Generally, areas of higher than average Chl-a were spatially associated with higher total
229 FA concentrations. Average water column (0-50 m) Chl-a measurements were higher in June
230 2017 and 2018 compared to Aug/Sep 2017 and 2019, though high variability existed among
231 stations and across all surveys (Fig. 1). Elevated water column average Chl-a concentrations (>6
232 mg m^{-3}) were present north of St. Lawrence Island within and north of the Bering Strait in both
233 June 2017 and 2018, areas that similarly showed elevated (> 15 mg m^{-3}) concentrations of total
234 FA. Total Chl-a concentrations had significant positive correlations with both the ratio of large
235 (> 5 μm) to small (< 5 μm) particle Chl-a, and the > 20 μm size-fractioned concentrations (Table
236 S1), indicating that communities were comprised of large phytoplankton in areas with high
237 concentrations of total Chl-a.
238
239 3.2. Seasonal dynamics of FA biomarkers
240 Total FA concentrations (mean±SD) in June 2017 were significantly higher than all other
241 surveys (average across stations: 28.2±21.1 mg m^{-3}, $p<0.05$, Tukey HSD, Figs. 1, 2A), followed
242 by FA concentrations in June 2018 (22.2±16.9 mg m^{-3}), Aug/Sep 2019 (18.8±16.5 mg m^{-3}), and
243 Aug/Sep 2017 (12.1±5.4 mg m^{-3}). Overall SFA, and MUFA concentrations were higher in June
244 compared to Aug/Sep (Fig. 2A), however percent PUFA levels were highest in Aug/Sep 2019
245 (Fig. 2D). The diatom biomarkers 16:1n-7, 16:4n-1, and EPA all varied significantly among
246 season and year (Tukey HSD, $F(3,163) = 10.6$, 4.2, and 4.3, respectively, $p< 0.05$, Fig. 2B).
247 Concentrations of 16:1n-7 and 16:4n-1 and EPA were significantly higher in June than in
248 Aug/Sep except for EPA, were values in Aug/Sep 2019 were similar to values in June. The
249 diatom biomarkers (percentage of 16:1n-7, 16:4n-1 and EPA, Fig. 2E) showed similar patterns to
250 the concentration data.

The concentration of dino+flag-associated biomarkers 18:5n-3(0.8± 1.0 mg m^{-3}) and DHA (1.5± 1.6 mg m^{-3}) were significantly higher in Aug/Sep 2019 compared to all other surveys (Tukey HSD, $p<0.05$, Fig. 2C). The dino+flag biomarker 18:4n-3 was significantly higher in Aug/Sep 2019 than in Aug/Sep 2017 (Tukey HSD, $p<0.05$), but otherwise showed no difference among seasons and years. The dino+flag percent FA data and the sum of n-3 PUFA showed overall similar patterns to the concentration data, with Aug/Sep 2019 values being the highest (Fig. 2F). Resultant DHA: EPA ratios were significantly higher in Aug/Sep compared to June (Tukey HSD, $p<0.05$, Fig. 2C). The diatom biomarkers of EPA, 16:1n-7, and 16:4n-1 were all correlated positively for both the concentration (Table S1) and percentage data (Table S2). Similarly, DHA correlated well with the dino+flag biomarkers 18:4n-3 and 18:5n-3 for both the concentration and percentage data (Table S1-S2).

Multivariate nMDS analysis of the FA percentage composition data similarly showed clear differences among seasons and years (Fig. 3). FA biomarkers most responsible for the separation of seasons were diatom biomarkers (i.e., 16:1n-7, 16:2n-4, 16:4n-1 and EPA), which appeared to be more highly associated with the June 2017 and 2018 samples. In contrast, dino+flag markers (i.e., 18:3n-3, 18:4n-3, 18:5n-3, and 22:6n-3) were more closely associated with the Aug/Sep 2017 and 2019 samples. However, substantial variability of the FA compositions within each survey also indicate clear spatial differences in phytoplankton communities across years and seasons.

3.3. Taxonomic comparison of FA biomarkers and FlowCAM images

FlowCAM-measured diatom and dinoflagellate biovolumes correlated positively with their taxa-associated FA biomarkers. Significant positive correlations were observed between

$\log_{10}$-transformed diatom biovolumes and FA concentrations of EPA (Fig. 4A, $r^2 = 0.41$, $p < 0.01$, df = 38), 16:1n-7 (Fig. 4C, $r^2 = 0.45$, $p < 0.01$, df = 38), and 16:4n-1 (Fig. 4E, $r^2 = 0.46$, $p < 0.01$, df = 38) in June 2017 and Aug/Sep 2017. However, when analyzing only the Aug/Sep 2017 diatom data, correlations were not significant ($p > 0.05$, df = 20). Dinoflagellate biovolumes correlated positively with FA concentrations of DHA (Fig. 4B, $r^2 = 0.51$, $p < 0.01$, df = 20) and 18:5n-3 (Fig. 4D, $r^2 = 0.55$, $p < 0.01$, df = 20) in June 2017. Additionally, the ratio of DHA to EPA correlated positively with the FlowCAM-measured ratio of dinoflagellate to diatom biovolumes (Fig. 4F, $r^2 = 0.45$, $p < 0.01$, df = 20) in June 2017.

3.4. Associations between FA biomarkers and environmental variables

Next, we analyzed associations between the individual environmental variables and the FA concentration and percentage biomarkers using $\log_{10}$-transformed data from discrete samples. Some of the main primary pairwise correlations shown in Figure 5 and highlighted below, while all regressions are presented in Table S1 and Table S2.

Overall, the majority of the concentrations of individual FA correlated positively and significantly with total and size-fractionated (<5 µm, 5-20 µm, >20 µm) Chl-a data (Fig. 5A-F, Table S1). The strongest relationship for total FA was with total Chl-a and >20 µm fraction ($r^2 = 0.52$, $p<0.01$), which in turn were highly correlated ($r^2= 0.90$, $p<0.01$) (Fig. 5A, Table S1). Significant correlations were also found for PUFA concentrations, common diatom biomarkers 16:1n-7, and EPA with total and >20 µm Chl-a concentrations (Fig. 5B-D, $r^2 = 0.37$ to 0.52, $p<0.01$, Table S1). In contrast, dino+flag biomarkers 18:5n-3, 18:4n-3 and DHA had the highest correlations with small size fractions of Chl-a (< 5 um) ($r^2 = 0.36$ to 0.67, $p<0.01$, Table S1); positive but weaker correlations were also found with total Chl-a (Fig 5.E, $r^2 = 0.05$ to 0.23,

297 $p<0.05$). Nutrients correlated negatively with temperature and positively with salinity (Fig. 5G,
298 Table S1). We found few significant relationships between FA concentrations and temperature,
299 salinity, and nutrient concentrations and those were weak (Table S1). DHA: EPA ratios were
300 lowest in cold, high salinity waters (Fig. 5H) and correlated negatively with nitrate
301 concentrations (Fig. 5I, $r^2 = 0.31$, $p<0.01$, Table S1).

302 Overall, the percentage FA results suggested that diatoms are higher in relative biomass
303 in colder, high salinity waters and in areas of higher nitrate (Table S2). dino+flag FA biomarker
304 percentages were higher in warmer waters, shallower depths, and in areas with low nutrient
305 concentrations (Table S2). Total and large (>20 μm) size-fractioned Chl-a correlated positively
306 with the percentage diatom biomarkers (16:1n-7, 16:4n-1, 16:2n-4, and EPA) but negatively with
307 the percent contribution of dino+flag-associated FA biomarkers (18:4n-3, 18:5n-3, and DHA)
308 and the ratio of DHA to EPA (Fig. 5F, Table S2). Percentage diatom FA biomarkers associated
309 negatively with the dino+flag and SFA. The percentage contribution from bacterial FA
310 biomarkers correlated positively with the diatom biomarkers, >20 μm, and 5-20 μm and total
311 Chl-a, but negatively with several dino+flag biomarkers. For both the percentage and
312 concentration data, the patterns observed for all 4 surveys combined were generally also visible
313 within each survey (data not shown).

314 Mixed effects models using the FA percentage data showed that several environmental
315 variables influence FA phytoplankton dynamics. The most parsimonious mixed effects models
316 consistently included survey as a random effect. All statistical values are reported in Table S3;
317 below we report the main findings. Percent EPA contribution correlated positively with total
318 Chl-a concentrations and with vertical depth position (Table S3). EPA values were higher below

319 the mixed layer and though the effect of vertical position was included in the final model, its
320 influence was minor (i.e., delta AICc with the vertical position included or not, was small).
321 The diatom biomarker 16:4n-1 showed a significant positive relationship with total Chl-a
322 and nitrogen concentration but a negative relationship with temperature. Percent DHA was
323 positively related to total Chl-a, but negatively related to nitrogen concentrations (Table S3). The
324 dino+flag marker 18:5n-3 was negatively related to both total Chl-a and nitrogen concentrations.
325 DHA: EPA ratios also were negatively related to Chl-a and nitrogen concentrations, while
326 relating positively with salinity and temperature. The ratio of PUFA: SFA increased with Chl-a
327 concentrations, but decreased with nitrogen concentrations and temperature (Table S3).
328 Lastly, we used a mixed effects model to enable predictions of absolute EPA
329 concentrations (Fig. 6). The most parsimonious model, assessed using AICc, included log-
330 transformed total Chl-a and log-transformed nitrogen (sum of nitrate and ammonium) as the
331 fixed effect and a random structure consisting of an interaction of Chl-a and survey (Table S4).
332 Model prediction of EPA correlated overall strongly with measured EPA concentrations (r^2 =
333 0.63, $p < 0.01$, df = 151, Fig. S1A). Variability and thus uncertainty of EPA model predictions
334 were highest in samples with total Chl-a concentrations >5 mg m^{-3} (Fig. S1B). Water column
335 integrated EPA concentrations differed significantly among all four surveys (Fig. 6, Tukey HSD,
336 $p<0.05$), with average values highest in June 2018 (93 ± 60 mg m^{-2}), followed by June 2017 (66
337 ± 46 mg m^{-2}), Aug/Sep 2019 (54 ± 30 mg m^{-2}), and Aug/Sep 2017 (30 ± 8 mg m^{-2}). Throughout,
338 there was high spatial variation in the predictions with the highest concentrations reaching levels
339 of 264 mg m^{-2} and 241 mg m^{-2} in June 2017 and 2018, while highest values in Aug/Sep 2017
340 were 54 mg m^{-2} and 198 mg m^{-2} in Aug/Sep 2019.
341

4. DISCUSSION

Seston FA biomarkers reflected phytoplankton community shifts from diatoms dominating in spring followed by late summer increases of dinoflagellates and small flagellates. High total FA and PUFA concentrations in late spring (June) primarily synthesized by diatoms suggest that phytoplankton FA from this time period provide important dietary subsidies for consumers (Grebmeier et al., 2006). Diatom and dinoflagellate biovolume measurements from FlowCAM images correlated positively with their respective FA biomarkers, confirming that in general FA compositional data can provide reliable information on phytoplankton community dynamics. Measured phytoplankton FA composition (concentrations and percentages) varied with changes in temperature and nutrients, likely due to a combination of species-specific changes in physiology as well as changes in the phytoplankton community composition (Grosse et al., 2019; Jiang and Gao, 2004). Lastly, derived EPA concentrations based a model using commonly sampled survey data (e.g., temperature, nitrogen, and Chl-a) may provide broad-scale water column integrated estimates of dietary EPA availability for consumers in the northern Bering and Chukchi Sea ecosystems.

4.1 FA biomarker and FlowCAM estimates of diatoms and dinoflagellates

Taxonomic information from microscopy imaging techniques generally confirmed that observed FA biomarker patterns can be associated with major phytoplankton taxa groups. Although FlowCAM-measured diatom and dinoflagellate biovolumes correlated positively with diatom and dinoflagellate FA biomarker concentrations, these data also revealed substantial unexplained variance. The combined June and Aug/Sep 2017 data yielded significant trends for diatom biovolumes and their FA biomarkers (16:1n-7, 16:4n-1 and EPA) however, similar

365 diatom trends were insignificant when using only samples from Aug/Sep 2017. Whether the lack
366 of clear correlation was due to variable FA concentrations among diatoms species, less
367 dominance of this taxa compared to spring samples, variable environmental conditions (Sushchik
368 et al., 2004), or FA contributions from other phytoplankton groups is unclear. For example,
369 *Synechococcus,* which can contain 16:1n-7 (Jónasdóttir, 2019), were observed in up to 20% of
370 the phytoplankton carbon biomass during Aug/Sep 2017 (data not shown). Similarly,
371 chlorophytes containing 16:4n-1, or chlorophytes and cryptophytes containing EPA (Jónasdóttir,
372 2019), could have contributed to the FA pools of the diatom associated biomarkers.
373 Differentiating between dinoflagellates, heterotrophic flagellates and flagellates using FA
374 biomarkers alone is challenging. The observable trends between 18:5n-3 and DHA with
375 dinoflagellate identified from the FlowCAM suggest that noticeable FA contributions at least
376 partially originated from dinoflagellates, however, small flagellates, not measured with the
377 FlowCAM analysis, may also be important. Dinoflagellate and small flagellates often co-occur.
378 Higher percentages of 18:1n-9 and 18:0 in some Aug/Sep 2017 samples could indicate increased
379 contributions from smaller flagellates (Reuss and Poulsen, 2002), but these quite ubiquitous FAs
380 that are also present in several other taxa (Cañavate, 2019). The significant association between
381 dinoflagellate biovolumes and their specific FA biomarkers (DHA, 18:5n-3) differ from a recent
382 study by Marmillot et al. (2020) which found no significant relationships for dinoflagellates. We
383 speculate that these differences may be explained by the fact that flagellates are a diverse group
384 of organisms including auto, mixo and heterotrophic species, which can vary substantially in
385 their FA signatures depending on their diet intake and responses to environmental conditions.
386 Overall, and despite considerable variation, our results are in general agreement with previous
387 field studies (Marmillot et al., 2020; Reuss and Poulsen, 2002; Sushchik et al., 2004) and

388 highlights the utility of FA biomarkers for depicting relative contributions of major
389 phytoplankton taxonomic groups.
390
391 4.2. Factors influencing seston FA dynamics
392 Shifting environmental conditions influence seston FA dynamics through both individual
393 phytoplankton species and community composition responses (Cañavate et al., 2019; Miller et
394 al., 2017). Seasonal environmental shifts were clearly visible in the FA biomarkers, with highest
395 abundances of diatom FA in spring followed by increasing dino+flag FA in late summer. These
396 seasonal shifts agree well with phytoplankton taxonomic analysis from the northern Bering and
397 Chukchi Seas (Laney and Sosik, 2014; Lee et al., 2019; Sukhanova et al., 2009) and with FA
398 biomarker studies in other Arctic regions (Connelly et al., 2016; Falk-Petersen et al., 1998). Chl-
399 a concentration was the primary predictor variable for the concentrations of almost all FA
400 biomarkers. These linkages were particularly strong between absolute concentrations of the
401 diatom biomarkers, 16:4n-1, 16:1n-7 and EPA, and the total and the large (>20 μm) size fraction
402 Chl-a. The high positive correlation of >20 μm with total Chl-a suggests that large phytoplankton
403 primarily of diatom origin were driving changes in total Chl-a concentrations.
404 Temperature and nitrogen concentrations also influenced the percentage FA patterns.
405 Temperature correlated negatively with the ratio of PUFA to SFA, a pattern that is likely driven
406 by decreasing PUFA concentrations with warming (Hixson and Arts, 2016; Jiang and Gao,
407 2004), due to both individual species and community compositional responses to variable
408 environmental conditions (Hixson and Arts, 2016). Relative concentration of dino+flag
409 biomarkers increased with decreasing nitrogen concentrations, warmer temperatures and lower
410 salinity, supporting that dinoflagellates and small flagellates are commonly more prevalent in

411 low nutrient environments as observed during summer in the eastern Bering Sea (Moran et al.,
412 2012; Sukhanova et al., 2009). Differences in residual nutrient concentrations among water
413 masses are associated with different phytoplankton communities (Danielson et al., 2017), which
414 likely explain the higher percentages of FA diatom biomarkers in colder, more saline, nutrient-
415 rich waters. Differences in FA compositions with depth also indicate that diatoms are more
416 prevalent in deeper, higher nutrient waters near the subsurface Chl-a maximum which are
417 common phenomena in summer in these ecosystems (Lowry et al., 2015; Martini et al., 2016). In
418 contrast, higher abundance of FA dino+flag biomarkers occurred closer to the surface in waters
419 with lower nutrient concentrations, where they may have an advantage compared to, for example
420 diatoms. Higher surface area to volume ratios of small flagellates allow enhanced access to
421 nutrients at low concentrations (Edwards et al., 2012), while many dinoflagellates maintain
422 higher growth by migrating daily from deeper, nutrient rich water to the surface (Jephson and
423 Carlsson, 2009) and also engage in heterotropy.
424
425 4.3. Importance of dietary FA for consumers
426 Variation in plankton communities and their nutritional quality (i.e. lipid and essential
427 FA) influence spatiotemporal trends in food quality available to consumers (Twining et al.,
428 2016). The availability of essential EPA strongly influences copepod nauplii growth rates
429 (Leiknes et al., 2016), fish (Copeman and Laurel, 2010), juvenile crab (Copeman et al. 2021),
430 benthic organisms (Schollmeier et al., 2018) and overall ecosystem production (Litzow et al.,
431 2006). Using ancillary data from all four surveys, we calculated water column integrated spatial
432 predictions of EPA concentrations. Overall, the modeled EPA predictions compared well to
433 measured EPA concentrations. Modeled EPA data may provide a first step towards a broader

characterization of dietary availability of essential FA in these ecosystems. Overall, predicted EPA concentrations were highest in spring with lower concentrations in late summer, particularly Aug/Sep 2017. Our mixed effects model analyses also show that FA spatial predictions vary between seasons and years, as "survey" was a significant explanatory variable in the model. Survey should be considered a proxy for seasonal and inter-annual changes in the FA pools associated with the phytoplankton community composition. Thus, predictive power increases when accounting for inter- and intra-annual differences in FA composition patterns, and best results are retrieved if model predictions are coupled with a smaller subset of FA phytoplankton information from the specific year in question. Additional improvements of the current model framework would be inclusion of data from colder years that may have noticeably different phytoplankton communities (Hill et al., 2005) compared to the years 2017-2019, and laboratory studies of regional zooplankton or benthic invertebrate (e.g., crabs, Copeman et al. 2021) growth and reproduction rate responses to dietary availability of essential EPA.

An expected future consequence of warming and increased stratification is a shift in phytoplankton community structure towards smaller sized cells (Morán et al., 2010) and a prospective decrease in PUFA concentrations (Hixson and Arts, 2016). Such shifts in FA compositions are due to a combination of direct physiological effects on phytoplankton FA synthesis as well as due to phytoplankton community shifts. How changing sea ice phenology and the resulting effects on ice-associated phytoplankton (Clement Kinney et al., 2020), and spring and summer open water blooms influences the availability of carbon and thus important dietary FA in the northern Bering and Chukchi Sea ecosystems, remains an open question. Our analyses and model framework provide new regional baseline information on phytoplankton FA

seasonal and inter-annual variations. Such information will increase the ability to evaluate the impacts of changing dietary lipid on higher trophic level consumers at broader spatial scales.

DECLARATION OF COMPETING INTEREST

The authors declare no known competing financial interests or personal relationships that could have appeared to influence the work reported in this manuscript.

ACKNOWLEDGEMENTS

We are grateful to Brendan Smith, Miranda Irby, Ed Farley, Anna Mounsey, Haley Cynar, Jeff Krause, Harmony Wayner, and Steven Baer for help during field sampling, for analysis of the nutrient data, and the crews of the *R/V's Ocean Star* and *Sikuliaq*. We are thankful to Lauren Rogers for help with mixed effects models and comments from Jeanette Gann and Fletcher Sewall that substantially helped improve the manuscript. We thank Carlissa Salant Michelle Stowell and Jami Ivory for general analytical assistance in the Marine Lipid Ecology Lab in Newport, OR, and the funding sources; NPRB Arctic IERP (Arctic IES LTL (A92), ASGARD, Phytoplankton Gap proposal (A96), National Science Foundation Office of Polar Programs award numbers OCE-1603460 (ML)). The findings and conclusions in this paper are those of the authors and do not necessarily represent the views of the National Marine Fisheries Service, NOAA. Reference to trade names does not imply endorsement by the National Marine Fisheries Service, NOAA. This is EcoFOCI contribution number EcoFOCI-1005 and PMEL contribution number 5325. This publication was partially funded by the Cooperative Institute for Climate, Ocean, & Ecosystem Studies (CIOCES) under NOAA Cooperative Agreement NA20OAR4320271, Contribution No 2021-1168.

No figure… journal TBD

Introduction: Resolving carbon flows in marine planktonic foodwebs is a fundamental first step for understanding the energy available for higher trophic level consumers and overall food web processes, production and function. Inverse food web modeling is a convenient data driven modeling approach for estimating carbon fluxes in marine food webs.

Methods: Using empirical biomass and rate measurements, inverse food web modeling allows reconstruction of trophic flows and quantification of biological rates that are commonly challenging to measure. Here we use in-situ phytoplankton, microzooplankton, zooplankton, sedimentation and primary production data collected from 4 ecosystem surveys in the Chukchi and Northern Bering seas, June (spring) 2017 and 2018, and August-September (summer) 2017 and 2019.

Results and Discussion: Specifically we assess, 1) partitioning of energy, in terms of carbon, between the pelagic food web and deposition to the benthos, 2) how does transfer and major pathways vary between seasons (June vs August/September), and 3) how does food web carbon pathways vary between nutrient replete and deplete areas. Initial simulations indicate seasonal differences in major carbon pathways. Higher carbon fluxes appeared to be available for benthic consumers in spring (in areas of high primary production) compared to late summer. Our initial analyses also revealed the importance of carbon uptake and transfer in microzooplankton and bacterial compartments, organisms and processes that are often underestimated on many ecosystem models. Overall, our results indicate variable carbon transfer efficiencies among seasons and areas of nutrient replete and deplete conditions, something that should be considered when evaluating larger food web processes.

Chapter 22: Flow patterns over the Chukchi continental shelf: 2010-2020: A decade of observations in the Chukchi Sea

Stabeno, P.J., NOAA Pacific Marine Environmental Laboratory, phyllis.stabeno@noaa.gov

McCabe, R.M.

Stabeno, P. J. and R. M. McCabe (in preparation). Flow patterns over the Chukchi continental shelf: 2010-2020: A decade of observations in the Chukchi Sea. DSRII

Introduction: The Chukchi Sea consists of a broad shallow (<80 m) shelf, extending >800 km northward from its southern boundary at Bering Strait to the shelf break bounding the Arctic basin. The Chukchi continental shelf is generally referred to as an inflow shelf for the Arctic and is the only source of Pacific-origin water to the Arctic Ocean. Most of the flow originates in Bering Strait, and flows northward over the Chukchi shelf. This current system is a major source of heat, nutrients, salt and freshwater to the Arctic.

Methods: From 2010 to 2019, moorings were deployed in the Chukchi Sea at a dozen sites. Deployment duration varied from 10 years at a site off Icy Cape to a single year at a site north of Hanna Shoal. Currents were measured at each site, usually with acoustic Doppler current profilers (ADCPs). In addition, a total of 47 satellite-tracked drifters (drogue depth 25–30 m) were deployed in the region during 2012–2020. A primary goal of these deployments was to better understand the patterns and magnitude of flow on the US Chukchi shelf.

Results and Discussion: Together, these data provided insight into the temporal and spatial variability in the currents over eastern Chukchi continental shelf. There is a 10-year time series of transport at Icy Cape, which accounts for most of the northeastward flow in Barrow Canyon. The annual volume transport near Icy Cape ranged from ~0.3 x 10^6 m^3 s^{-1} (10^6 m^3 s^{-1} = 1 Sv) during September 2011 – August 2012 to ~0.7 Sv during September 2017 – August 2018, with a 10-year average of ~0.4 Sv. This transport accounts for approximately 40% of the flow through Bering Strait and varies seasonally, ranging from >50% of summer transport to only 20% of winter transport in Bering Strait. Anomalous winds toward the north-northeast in the winter of 2017/2018 likely contributed to the higher annual transports in September 2017–August 2018. There are three years (2016–2017, 2017–2018 and 2018–2019) of more intense spatial sampling. For those years, current measurements were made at 8 locations on the eastern Chukchi shelf: southern Chukchi shelf (1 mooring), Central Channel (2 moorings), Icy Cape (3 moorings) and Barrow Canyon (2 moorings). These measurements provide insight into patterns of flow across this shelf. As expected, bathymetry plays an important role in steering the flow patterns on the shelf. Measurements of transport at Icy Cape and in Central Channel indicate that most of the transport at Icy Cape is a continuation of the flow in Central Channel, which flows to the south of Hannah Shoal.

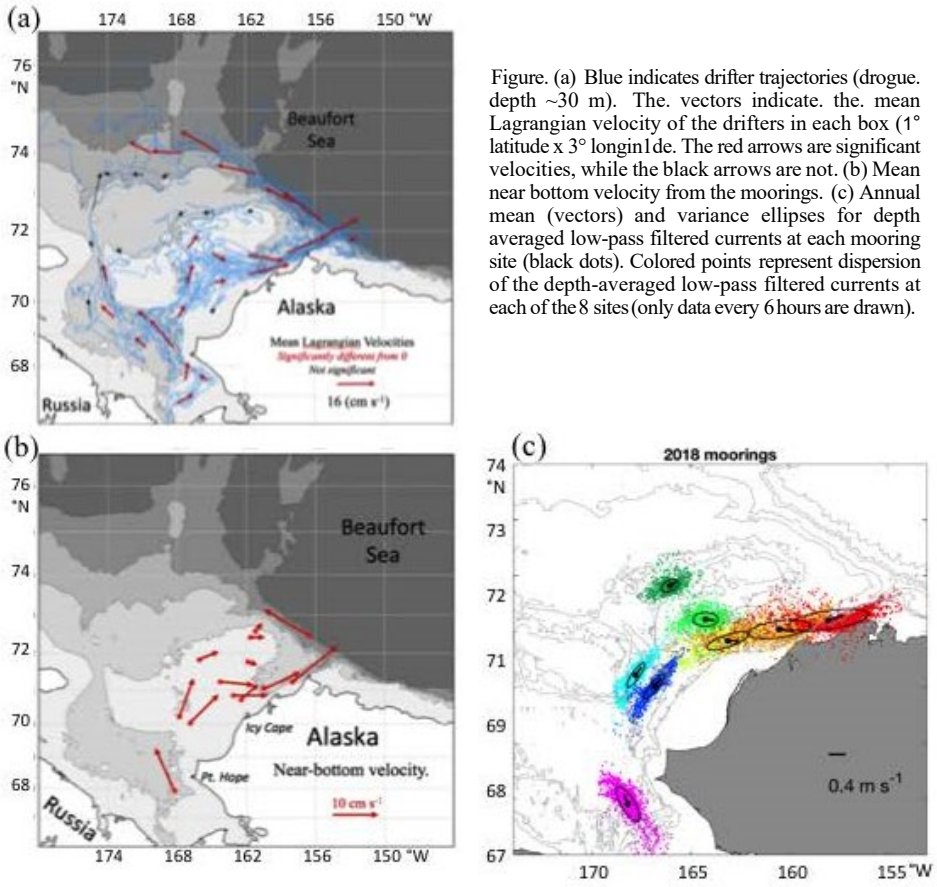

Figure. (a) Blue indicates drifter trajectories (drogue. depth ~30 m). The. vectors indicate. the. mean Lagrangian velocity of the drifters in each box (1° latitude x 3° longin1de. The red arrows are significant velocities, while the black arrows are not. (b) Mean near bottom velocity from the moorings. (c) Annual mean (vectors) and variance ellipses for depth averaged low-pass filtered currents at each mooring site (black dots). Colored points represent dispersion of the depth-averaged low-pass filtered currents at each of the 8 sites (only data every 6 hours are drawn).

Chapter 23: A decade of measurements of ice draft in the Chukchi Sea

Sullivan, M.E., CICOES, University of Washington, peggy.sullivan@noaa.gov

Stabeno, P.J.

A decade of measurements of ice draft in the Chukchi Sea

Sullivan, M.E. and Stabeno, P.J.

Introduction: The Chukchi Sea has seen dramatic warming and sea-ice changes in recent years. Sub-Arctic ice processes, shaped by wind, currents and bathymetry, show a shrinking sea ice season with a longer duration of open water. Changes to this seasonal ice zone imply changes to the ecosystem as a whole, to the success of organisms at all trophic levels, and to the flow of energy within the system.

Methods: Sonar ice draft data were collected, 2010-2019, at multiple mooring locations on the Chukchi Sea shelf to examine the longer-term trend of sea ice changes on the shelf, and related influence on the ecosystem and on marine mammals. Data were collected every second using an ASL Environmental IPS5 ice profiler at 420 kHz and 1.8° beam width. Tilt corrections, removal of atmospheric pressure and removal of outliers occurred during processing. Year-long data are presented in the figure with a focus on three mooring sites (C1, C2 and C3) near 71° N off Icy Cape, Alaska that stretch northwest toward Hanna Shoal, where data collection occurred more frequently. Site C2 data encompass the years 2010 to 2019, fall to fall. Sites C1 and C3 cover most of the same years. Reference is made to three other sites in the region: sites C4 and C5 close to Barrow Canyon, and C6 northeast of C2 near Hanna Shoal, that have fewer data sets. All the sites are in 42-53 meter water depth and were deployed in late summer or fall. We demonstrate localized variations in the larger picture of a changing seasonal ice zone.

Results and Discussion: Fall transition from open water to ice cover can occur November to mid-December, and is a more organized process than the spring melt transition. Cooling of the water column is attributable to cooler air, winds, diminishing solar insolation and advected ice from the north and west. A cycle of ice formation and melt occurs until the water-column temperature cools enough for ice to form and remain. Ice draft data signals clearly show dampening of waves, and a dynamic mix of waves and frazil ice as the winter ice cover forms. This process can extend from a day to a month. Year-to-year trends at sites C1 and C2 show the freeze up trending later in recent years. January-March are mostly ice-covered, with daily mean ice draft values increasing within that time frame: the average of daily median values at C2, 2011-2018, January, February, March, are respectively 0.577, 0.825 and 1.073 m. Deeper ice keels > 20 m occur predominantly April to mid-June and more often occur at C1 and C2, likely due to more open water and polynya exposure, and ice rafting during the spring transition to open water. A very deep keel of 31.3 m occurred at C1 on May 15, 2015. Comparison of VIIRS True Color satellite images with the ice draft signal show cross-shelf ice keel depth variations along the Icy Cape Line, C1, C2, and C3 as the spring breakup chaotically moves ice into and out of the mooring site areas.

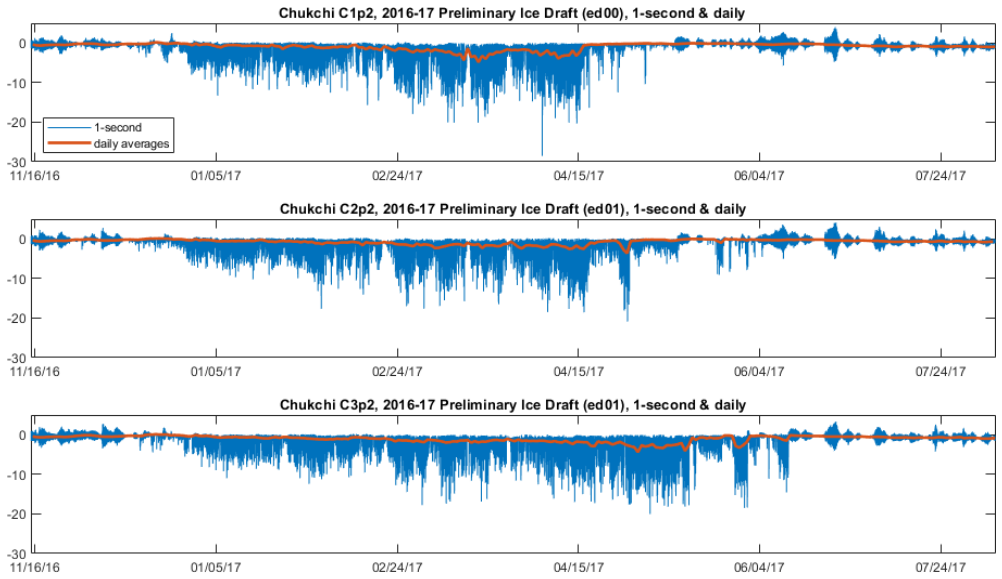

Figure 1. Ice draft data in 2016-2017 from moorings C1 (top), C2 (middle) and C3 (bottom) near 71° N off Icy Cape, Alaska that stretch northwest (C1 to C3) toward Hanna Shoal in the Chukchi Sea.

Chapter 24: Variations in phytoplankton community composition, phytoplankton biomass, and primary production in a warming Arctic

Eisner, L., NOAA Fisheries, lisa.eisner@noaa.gov

Gonzalez, S., Lomas, M., Nielsen, J., Stockwell, D.

Eisner, Gonzalez, Lomas, Nielsen, Stockwell, et al. (in preparation), Variations in phytoplankton biomass, community composition and size structure, and primary production in a warming Arctic.

Introduction: Marine phytoplankton community composition and size structure, biomass and primary production are important to carbon cycling and consequently also the quality and quantity of dietary resources for higher trophic level consumers. Phytoplankton population dynamics can vary considerably between spring and summer, nutrient deplete and replete water masses, and between surface and subsurface depths in Arctic seas.

Methods: Discrete water samples for phytoplankton community composition (e.g., dinoflagellates and diatoms), chlorophyll a (chla) biomass (total and size fractionated for < 5, 5-20, and > 20 µm), and primary productivity (total, < 5, > 5 µm) data were collected during ecosystem process surveys in the Chukchi Sea as part of Arctic ecosystem projects: Arctic Shelf Growth, Advection, Respiration & Deposition (ASGARD) and the Arctic Integrated Ecosystem Survey (Arctic IES) in June (spring 2017 and 2018) and August-September (summer 2017 and 2019), respectively. Phytoplankton taxa were evaluated using Flow Cam analysis (imaging microscope) of live water samples. Chla samples were filtered and stored frozen at -80 °C until later analysis (within 6 months) with a bench top fluorometer following standard acidification methods (Parsons et al. 1984). Water samples for primary productivity stable isotope (^{13}C and ^{15}N) experiments were collected at 4 light levels ranging from 1.5 - 100% surface irradiance, inoculated with isotopes, placed in screen bags (to simulate light levels at the water column depths where samples were collected) and incubated for 6 h encompassing solar noon in an on-deck transparent tank cooled with surface seawater. Samples were then filtered onto GFF (nominal pore size 0.7 µm) and 5 µm filters, and stored frozen at -80 °C until analysis at a shore-based facility; detailed methods described in Lomas et al. (2020). Discrete nutrient samples (nitrate, ammonium, nitrite, phosphate and silicate) were frozen and later analyzed following standard colorimetric methods (Gordon et al. 1993). CTD vertical profiles of temperature, salinity, irradiance (photosynthetically active radiation (PAR)) and chla fluorescence were conducted at each station.

We evaluated spatial variations chlorophyll and primary production for the 4 surveys. We also evaluated seasonal changes in phytoplankton blooms (~ > 1 mg m^{-3} chla) at surface (< 15 m) and subsurface (> 15 m) depths, and the factors limiting phytoplankton growth for data collected in 2017, the year that both seasons were sampled. Nutrients were averaged above and below the mixed layer depth (MLD), defined as the depth where the change in density was greater than 0.1 kg m^{-3} from the 5 m value (Danielson et al. 2011). The measured primary production was compared to modelled phytoplankton growth based on equations incorporating light (PAR), temperature, and nutrient (nitrate) data (Kremer et al. 2017; Palmer et al. 2013).

Results and Discussion:

Chla and Primary Productivity: In June 2017 and 2018, chla integrated over the top 50 m (or to the bottom if shallower than 50 m) was highest in the > 5 µm size fraction (Figure 1). The total chla and the > 5 µm and >20 µm (data not shown) size fractions had very similar concentrations indicating that most cells in June were large particles (e.g., diatom chains). Small phytoplankton were more dominant closer to shore. Large particles and total chla were highest offshore of Point Hope and in the Bering Strait. In August-September, in 2017, low chla was associated with the < 5 µm (small particle) fraction (Figure 2). In 2019, high and low chla were associated with the < 5 µm fraction, depending on station.

In June 2017, total primary productivity (integrated from the surface to the 1% light level) was patchy with the highest production at a station impacted by the nutrient-rich Anadyr Current (Figure 3) offshore of Pt. Hope in an area of high chla. Overall, June 2018 was similar to 2017, with a few stations with slightly higher productivities. In August – September, total primary productivity was generally lower than in June. The fraction of primary production in the < 5µm fraction was quite high in June 2017 (Figure 4). The values in June 2018 and August-September 2017 and 2019 are more in line with expectations at up to 20% in spring, and 20-50% in late summer/fall. Productivities (and chla biomass) were higher in the < 5 µm fraction in late summer 2019 (the warmest year) compared to 2017. The higher abundances of *Synechococcus* sp. (small photosythetic bacteria) in late summer/fall 2019 compared to2017, support these findings (Lomas et al., Chapter 16).

For all 4 surveys, most of the chla was found in larger (> 5 µm) phytoplankton, and the majority of the primary production was from large phytoplankton, particularly in spring. However, small cells are more important to total carbon (C) in both the spring and summer, due to inverse relation of C: Chla ratio and size. Primary production rates and total chla biomass were higher, although more patchy, in spring than in late summer/fall (Figures 1-5).

Subsurface blooms: Subsurface blooms, common features in the Chukchi Sea in summer (Martini et al. 2016), were less prevalent in spring than in late summer/fall in 2017 (Figure 6). In June, 7% of the stations had surface blooms (blue square), 26% had subsurface blooms (blue circle), and 67% had non-blooms (chla < 1 mg m^{-3}, red triangle). In August-September, 8% of the stations had surface blooms, 41% had subsurface blooms, and 51% had non-blooms. Phytoplankton growth depends on nutrient availability and will experience tradeoffs of light and temperature to acquire nutrients. Stratified surface waters (above MLD) often become nutrient-limited, as was observed in summer 2017, leading to subsurface blooms below the nutrient-depleted surface waters (Figures 7-8).

Models of phytoplankton growth: Theoretical models incorporating temperature, irradiance, and nitrate availability were used to predict the realized growth of phytoplankton for a vertical profile in spring and a vertical profile with a subsurface bloom in late summer 2017 (Figure 9). Preliminary results indicate nutrient-limited conditions for the late summer example, but not for the spring example. These models will be further evaluated and generalized using to the entire dataset.

Community composition: As expected, diatoms (primarily large diatom chains) were in higher abundance in spring than fall (data not shown), as also confirmed by fatty acid analysis (Nielsen et al., Chapter 20). Although, diatoms (as well as dinoflagellates) were observed at many stations in summer. Harmful algal bloom (HAB) species *Alexandrium catenella* was observed at several stations in summer with high concentrations off Icy Cape in 2017, an area with known *A. catenella* cyst beds and vegetative cells (Anderson et al. 2021).

Conclusions:

Chla biomass and production of the small (< 5 µm) size fraction was higher in summer 2019 (the warmest year) than 2017. These changes in phytoplankton community dynamics, in addition to reduced biomass and primary productivity, are likely to result in reduced food quality with negative ramifications for higher trophic levels. Small copepods (e.g., *Pseudocalanus* sp.) were also higher in abundance in 2019 (Kimmel et al., Chapter 14), suggesting a small sized planktonic (phytoplankton and zooplankton) community may occur as Arctic waters continue to warm. Future analyses will evaluate the factors

driving seasonal and spatial changes in phytoplankton community composition and size structure, biomass and growth.

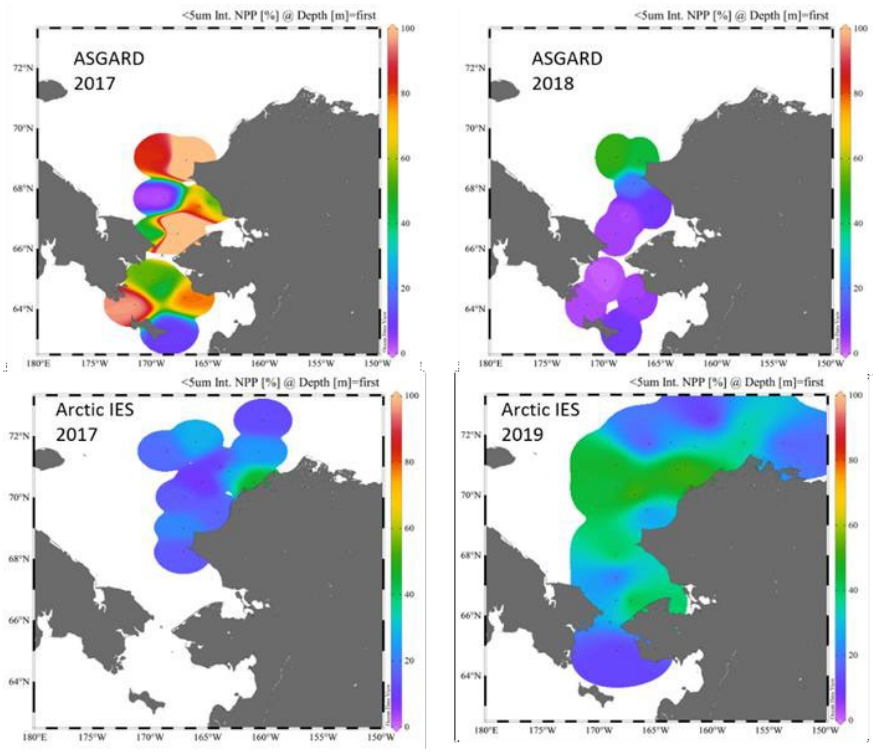

Figure 4. Percent of total primary productivity in the < 5 µm size fraction.

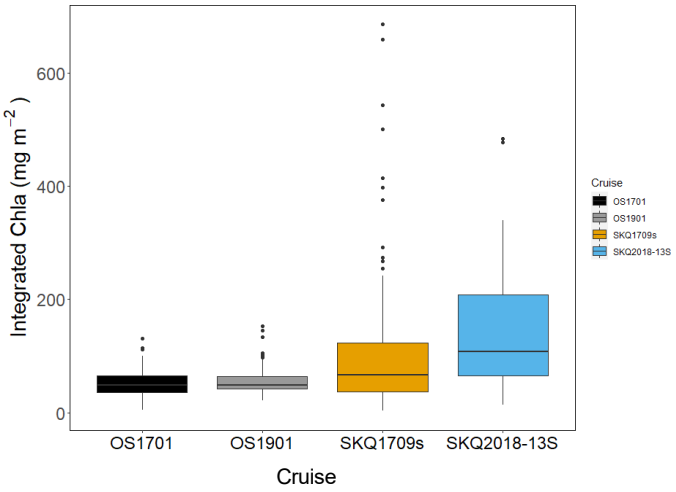

Figure 5. Box plot comparison of chla integrated over the top 50 m or to bottom if shallower than 50 m, for all 4 surveys (OS are August-September surveys and SKQ are June).

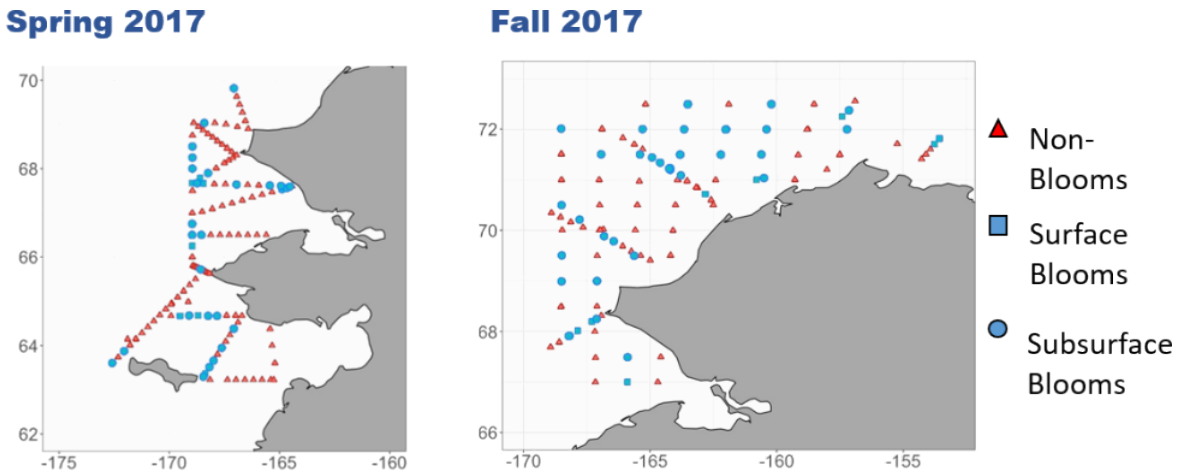

Figure 6. Stations with surface (blue box), subsurface (blue circle) and non-blooms (red triangle) in June (spring) and August –September (late summer/early fall) 2017.

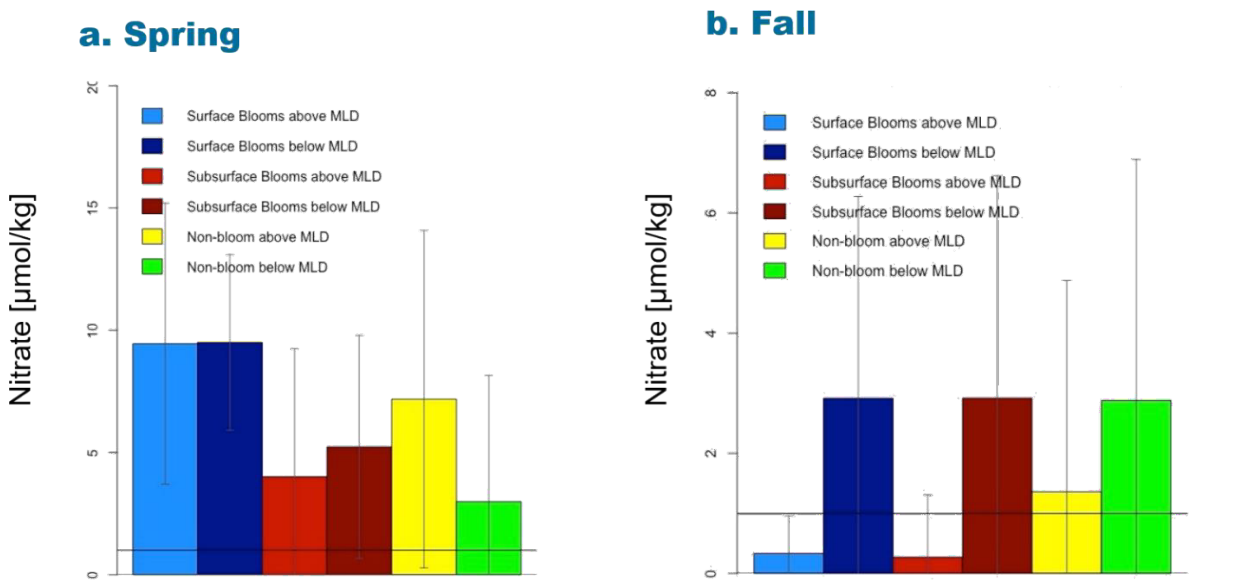

Figure 7. Nitrate Concentrations above and below the MLD for stations with surface blooms (blue), subsurface blooms (red), and non-blooms (yellow/green) for a) June (spring) and b) August –September (late summer/early fall) 2017. The black horizontal line depicts the threshold nitrate concentration of 1 µmol kg^{-1} for nitrate limitation.

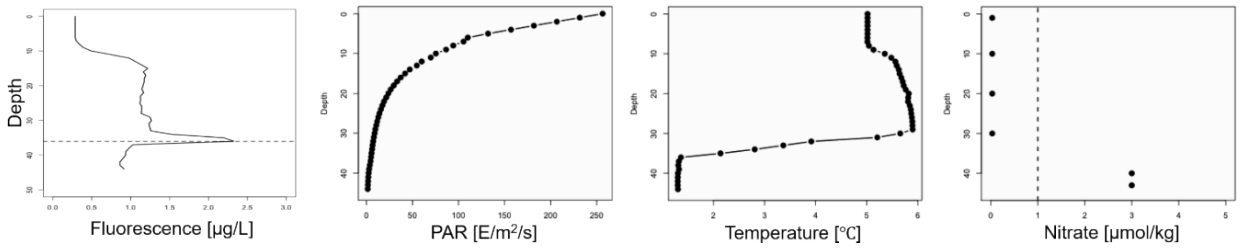

Figure 8. Example subsurface bloom profile from late summer/fall 2017 showing chla from the CTD fluorometer , light (PAR), temperature, and nitrate concentration. Dotted lines depict the threshold concentration for nutrient limitation at 1 µmol kg^{-1}.

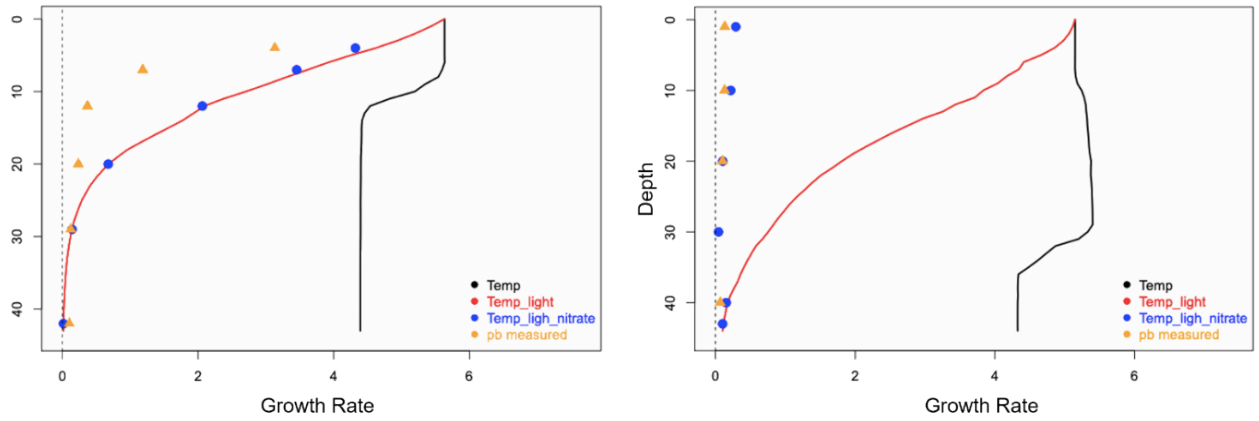

Figure 9. Phytoplankton productivity model examples for left) spring non-nutrient limited, and right) late summer /fall surface nutrient-limited conditions during 2017. The vertical profiles of fluorescence, PAR, temperature and nitrate for the right plot are shown in Figure 8. Models included temperature (black line), temperature + light (red line) and temperature + light + nitrate (blue dots). Pb measured (yellow dots) is phytoplankton specific growth estimated from discrete primary productivity samples. In left plot, nitrate is not limiting (adding nitrate to the model did not improve the model beyond the model with temperature + light and appears to show similarity to the in situ Pb profile data). In contrast, in right plot, adding nitrate to the model appeared to produce results similar to the Pb data.

an understanding of larval access to nurseries is hindered by the probable modeling limitation of under-representing larval transport to inshore habitats in the BS. Another consideration when spatially contemplating nursery occupation, is that demersal-stage juveniles are essentially invisible to survey gear from settlement to 2 years of age and considerable migration may occur during that time. Discrepancies between modeled and empirical abundances of juvenile flatfish in the BS have been observed in the past utilizing an earlier ROMS iteration (Cooper et al., 2013), suggesting that the IBM may be limited in its ability to simulate cross-isobath transport. There are several mechanisms that may impact the ability for the oceanographic model to capture cross-shelf transport. Cross-shelf transport associated with sub-mesoscale eddies or bathymetric steering via seafloor terrain features may play a role in on-shelf movement that can only be captured with higher resolution ocean models (Hermann et al. 2009; Combes et al. 2013; Gibson et al. 2013; Opdal and Vikebø 2016; Vestfals et al. 2014; Mordy et al. 2019). In addition to potential limitations of the physical model, due to lack of empirical data, the IBM did not incorporate orientation to nurseries or directed horizontal swimming behavior that has been observed for some species (Huijbers et al., 2012; Igulu et al., 2013) and has been hypothesized to be relevant for nursery recruitment of sablefish (Gibson et al., 2019). Larval swimming abilities and vertical movement that were not captured by the model may also facilitate transport to settlement habitats (Cowen and Castro 1994). For example, rock sole larvae in the BS are likely transported from the slope to the shelf through vertical movement of larvae that is synchronized with tidal periodicity (Wilderbuer et al., 2016). Modeling constraints due to resolution as well as biological parameterization also have the potential to impact quantitative estimates of transport and connectivity. Unlike cross-shelf transport in the BS, the model did capture larval transport through Unimak Pass; however, model resolution may impact estimates of transport and potentially underestimate the contribution of smaller island passes (Gibson et al. 2013).

Despite these potential limitations, basin-scale larval connectivity of Pacific halibut between the GOA and the BS was consistent across years and larval transport patterns suggest that spawning within the southern BS may subsidize components of the population to the west. Along the north Pacific Asiatic coast there is an established population of Pacific halibut (Schmidt 1934; Best 1979) but details of size composition, growth, and migration rates are largely unknown. Modeling results suggest populations of Pacific halibut along the north Pacific Asiatic coast may be supported by spawning in the southern BS and that juvenile settlement in the BS may be subsidized by larvae that originate in the western GOA.

Our modeling approaches did not provide evidence of possible factors that contribute to the determination of cohort strength, in this case fluctuations in abundance observed with the strong 2005 and the weak 2009 year classes. The Thompson-Burkenroad debate in the early part of the twentieth century discussed fishery and environmental factors as separate and distinct possible causes of fluctuations in Pacific halibut abundance (Skud 1975), but more recent studies have concluded that both factors can affect fish populations. Pacific halibut spawning biomass declined in the period between 2005 and 2009 (Stewart & Hicks, 2018), but it has been shown that cohort strength does not correlate well with spawning biomass (Clark & Hare, 2002). However, given that Pacific halibut is a fully exploited resource, fishing pressure may play a role in cohort strength and distribution, either through direct removals from the population or in combination with climate-related factors that apply stress to the population (Planque et al. 2010). Likewise, other studies have shown that variation in the distribution of fish species can be driven primarily by climatic factors (e.g. Sunday et al., 2015; McLean et al., 2018). Although this modeling effort has illustrated that Pacific halibut early life distributions remained relatively constant over two temperature stanzas, the interaction potential among species occupying a particular habitat can change in response to thermal habitat shifts. (Kleisner et al., 2016). In the case of Pacific halibut, variations in temperature could affect predator and prey species proximity, thus altering Pacific halibut abundance through top down (predation mortality) or bottom-up (food availability)

processes (Ferreira et al. 2020; Durant et al. 2007). Furthermore, Hunt et al. (2011) and Sigler et al. (2014), among others, showed that climate impacts recently experienced in the BS can affect the total caloric energy contained within the biological system so that changes in lower trophic levels influence upper trophic levels. Shifting productivity of spawning grounds (Somarakis et al., 2019) and spatial shifting of spawning grounds (Kanamori et al., 2019), both related to temperature, could also play a role in total productivity.

Movement patterns of juvenile Pacific halibut have not been well understood, particularly within the BS and between the BS and GOA. While there was extensive historical tagging of Pacific halibut in the BS and GOA (Best, 1977), recovery rates were generally low and only broad-scale movement pathways from the BS to GOA (Webster et al. 2013) and from shallow inshore waters to offshore habitats could be inferred from these data (Skud, 1977). In addition to widespread dispersal to deeper habitats, the results of the spatio-temporal modeling of demersal Pacific halibut illustrate the specific dispersal patterns of young fish from settlement grounds to a major inter-basin connection pathway by age-4-6 years. These results suggest that juvenile and adult migration occurs counter to larval dispersal. Compensatory Pacific halibut migration from settlement grounds in the southeastern BS south and east to the GOA is further supported by genetic studies that have found a lack of genetic differences between Pacific halibut in the eastern BS and GOA (Nielsen et al. 2010; Drinan et al. 2016) While there were similarities between year classes in their general direction of movement, there were also notable differences. In this study, the weaker 2009 year class occupied similar post-settlement redistribution pathways to the stronger 2005 year class, but appeared less aggregated overall and continued to occupy settlement grounds in Bristol Bay, whereas the 2005 cohort appeared to be highly aggregated as young fish and migrated away from settlement grounds before becoming more widely dispersed at older ages. The 2009 average size of sampled fish was larger than for 2005. It is unclear if this played a role in the migratory patterns for each cohort, e.g. smaller size could indicate relatively less food and a higher

migration rate to areas with increased food availability. Modeling of the supplemental years reinforced these inter-annual differences, but the general pattern of distribution was consistent across years and temperature stanzas. It is possible that these pattern differences were in part a response to density-dependent processes within the nursery areas (Le Pape & Bonhommeau, 2015) that were not investigated here.

We have used the spatiotemporal modelling to infer patterns of movement for individual Pacific halibut cohorts, but factors other than migration can influence the apparent distribution of fish, including factors affecting gear selectivity. The NMFS trawl survey does not sample the shallowest waters in the BS inside Bristol Bay, and thus young Pacific halibut in such inshore habitats will be missed by the survey. Indeed, this appears to be what happened to the 2011 cohort, which had no age-2 fish captured in 2013, yet the cohort showed up strongly in Bristol Bay the following year (Supplemental Table 2; Supplemental Figure 12). Selectivity to the trawl gear may also be influenced by habitat type, environmental conditions, or sea state, as documented for some other species (e.g., Somerton et al., 2013; Cooper and Nichol, 2016; and Somerton et al, 2018). While acknowledging that such factors may have some effect on the data and thus our model output, the distributional changes we see are both broad-scale and generally consistent among cohorts. This leads us to conclude that movement of Pacific halibut cohorts over time is the most plausible explanation for the patterns described in our work.

This study contributes new knowledge regarding the life cycle of Pacific halibut in the GOA and BS and is a step towards better understanding stock structure. Connectivity driven by dispersal at the larval stage and migration during the early demersal stage impacts species distributions, and leads to large-scale ecosystem connectivity and habitat use. Basin-wide connectivity and habitat use or dependence among life stages suggests that it is imperative for managers to be aware of potential environmental impacts to various geographic components of the stock. The Pacific halibut fishery is currently managed via an

ensemble of stock assessment models that lead to a decision table which outlines risks of various harvest scenarios (Stewart et al. 2020). A better understanding of risk to the spawning biomass and thus the future population as shown here, can lead to improved comprehension of consequences associated with different harvest levels, and provide a connection to how management decisions affecting fish stocks made in one area or region may impact fisheries in other areas, including between ocean basins.

Until recently, details of Pacific halibut early life history dispersal and migration have remained elusive. However, improved data streams and modelling approaches used in this study have supported the notion of broad scale connectivity, as hypothesized in earlier literature. Our building knowledge of Pacific halibut early life history will benefit from future research aimed at improving our understanding of the relative contributions from geographically distinct spawning grounds to nursery habitats, i.e. the sources of replenishment, purported sinks, as well as of the capabilities of young Pacific halibut to actively migrate prior to their detection in standardized surveys as 2-3 year olds.

Arctic food webs

ABSTRACT

The Chukchi Sea has recently experienced increased water temperatures, increased advection of water from the Bering Sea, declines in sea-ice concentration, and shorter periods of ice coverage. These physical changes are expected to impact trophic food-webs and ecosystem attributes. In this study, a series of research surveys were conducted in the summers of 2011–2015 to characterize the physical environment and its relation to the abundance of large zooplankton. Large zooplankton are key prey for many higher trophic level organisms including seabirds, marine mammals, and fishes. Yearly advection from the Bering Sea influenced the adult large zooplankton abundance, but this influence was less apparent in the earlier development stages. Known development times of stages of zooplankton, along with their location within the study area, suggested that a fraction of the zooplankton standing stock was the result of local production. Decreased advection and later ice retreat resulted in higher abundances of the lipid-rich copepod *Calanus glacialis*. Warmer conditions with increased advection from the Bering Sea resulted in higher abundances of euphausiids. Warming, sea-ice melting, and increases in transport of Bering Sea water and plankton into the Chukchi Sea are ongoing, and changes in food-web structure are likely to result.

1. Introduction

The zooplankton of the Chukchi Sea shelf consist of taxa that are more similar to the Pacific Ocean community than the Arctic Ocean community (Ashjian et al., 2010, 2017; Hopcroft et al., 2010; Eisner et al., 2013; Questel et al., 2013; Pinchuk and Eisner, 2017), a result of the transport of North Pacific water through the Bering Strait into the Arctic. Northward advection through the Bering Strait combines several water masses that results in the transport of relatively warm, nutrient-rich water, as well as primary and secondary producers into the Arctic (Woodgate et al., 2005; Gong and Pickart, 2015; Danielson et al., 2017; Stabeno et al., 2018). Northward advection through the Bering Strait in the summer, along with sea-ice melting and episodic upwelling from the Beaufort Sea on to the shelf and Barrow Canyon, results in a highly productive and complex shelf ecosystem that responds to local, regional and global forcing (e.g. Bond et al., 2018). Adding to the complexity of the Chukchi Sea shelf ecosystem, recent reports have shown dramatic changes in timing and extent of sea-ice coverage, along with considerable increases in sea surface temperatures (National Snow and Ice Data Center, nsidc.org; Timmermans and Ladd, 2019; Perovich et al., 2019).

In summer, the northern Bering and Chukchi seas experience increased day length and melting sea ice, resulting in a phytoplankton bloom. The bulk of the bloom sinks to the bottom due to the shallow depth (<50 m) and relatively low grazing impact on phytoplankton (Campbell et al., 2009), supporting a robust benthic community. Recent studies, however, have shown a temporal decrease in benthic biomass in the northern Bering Sea, suggesting a possible weakening of benthic-pelagic coupling as the ice retreat now occurs earlier in the season (Grebmeier et al., 2006a; Grebmeier et al., 2006b; Grebmeier, 2012). Concurrently, zooplankton biomass in the Chukchi Sea has increased over the past seven decades (Ershova et al., 2015), which can be explained, in part, by increasing temperatures, reduction in sea ice, and an increase in northward water transport through the Bering Strait (Ershova et al., 2015; Woodgate et al., 2015; Woodgate, 2018). These trends suggest a potential ecosystem regime shift is underway in the Pacific Arctic, with consequences for local food webs. These changes emerge from both direct and indirect effects on both the indigenous biota residing in the ecosystem as well as the introduced species. Changes in the timing and type of production within the pelagic and

benthic communities, will result in changes in benthic-pelagic coupling that have the potential to effect higher trophic levels such as birds, marine mammals, fish, and the people who live in the region.

One specific taxon of interest for our studies were bowhead whales (*Balaena mysticetus*) that forage as they migrate southwestward in the fall through the Utqiagvik (formerly known as Barrow) region from the Beaufort Sea (Moore et al., 2010; Quakenbush et al., 2010; Citta et al., 2012). Studies have reported improvements in bowhead body condition in association with earlier ice retreat and increase in the area of open water (George et al., 2015). The observed improvements in bowhead body condition may be the result of increased prey populations, specifically euphausiids and copepods that dominate the prey in stomachs of bowhead whales harvested near Utqiagvik, Alaska (Lowry et al., 2004; Ashjian et al., 2010; Moore et al., 2010; George et al., 2015). Previous studies suggested that euphausiids are advected along the bottom from the northern Bering Sea into the Chukchi Sea, and subsequently concentrated into dense aggregations through upwelling onto the Beaufort Sea shelf towards Barrow Canyon (Berline et al., 2008; Ashjian et al., 2010). Zooplankton sampling in the Chukchi Sea has generally underestimated populations of euphausiids because estimates were based on collections from small (0.25–0.6 cm diameter) aperture size plankton bongo nets (Hopcroft et al., 2010; Eisner et al., 2013; Questel et al., 2013; Ashjian et al., 2017; Pinchuk and Eisner, 2017) and because the predominantly daytime vertical or oblique sampling failed to target krill layers near the bottom (Coyle and Pinchuk, 2002).

The main objectives of this study were 1) to understand the transport pathways of euphausiids from the Bering Strait to Barrow Canyon, 2) evaluate the abundance of other large planktonic prey for whales in the region, and 3) provide data on the status and trends of Chukchi Sea zooplankton communities. This study builds on other research based on conceptualized modeling to explain the dynamics of late-summer euphausiid populations in this region (Berline et al., 2008; Ashjian et al., 2010) by providing empirical data collected from epibenthic and plankton tows that should more accurately reflect the abundance of euphausiid and other epibenthic taxa. We compared epibenthic and pelagic zooplankton abundances to assess whether they were significantly different and to explore whether epibenthic tows were a more accurate reflection of near-bottom taxa. We hypothesized that advection of zooplankton from the Bering Sea to be the main driver of zooplankton abundance in the region. To test this, we compared zooplankton abundance across years and locations, and calculated krill development times to see if euphausiids captured in this study could have reached that stage after having been advected from the Bering Sea.

2. Methods

2.1. Study area

The Chukchi Sea has a broad, mostly shallow (<50 m) shelf situated between Alaska and Siberia (Fig. 1). Survey transects varied among years, 2011–2015, depending on the scientific focus for the year, available ship time, and ice distribution. Surveys were conducted in the late summer, lasting approximately 30 days (~August 5th – September 5th), except for 2014, which was September 22nd – October 12th. For analysis and description purposes, the study area was divided into 'Beaufort', 'Southwest,' 'Central,' and 'Northeast' regions that are established from statistically different oceanographic conditions (Eisner et al., 2013; Randall et al., 2019).

2.2. Physical data

Hydrographic data, including temperature and salinity, were collected using a SBE 911plus and FastCAT SBE 49 systems (SeaBird Electronics). Sea Surface temperatures (SST) were averaged from 5 – 10 m depth. We quantified broad-scale patterns in sea-ice concentration using satellite data. Sea-ice concentration (percentage of ocean covered by sea-ice) and extent data were obtained after the surveys from a Scanning Multichannel Microwave Radiometer (SMMR) on the Nimbus-7 satellite and from the Special Sensor Microwave/Imager (SSM/I) sensors on the Defense Meteorological Satellite Program's (https://nsidc.org; Comiso, 1999). Bering Strait volume transport data were acquired from moored Acoustic Doppler Current Profiler (ADCP)

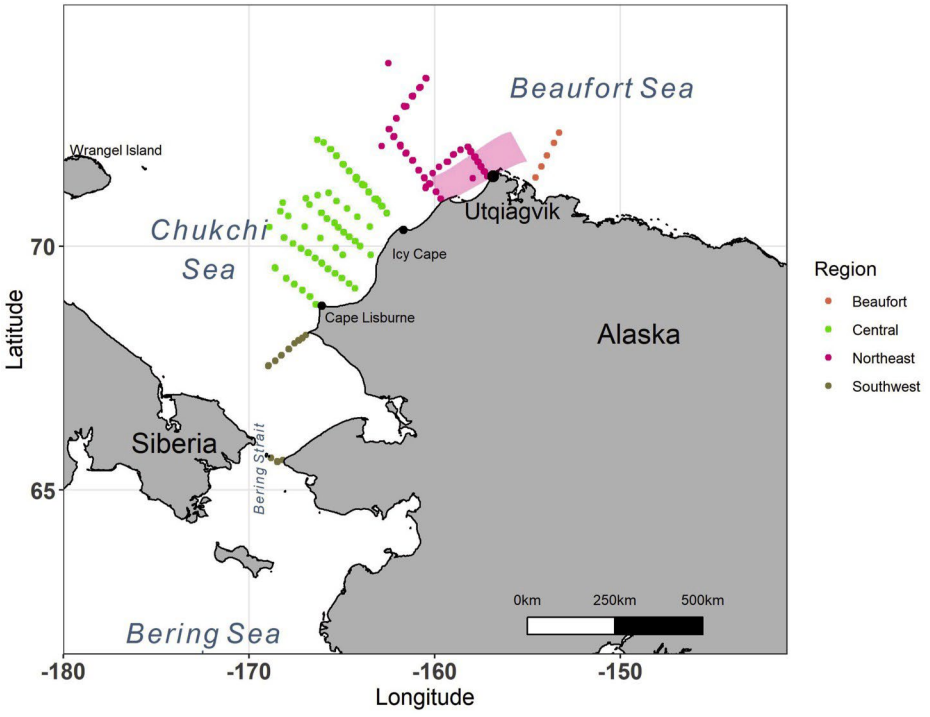

Fig. 1. Study area in the Chukchi Sea. Each region is symbolized by a colored circle. The study area was split up into southwest, central, northeast, and Beaufort regions. The pink shaded region indicates Barrow Canyon.

measurements (Woodgate et al., 2015; Woodgate, 2018). Northeastward water column volume transport, in Sverdrups (Sv), was calculated according to Stabeno et al. (2018) from current data measured at C1, C2, and C3 moorings along the Icy Cape transect. Transport was averaged over 14 and 30 days leading up to the date that the station was sampled.

2.3. Zooplankton net data

Zooplankton were collected primarily during daylight hours using a multiple-opening and closing 1 m^2 Tucker Sled trawl equipped with a FastCAT, and sled-like runners at the bottom so that samples could be taken in close proximity to the bottom. A 505 μm (2013–2015) or a 333 μm (2011–2012) mesh net sampled while the sled was towed at a speed of 1.5–2.0 knots along the bottom for 2 min, then mechanically tripped to close and simultaneously open a second net to sample the entire water column from the bottom to the surface (wire retrieval rate 20 m min^{-1}). For smaller taxa, a 25 cm net with 150 μm mesh was suspended in the larger net that profiled the entire water column. Note that this setup is not ideal in cases where clogging in the 20- cm net occurs, thus the possibility of inaccurate volume filtered readings exist in this study. Samples that appeared questionable (e.g. low flowmeter readings, large jellyfish in the net) were excluded from the analysis. Smaller taxa such as *C. glacialis* and euphausiid furcilia were enumerated in the water column only and not in the epibenthic samples. Both Tucker nets were equipped with a separate calibrated General Oceanics flow meter to estimate volume filtered. Plankton captured by the nets were washed into the cod-ends, sieved through appropriately-sized wire mesh screens and preserved in glass jars with sodium borate-buffered 5% Formalin. Samples were inventoried at the end of the cruise and then sent to the Plankton Sorting and Identification Center in Szczecin, Poland, for processing. Subsampled taxa were enumerated and identified to lowest possible genera and life stage and returned to the Alaska Fisheries Science Center for verification. Ten percent of the returned samples were checked for quality assurance/quality control of species identification and enumeration.

2.4. Zooplankton data analysis

Zooplankton abundance was reported as four general categories in the context of known bowhead whale prey in the region (Lowry et al., 2004; Moore et al., 2010), including: euphausiids (primarily *Thysanoessa raschii*), amphipods (dominant species included *Themisto libellula* and unidentified Gammaridea), mysids (dominant species included *Neomysis rayii* and *Pseudomma truncatum*), and copepods (*Calanus glacialis*). Analysis of variance (ANOVA) was used to examine epibenthic and pelagic variation across years in *T. raschii*, mysid, and amphipod abundance.

Development times of *Thysanoessa* spp. stages were estimated using the formula:

$$R_2 = R_1 * Q_1^{\frac{T_2 - T_1}{10}}$$

where R_1 and R_2 are the development rates (d^{-1}) at temperature T_1 and T_2 (°C), respectively (Teglhus et al., 2015). We used the Q_{10} of 2.04 (Pinchuk and Hopcroft, 2006). The calculated temperature (T_2) and development rate (R_2) were normalized to 5 °C and 0.016 d^{-1} (for furcilia; 0.045 d^{-1} for calyptopis), obtained from Teglhus et al. (2015). We chose the measured rates from Teglhus et al. (2015) because of the similar temperature conditions (5–8 °C) and because a mixed population of krill was used as we also have a mixed community. These were also the slowest known development rates for *Thysanoessa* spp. furcilia compared to previous studies (see Table 3 in Teglhus et al., 2015); this prevented an overestimation of development rates of *Thysanoessa* spp. under conditions that may be significantly influenced by availability of food such as phytoplankton (Pinchuk and Hopcroft, 2007). Development times were then compared to satellite-tracked drifter data (Stabeno et al., 2018) to explore the possibility of recent reproduction in the Chukchi Sea.

We used the mgcv package (Wood, 2011) in R (R Core Team, 2019) to fit generalized additive models (GAM) with Gaussian distribution to relate changes in C2 and C5 stages of *C. glacialis, T. raschii* (adult and juvenile), and euphausiid furcilia mean abundance to environmental variables. These two particular stages in each species were chosen to contrast different ages, with C2 representing younger and C5 representing older *C. glacialis*, and furcilia representing younger and adults/juveniles representing older *T. raschii*. For simplicity, we excluded stages C3 and C4 from the analysis as these stage abundances are correlated to the C5 stage (data not shown). We chose to exclusively use epibenthic abundances of *T. raschii* since most of our sampling occurred primarily during the day and when the vast majority of euphausiids would be at or near the bottom. Restricted Maximum Likelihood (REML) method was used as the smoothing parameter estimation. The model selection was done by assessing deviance explained, R^2, and Akaike information criterion (AIC). Residuals were analyzed to ensure there were no obvious deviations from normal distributions, and we examined the response versus. fitted value for patterns. We assessed ten environmental variables for inclusion in the GAMs including: latitude, longitude, bottom temperature, surface temperature, bottom salinity, surface salinity, 14 and 30-day northeastward transport, year, and day of the year (hereinafter referred to as ordinal day).

3. Results

3.1. Environmental conditions

Sea surface temperatures (SST) were warmest in 2011 (mean SST 6.89 ± 1.35 °C) and coldest in 2013 (mean SST 2.64 ± 2.61 °C). Both 2012 (mean SST 5.46 ± 2.41 °C) and 2015 (mean SST 6.13 ± 2.18 °C) had similar warm SSTs towards the central and southwest portion of the survey, and colder SSTs across the northeast portion; however, 2012 was colder in the northeast region (Fig. 2). Sea surface temperatures in 2014 (mean SST 3.09 ± 1.62 °C) were colder over the entire survey area and had substantially less northeast to southwest variability. Randall et al. (2019) using the mean bottom temperatures in the central region, found 2013 (−1.4 °C) to be the coldest year, with 2011–2012 and 2014–2015 having similar warmer bottom temperatures (~2 °C). Similarly, differences between years were evident from initial dates at which ice concentration was less than 10% (Table 1). Sea-ice remained in the northeast region until mid to late August in years 2012–2014, and melted in mid-to late July in 2011 and 2015.

Monthly mean northward transport (Sv) through the Bering Strait tended to peak in the spring and summer (~May–August), with lower transport in the winter (Fig. 3). Higher spring/summer transport occurred in 2011and 2015, peaking at around 1.92 (±0.09) Sv in May and 1.87 (±0.06) Sv in July of 2015 and 1.91 (±0.10) Sv in June of 2011. Spring and summer transport was moderate in 2014 and lower in 2012 and 2013, with mean values as low as 1.14 (±0.18) and 1.18 (±0.14) in August of 2012 and 2013, respectively.

3.2. Zooplankton abundance

Average pelagic amphipod abundances increased from 2011 to 2015; average benthic abundances were generally higher than pelagic abundances but also increased over the same period (Fig. 4a). Overall, 2013, 2011 had the highest and lowest average amphipod abundance respectively. Mysid epibenthic and pelagic abundances were relatively low across all years (Fig. 4b), but epibenthic abundances were relatively higher in all years and there were no increasing or decreasing trends across the years. The euphausiids community consisted of four species of the genus *Thysanoessa*: *T. inermis, T. longipes, T. spinifera, and T. raschii*; the latter, being the most abundant (approximately 70% of total abundance) of the four, was singled out in this study for purposes of

Fig. 2. Sea surface temperature (°C) averaged from 5-10 m for each year.

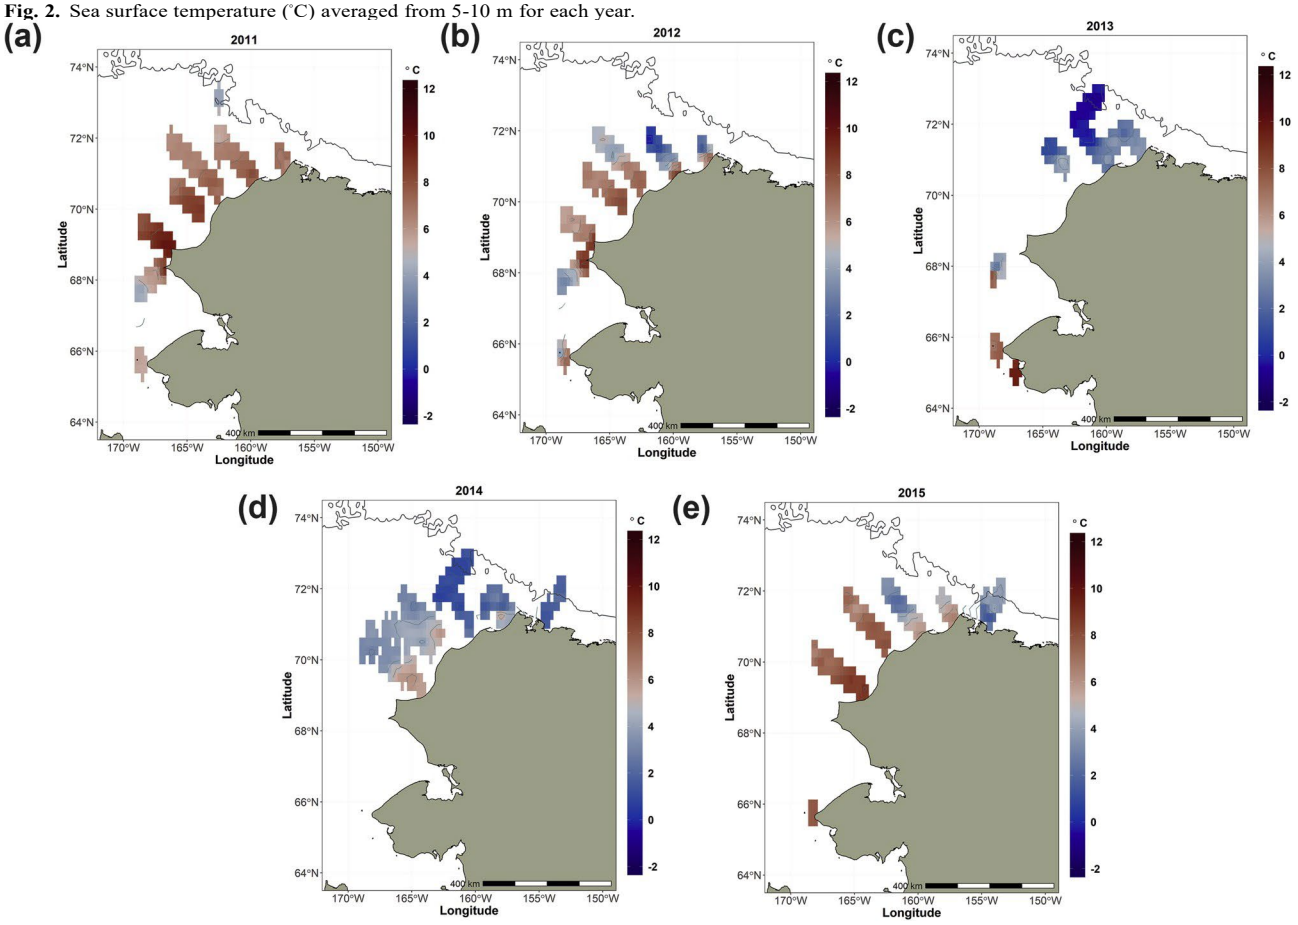

Fig. 2. Sea surface temperature (°C) averaged from 5-10 m for each year.

Table 1
Estimate of the initial date at which ice concentration was less than 10% within the southwest and northeast region of the sampling area.

	Southwest	Northeast
2011	3 June	15 July
2012	22 June	19 August
2013	29 June	31 August
2014	16 June	16 August
2015	14 June	18 July

simplicity. Epibenthic *T. raschii* abundances were lowest in 2013 and highest in 2014 (Fig. 4c). Pelagic *T. raschii* abundance was lowest in 2011 and highest in 2015.

There were no consistent differences in the abundance of *T. raschii*, mysid, and amphipods between the bottom layer and water column when we took into account year and a depth-year interaction in our analyses. ANOVA results did not show significant differences between epibenthic and pelagic *T. raschii* abundances independent of year. However, *T. raschii* abundance did show significant differences between years ($F = 3.20$, $p = 0.01$), independent of depth and depth/year interactions ($F = 5.56$, $p < 0.001$). Similarly, ANOVA results did not show significant differences between epibenthic and pelagic amphipods independent of year ($F = 2.16$, $p = 0.14$). However, amphipod abundances did show significant differences among years independent of depth ($F = 4.467$, $p = 0.001$) and depth/year interactions ($F = 3.294$, $p = 0.01$). ANOVA results showed significant differences between epibenthic and pelagic mysids independent of year ($F = 9.59$, $p = 0.002$), years independent of depth ($F = 4.80$, $p = 0.0008$), and depth/year interactions ($F = 0.84$, $p = 0.50$). Time of day was hypothesized to influence euphausiid

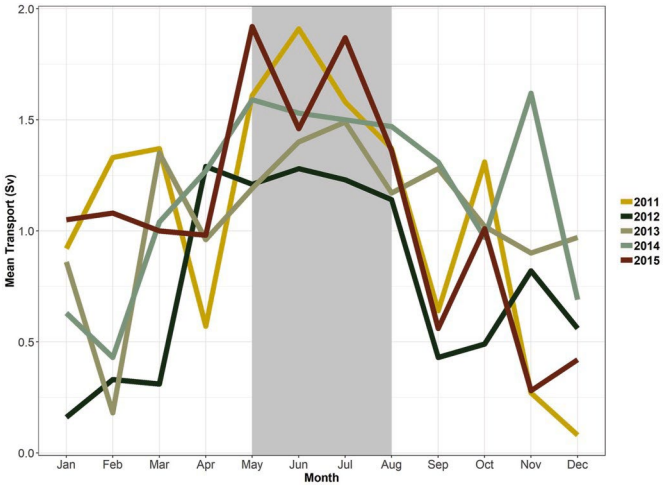

Fig. 3. Mean transport (Sv) of water by month for each year through the Bering Strait. The grey underlay highlights the approximate peak transport months.

abundance, however, ANOVA results did not find differences in day/night sampling abundances of *T. raschii* at the $p < 0.05$ significance level.

A post-hoc Tukey's 'Honest Significant Difference' test of depth-year interactions of *T. raschii*, mysids, and amphipods showed 2014 and 2015 were significantly ($p < 0.05$) different from most previous years (Table 3). Within years 2014 and 2015, *T. raschii* showed significant ($p < 0.05$) differences between epibenthic and pelagic depths. Similarly, both mysids and amphipods showed significant ($p < 0.05$) differences

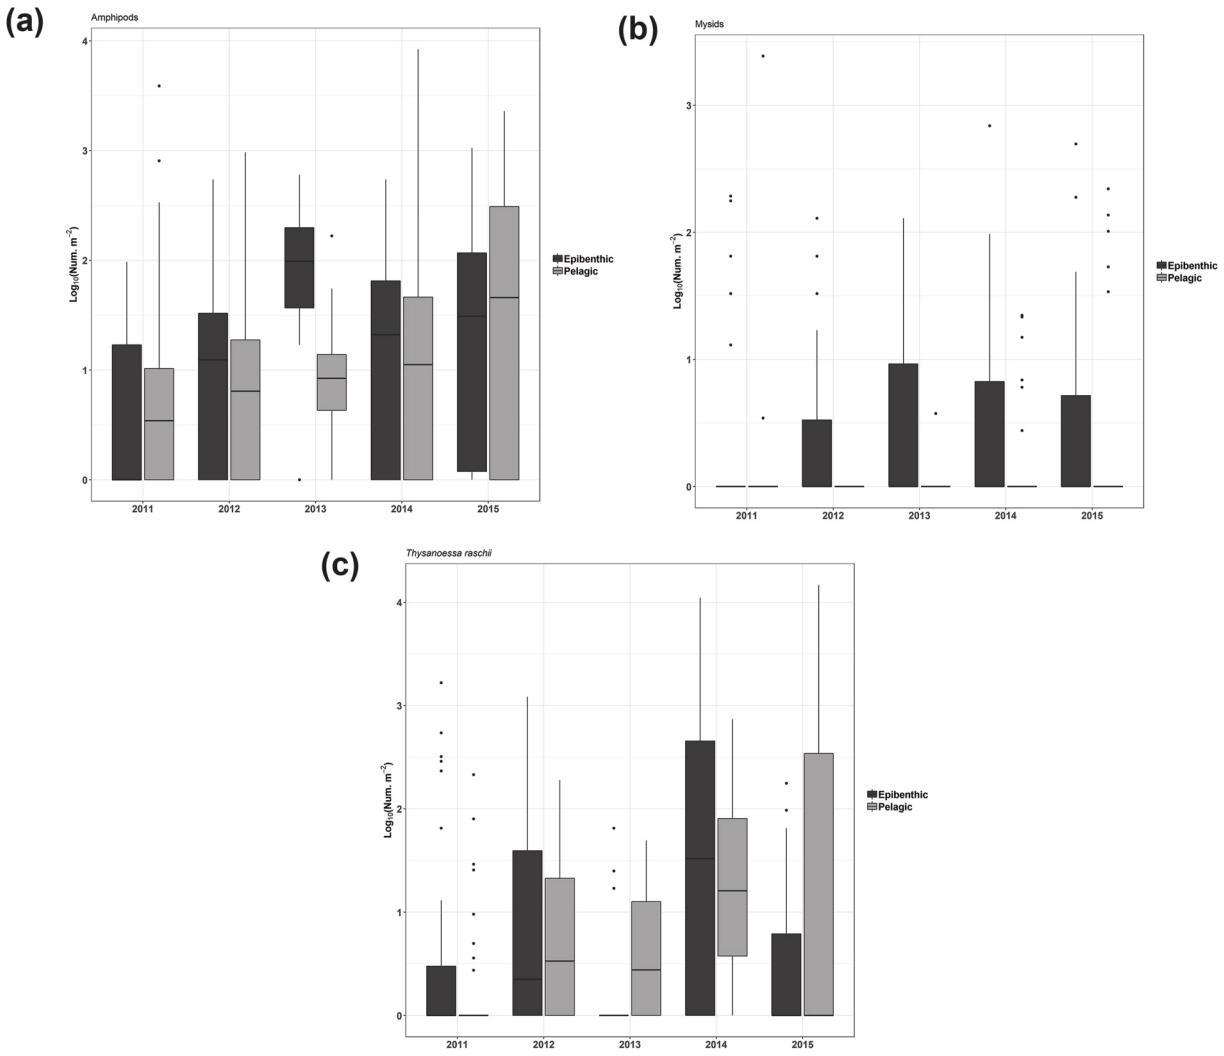

Fig. 4. Yearly epibenthic and pelagic total abundance (Log_{10}(Num m^{-2})) for amphipods (a), mysids (b), and *Thysanoessa raschii* (c).

between epibenthic and pelagic depths within 2014. Overall, we cannot independently assess year without noting whether *T. raschii*, mysids, or amphipods samples were caught in the water column or just above the bottom.

There was a lack of spatial differences among years for amphipods, with positive catches across all regions (Fig. 5a). The highest amphipod frequency of occurrence was in 2013, with complete absence in only one station (epibenthic and pelagic combined). Mysid abundance was low for each year across all regions (Fig. 5b); within years, more mysids were captured in the northeast than other regions. Mysid had the highest frequency of occurrence in 2014 with animals captured at stations in 3 of the 4 regions (epibenthic and pelagic combined). A lack of spatial differences of *T. raschii* among years was evident (Fig. 5c), with positive catches appearing across most regions. The highest *T. raschii* frequency of occurrence was in 2014, with presence detected from at least one station in three of the four areas (epibenthic and pelagic combined). There were no obvious trends in presence/absence or abundance as a function of distance from land.

Abundances of *C. glacialis* were lower in warmer years (2011, 2014, and 2015) and higher in colder years (2012, 2013; Fig. 6). *Calanus glacialis* were ubiquitous across all regions, with presence detected at most stations (Fig. 7).

3.3. Early life stages

Development time calculations suggest that it takes approximately 51 and 78 days at 8 and 2 °C water temperature, respectively, for *Thysanoessa* spp. stages to develop from eggs to furcilia (Table 2). Note that the furcilia counted in this study were not identified to species. Euphausiid furcilia stages were most abundant in the central and southwestern regions of each year (Fig. 8). Euphausiid furcilia were completely absent from the northeastern region in 2012 and 2013. Both 2011, 2014 had similar abundances along the central and southeastern regions, with 2011 having slightly higher abundances in the northeast. In 2015, highest abundances were located in the central region, with lower abundances extending into the northeast. Euphausiid calyptopis, a developmental stage of much shorter duration (~40 days shorter; Teglhus et al., 2015), were only caught in very low abundances (~1.0 log_{10} (Num. m^{-2})) in 2011 at 3 stations (map not shown) from the northeast and southwest regions.

Spear et al. (2019) estimated *C. glacialis* egg to C2 stages have approximate development times of 8 to 12 days at temperatures ranging between 12 and -1.5 °C respectively. *Calanus glacialis* C2 stages were almost exclusively caught in the northeast region, including Icy Cape (Fig. 9). Higher total abundances appeared in both 2012 (4.92 log_{10} (Num. m^{-2})) and 2013 (5.19 log_{10} (Num. m^{-2})), while the lowest total abundances were in 2011 (3.38 log_{10} (Num. m^{-2})).

Table 2
Amount of days at different temperatures for *Thysanoessa* spp. stages to develop from eggs.

Stage	12 °C	8 °C	2 °C	−1.5 °C
Calyptopis	13.4	17.8	27.3	35
Furcilia	38.2	50.9	78	100

3.4. Relationships between plankton abundance and physical variables

Bottom temperature, 30-day northeastward transport, longitude, and ordinal day were the most significant variables associated with mean *T. raschii* abundance (Table 4). The model helped explain 42.3% of the deviance with an r^2 of 0.38. Extreme lower and higher bottom temperature conditions were associated with lower *T. raschii* abundance (Fig. 10). There was a positive relationship between 30-day northeastward transport and *T. raschii* abundance. The longitude parameter also showed that *T. raschii* abundance was positively associated with the northeastern and southwestern portions of the study area. The strong positive relationship with ordinal day showed that higher abundances showed up later in the year in 2014. This is because the only year in which we sampled past day of year 260 was 2014. Furcilia abundance had significant relationships with bottom temperature, 14-day northeastward transport, year, ordinal day, and longitude. The model explained 56.8% deviance in abundance for euphausiid furcilia with an r^2 of 0.53 (Table 4). There was not a clear abundance pattern in relation to the bottom temperature (Fig. 11). In contrast to the relationship between transport and *T. raschii* adults, there was a negative relationship with furcilia abundance and 14-day northeastward transport.

The model helped explain 43% of the deviance with an r^2 of 0.39 of the *C. glacialis* C5 stage (Table 4). The most significant parameters included surface salinity, surface temperature, bottom temperature, 14-day transport, ordinal day, and year. Higher surface temperatures had a positive association, while lower surface had a slightly negative association, with C5 abundances (Fig. 12). Conversely, lower bottom temperatures had a positive relationship and higher bottom temperatures had a negative relationship with C5 abundance. Stage C5 abundance was also negatively associated with lower salinity seawater. There was a slight negative association with strong northeastward transport and C5 abundance. Interestingly, there was not a significant association with northeastward transport and *C. glacialis* C2 stages. The C2 stage was similar to C5 stages in the relationship with bottom temperatures, as there was a negative relationship with higher bottom temperatures and a positive relationship lower bottom temperatures (Fig. 13). There was positive association of C2 stages with higher longitudes. Overall, C2 stages had the strongest GAM model, which explained 57% of the deviance and a r^2 of 0.55 (Table 4).

4. Discussion

4.1. Euphausiid transport

T. raschii is an amphiboreal species whose distribution also extends to the Arctic Ocean and associated continental shelves. We observed the presence of *T. raschii* in all years near Utqiagvik, with relatively high abundances in 2014 and 2015. The annual presence of euphausiids there is important as they are a dominant component of the diet for bowhead whales in the region (Lowry et al., 2004; Moore et al., 2010). A positive association with northeastward transport and a positive association with higher longitudes, implies that *T. raschii* were advected from the south. The positive association with lower longitudes may be the result of krill being advected into the Chukchi Shelf from the Beaufort Sea as described by Ashjian et al. (2010); other explanations include lack of sampling in the central region in 2013, sampling later in the 2014, or because of the current patterns that tend to extend farther offshore in the central region (Stabeno et al., 2018), resulting in animal presence just outside of the sampled transect. Overall, these findings support the hypothesis of Berline et al. (2008) and Ashjian et al. (2010) that the

euphausiids concentrated by physical processes near Barrow Canyon likely originated from the northern Bering Sea.

Conversely, temperature-dependent euphausiid furcilia development times suggest their extent into the central and northeast regions in warmer conditions was a result of spawning in the Chukchi Sea. Transport of water takes ~90 days to reach Icy Cape from the Bering

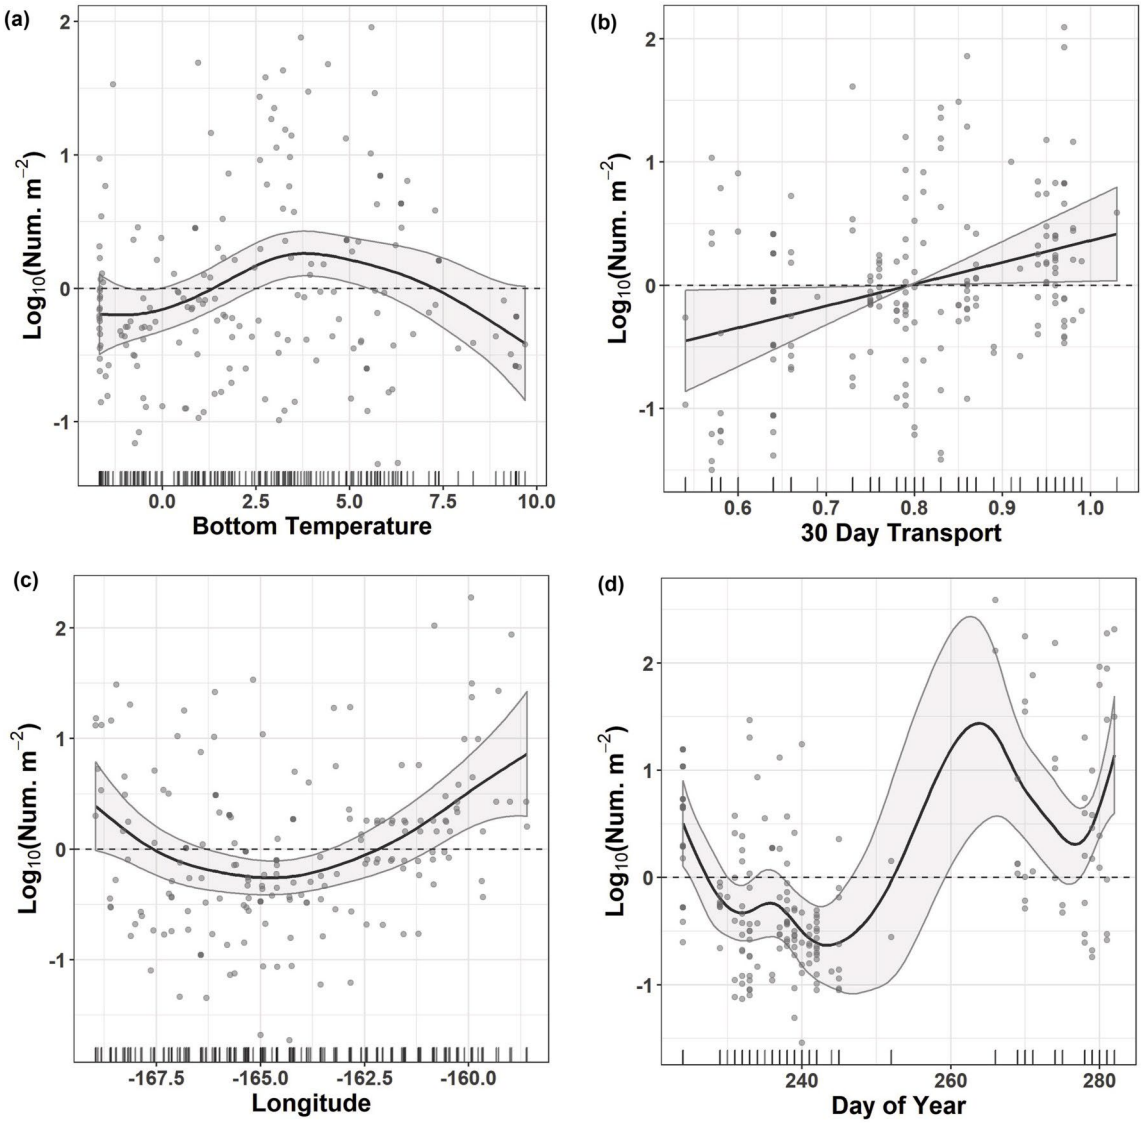

Fig. 10. GAM smooth for the distribution of *Thysanoessa raschii* epibenthic abundance (Log_{10}(Num m^{-2})), 2011–2015. Variables included mean bottom temperature (a), 30-day transport (b), longitude (c), and day of year (ordinal day) (d).

Strait (Stabeno et al., 2018). This is roughly 12 to 40 days longer than the development time from egg to furcilia at comparable temperatures. The hypothesis of local production is also supported by the negative relationship with 14-day transport or lack of clear relationship with bottom temperatures. In particular, the negative relationship with 14-day transport (in addition to a lack of association with 30-day transport) showed that the greater and more recent transport resulted in reduced abundances, suggesting they were likely recently spawned nearby and subsequently transported away.

Adult euphausiids were present in the northeast region in 2012 and 2013, even though overall transport during those years was low. The absence of younger stages could have resulted from a change in the timing of reproduction relative to our sampling, failed spawning, or very high mortality of the larvae because of cold temperatures or high predation. Euphausiid eggs were present in the northeast region in 2014 and 2015, but were absent in 2012 and 2013 (egg data not collected in 2011), suggesting reproduction only occurred when this region was not occupied by colder water masses.

The higher pelagic abundances of euphausiids in 2013 and 2015 were not due to a day/night effect as a comparison of day/night abundances found no significant differences (not shown). The significant increase in abundance of *T. raschii* in 2014, compared to remaining years, suggests that sampling later in the season likely had considerable impact. This is evidenced by the relationship between ordinal day and euphausiid abundance in 2014. Other environmental and physical results did not suggest any other anomalous features that may have caused this significant jump in abundance. Thus, it suggests that because we sampled later in 2014 we observed more euphausiids compared to other years. This is most likely the result of advection timing (as explained in Berline et al., 2008), but may also reflect local recruitment. Alternative explanations for increased abundance include local production or retained for a longer period of time. Most historical surveys have not sampled later than mid-September to avoid disturbing subsistence hunting by Iñupiat whalers as the whales migrate westward from the Beaufort. Thus previous surveys (Grebmeier and Harvey, 2005; Lane et al., 2008) reporting low numbers of euphausiids could be due to the mismatch between euphausiid transport from the south and survey timing.

Our estimates of adult euphausiid abundance may be somewhat improved over prior estimates derived from small mouth plankton nets towed only in the water column (e.g. Eisner et al., 2013). However, euphausiids are difficult to accurately estimate even with larger nets

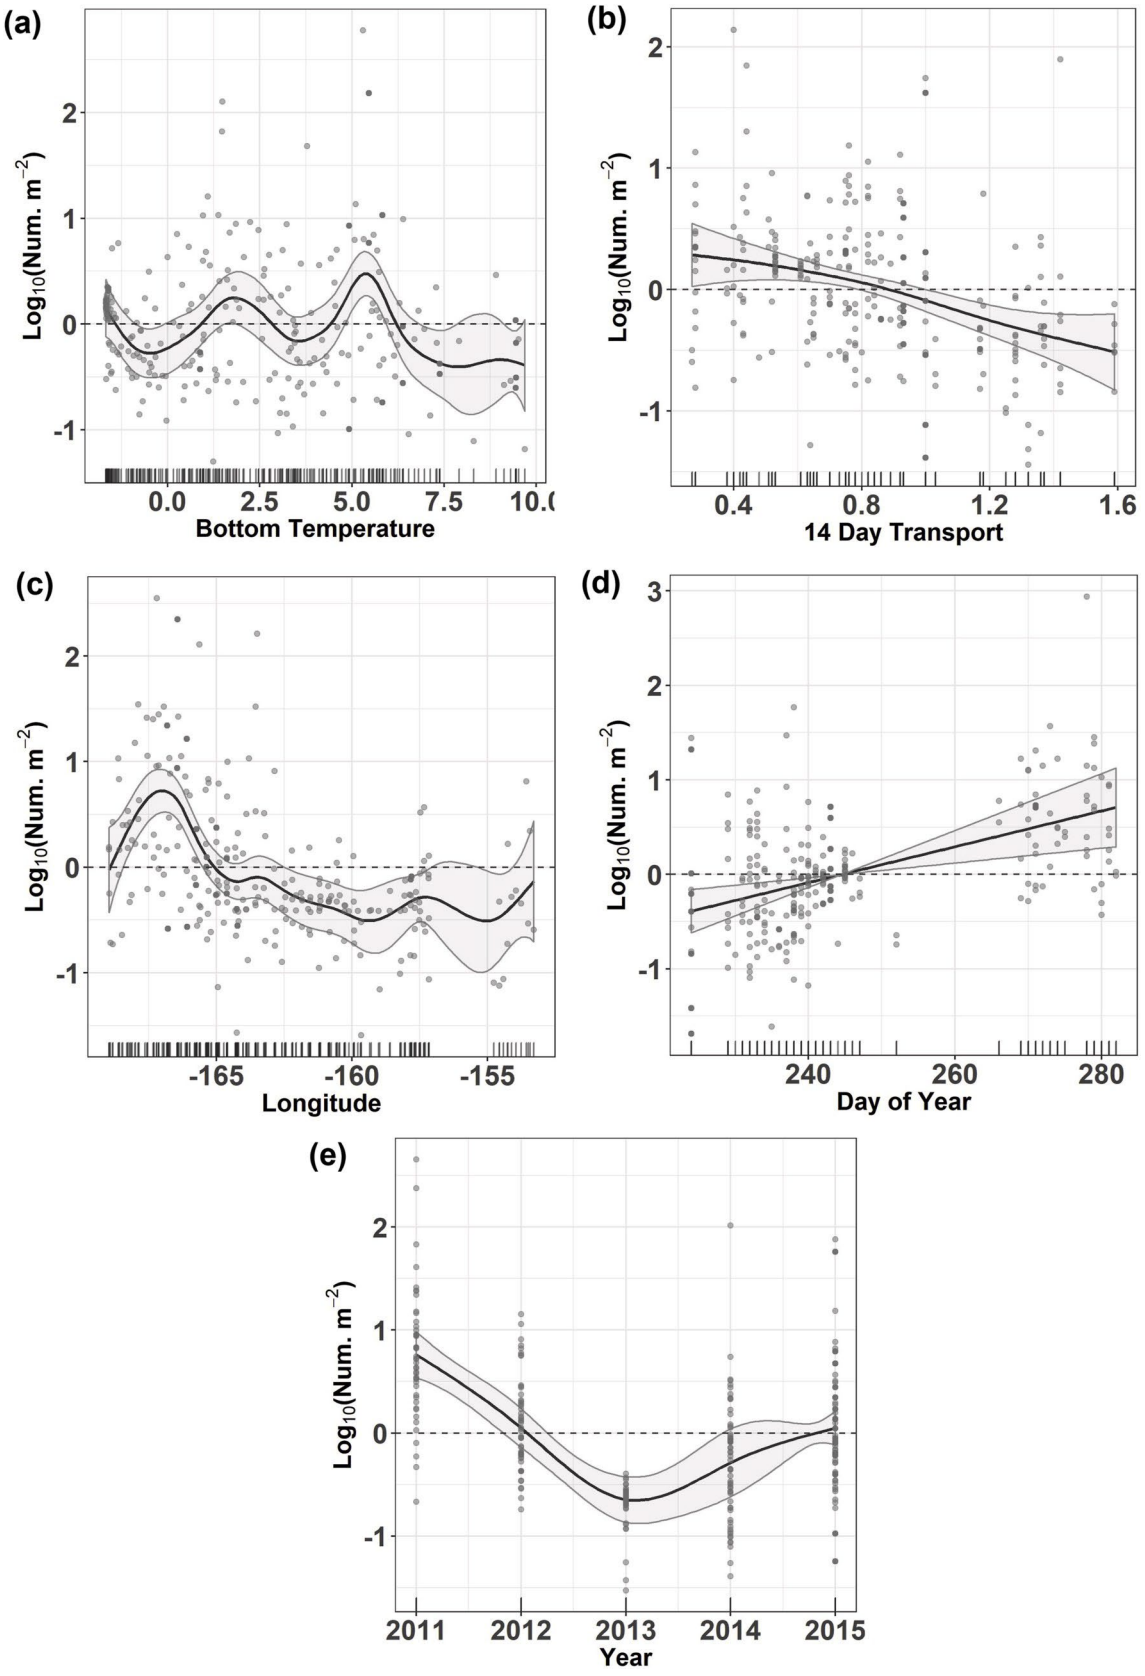

Fig. 11. GAM smooth for the distribution of euphausiid furcilia pelagic abundance (Log_{10}(Num m^{-2})), 2011–2015. Variables included mean bottom temperature (a), 14- day transport (b), longitude (c), day of year (ordinal day) (d), and year (e).

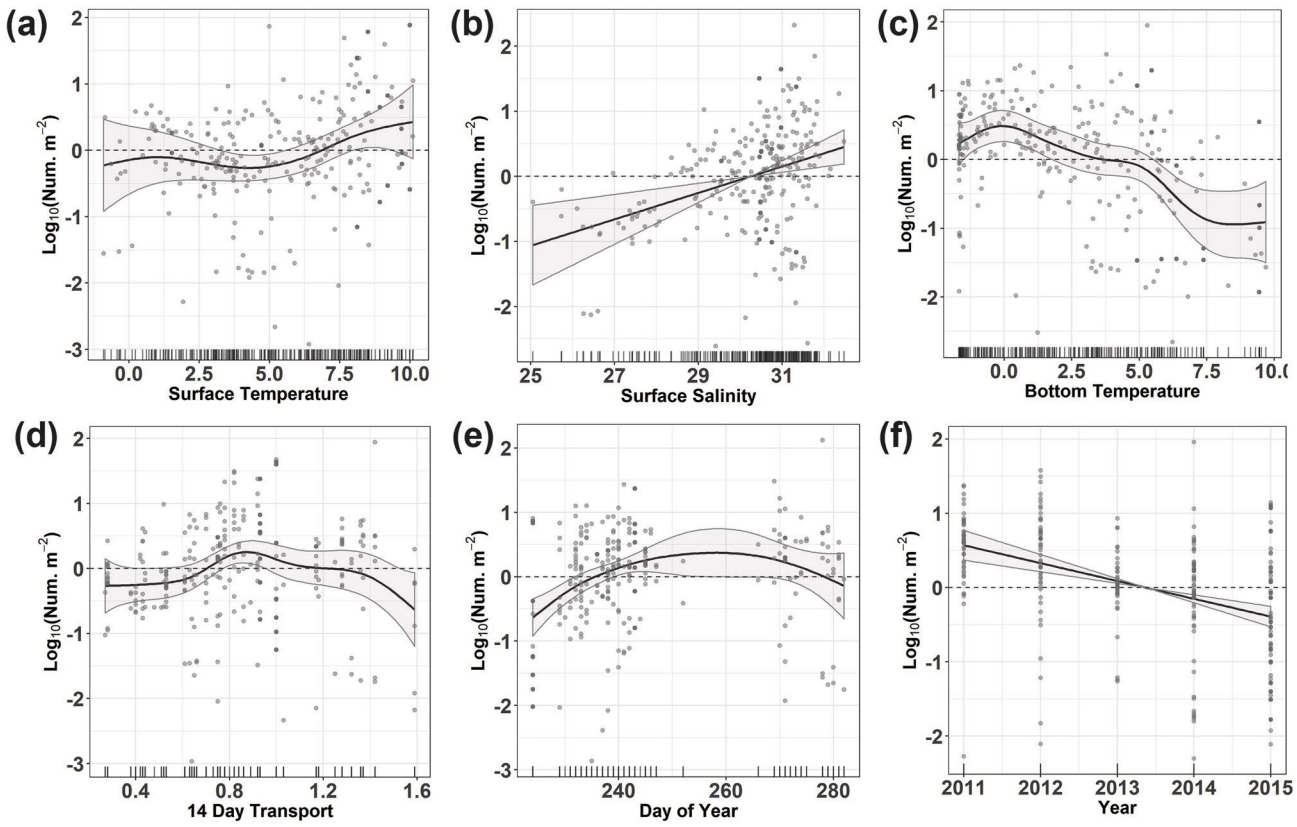

Fig. 12. GAM smooth for the distribution of *Calanus glacialis* C5 stage pelagic abundance (Log_{10}(Num m^{-2})), 2011–2015. Variables included mean surface temperature (a), surface bottom salinity (b), bottom temperature (c), 14-day transport (d), day of year (ordinal day) (e), and year (f).

that sample at faster tow speeds. (e.g. Hunt et al., 2016). Net avoidance by euphausiids has long been recognized as chronic problem in oceanographic studies (e.g. Brinton, 1967; Sameoto et al., 2011; Wiebe et al., 2013). Net avoidance abilities may even extend to the young stages (e.g. Smith, 1991). Future work using acoustical or optical techniques may be able to provide better estimates of euphausiid abundance, although as this study demonstrated there is a need to sample very close to the seafloor.

4.2. Other large zooplankton

We found that *C. glacialis* were most abundant in colder conditions, with the abundance increase being driven by earlier development stages. This finding is supported by research showing that *C. glacialis* were strongly tied to the ice edge algae production, which is increased in colder years (Søreide et al., 2010). Both C2 and C5 stages showed a significant positive association with colder bottom temperatures. The C5 stage, as opposed to the C2 stage, also had a positive association with warmer surface temperatures and significant relationship with northeastward transport, suggesting that C5 stages were more likely to be influenced by advection. The C2 stage had significantly higher abundances in the northeast region, a negative relationship with higher surface temperatures, and lack of a significant relationship with transport, suggesting local production rather than transported from the south. This is supported by previous research showing *C. glacialis* having approximate development times of 8 to 12 days at temperatures between 12 and -1.5 °C, respectively, from egg to C2 stage (Hirst and Lampitt, 1998; Kiørboe and Hirst, 2008; Spear et al., 2019). As described earlier, transport times from the Bering Sea to the northeast region were much longer than development times from egg to C2 Stage. C2 copepodites were also more abundant in 2012 and 2013, when temperatures were coldest in the northeast. This suggests that the overall abundance increases in *C. glacialis* in 2012 and 2013, when temperatures were colder, sea ice melted later in the northeast region, and advection was lower, was primarily due to local reproduction. Abundance increases in the northeast region could also be due to upwelling onto the Chukchi Shelf from the Beaufort Sea (Ashjian et al., 2010). Conversely, the lower abundances of C2 stages in warmer conditions may be a result of faster and earlier development into later stages. Thus the various stages of *C. glacialis* region likely have multiple sources (in situ reproduction and transport from the south and east), and the absolute abundance is a function of local and regional processes. This is a notable result; later stages of *C. glacialis* are known to be the primary prey of bowhead whales around West Greenland (Heide-Jørgensen et al., 2013), and a significant contribution to their diet in the Chukchi and Beaufort seas (Lowry et al., 2004; Moore et al., 2010). In addition, if *C. glacialis* are developing faster, they may enter into diapause earlier creating a mismatch with migrating whales.

The significant differences in pelagic and epibenthic abundance in both mysids and amphipod highlights the importance of sampling near the bottom. Mysids and some amphipod species may spend time in the water column; therefore, sampling the water column and epibenthic layer will yield improved estimates of their abundance. Epibenthic amphipod abundance was significantly higher in 2013 than any other year sampled in this study. This is a notable observation in the context of a changing climate, given that 2013 was also the coldest year and certain species of amphipods, in particular, have known ice-associated and bottom dwelling habits (Vinogradov, 1999; Gradinger and Bluhm, 2004). Both amphipods and mysids are prey for multiple marine mammals, including bearded seals (*Erignathus barbatus*; Cameron et al., 2010), Pacific walrus (*Odobenus rosmarus divergens*; Sheffield and Grebmeier, 2009), beluga whales (*Delphinapterus leucas*; Quakenbush et al., 2015), grey whales (*Eschrichtius robustus*; Nerini, 1984; Darling et al., 1998), and bowhead whales (Lowry et al., 2004). Given the

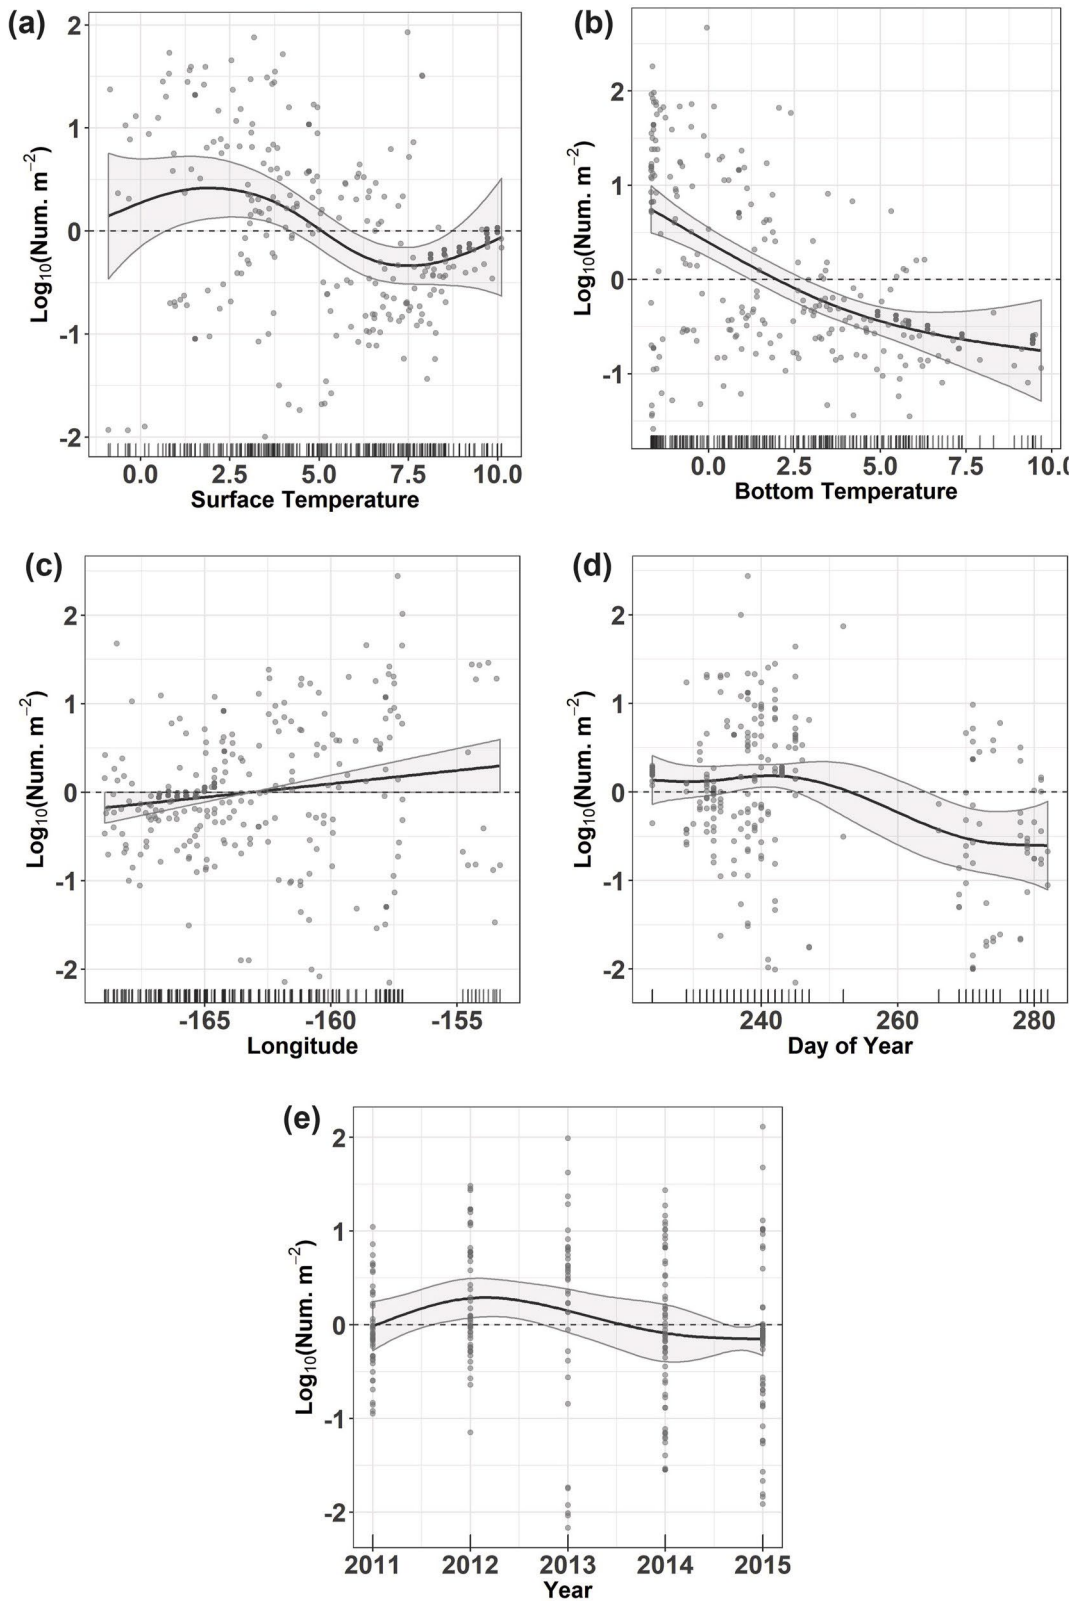

Fig. 13. GAM smooth for the distribution of *Calanus glacialis* C2 stage pelagic abundance (Log_{10}(Num m^{-2})), 2011–2015. Variables included mean surface temperature (a), bottom temperature (b), longitude (c), day of year (ordinal day) (d), and year (e).

importance of mysids and amphipods to Arctic food webs, it is important to monitor their response to changes in ice cover and water temperatures.

4.3. Chukchi Sea large zooplankton status and trends

The findings of this study are relevant to the potential response of lower trophic levels to climate warming, including changes in Arctic

food webs. Recent studies have found a 50% increase in water volume transport through the Bering Strait to the Chukchi Sea from 2001-2014; the immediate impact to the physical environment is an increase in heat flux that is a potential trigger for Arctic sea-ice melt and retreat (Woodgate et al., 2010; 2015; Woodgate, 2018). As the climate warms, increases in primary and secondary production will result in changes in abundance of lipid-rich zooplankton, but it remains to be seen what the overall lipid availability will be (Renaud et al., 2018). Two of the species targeted in this study, *C. glacialis* and *T. raschii*, have an average percent lipid content of approximately 11–15% and 3–5%, respectively, both having a higher average percent lipid content in colder years (Heintz et al., 2013). There is a general consensus that densities of sea ice-associated, lipid-rich *C. glacialis* are expected to decline due to loss of ice in the region. (Tremblay et al., 2012; Grebmeier et al., 2006a; Grebmeier, 2012; Moore and Stabeno, 2015; Renaud et al., 2018). In addition, this study provides evidence that increases in large zooplankton abundance such as euphausiids (which also contain depot lipids) is likely to occur, either via advection from lower latitudes or changes in local production. This is supported by previous studies which found an increase in zooplankton biomass over several decades in the Chukchi Sea (Ershova et al., 2015). An increase in abundance of prey such as euphausiids will likely benefit higher trophic level predators such as planktivorous fish, seabirds and marine mammals. Recently, studies have suggested that the abundance of other planktivores in the northern Bering Sea and Chukchi appear to be changing. For example, in the Bering Sea, there has been a decrease in the lipid-rich nodal species Arctic cod (*Boreogadus saida*) and an increase in the commercial species walleye pollock (*Gadus chalcogrammus*) and Pacific cod (*Gadus macrocephalus*; Stevenson and Lauth, 2019). Walleye pollock have been observed in the Chukchi and Beaufort seas (e.g. Logerwell et al., 2015) and is an important planktivore in the southeastern Bering Sea ecosystem consuming both euphausiids and large copepods (Dwyer et al., 1987; https://access.afsc.noaa.gov/REEM/WebDietData/DietDataIntro.php). Walleye pollock could become an effective competitor for large zooplankton with other fishes, seabirds, and marine mammals if its abundance continues to increase in the northern Bering, Chukchi and Beaufort seas. At present, however, there is evidence of improved body condition of bowhead whales returning from the Beaufort (George et al., 2015). This suggests that the plankton community in their summer feeding grounds has changed in either biomass, species composition or both.

The strong interaction between top-predators (whales, seabirds, and Arctic cod) and copepods/krill in the northern Chukchi appeared to be mediated by both advection and local production related to sea-ice dynamics. What remains to be seen is whether arctic shelf ecosystems will continue to be bottom-up forced by sea-ice dynamics or whether climate-mediated impacts on intermediate trophic levels (e.g. large zooplankton and small fishes) could become the predominant controlling mechanism, e.g. wasp-waist control (Gaichas et al., 2015; Griffiths et al., 2013; Fauchald et al., 2011). If warming continues, the bottom-up dynamics in this location would likely be disrupted by increased advection over longer time-periods as well as a lack of localized, lipid-rich, ice-associated production. Such a shift would greatly impact the trophic dynamics in the region.

5. Conclusions

This study analyzed five successive years of zooplankton abundance over a wide range of physical oceanographic characteristics in the Chukchi Sea to better understand the status and trends in prey availability for baleen whales, seabirds, and planktivorous fish. The coldest year (2013) was highlighted by later summer sea-ice melt, colder sea surface and bottom temperatures, and lower northward transport through the Bering Strait during the spring and summer months. Generally, the warmest years accompanied with earlier summer sea-ice melt, warmer sea surface and bottom temperatures, and higher Bering Strait transport during the spring and summer months. Adult euphausiid abundances differed across warm and cold conditions. These differences appeared most pronounced regionally (NE-SW gradient) and were related to transport, which suggests that most of these euphausiids are transported to the Chukchi Sea from the Bering Sea. The lack of furcilia in 2012 and 2013, (except in the SW), and the presence of furcilia in 2011 and 2014–15, suggests that only in these warmer years with higher advection were earlier stages transported to the northeast region of the Chukchi Sea. We also found that some euphausiids might be locally produced based on the development times. In contrast, the *C. glacialis* C5 stages were found across all years, but C2 stages were found primarily in the northeast and were more abundant under colder conditions which suggests local production of copepods. Thus, the large numbers of euphausiids and copepods that dominate the prey in stomachs of bowhead whales harvested near Utqiagvik, Alaska (Lowry et al., 2004; Ashjian et al., 2010; Moore et al., 2010; George et al., 2015) are likely the result of transport of euphausiids to this location and the contribution of locally produced *C. glacialis,* although *Calanus* found in the region potentially come from several sources or origins.

A B S T R A C T

Observations from a single mooring site on the northern Chukchi Sea continental slope near the 1000-m isobath are presented. This site was occupied consecutively for three years (spanning September 2014–August 2017). Vertically the flow divides into three depth ranges: the upper ~200 m, ~200—~850 m and near-bottom flow. In the upper ~200 m, the mean flow was northwestward and strongest in the summer months. During winter months, currents decreased in magnitude, and in some years even reversed in direction. Satellite-tracked drifter trajectories (drogue depth ~30 m) show this along-slope flow persists at least from 156 to 165 °W, with an average velocity of ~17 cm s^{-1}. This northwestward flowing current is the Chukchi Slope Current. From ~250 m to ~850 m, the flow reversed; this weak flow is the Arctic-wide cyclonic boundary current advecting Atlantic Water. The mean flow at ~900 m is weak and on an annual time scale not significantly different from 0 cm s^{-1}. It consists of Arctic deep water. In the upper two layers, currents vary on the scale of days to seasons, with short-term reversals common. Currents below 40 m were not significantly correlated with local winds nor wind stress curl. We hypothesize that the northwestward flowing Chukchi Slope Current is a consequence of dynamics associated with the Beaufort Gyre.

1. Introduction

The Chukchi Sea consists of a broad shallow (<80 m) shelf, extending >800 km northward from its southern boundary at Bering Strait to the shelf break bounding the Arctic basin (Fig. 1). Approximately 1 x 10^6 m^3 s^{-1} (1 Sverdrup [Sv]) of Pacific water enters the shelf through Bering Strait (Woodgate et al., 2005a, 2012) and continues generally northward following the bathymetry (Woodgate et al., 2005b). Most of this flow exits the Chukchi Shelf through two canyons—Barrow Canyon in the east (Coachman et al., 1975; Weingartner et al., 2005) and Herald Canyon in the west (Coachman et al., 1975; Pickart et al., 2010). The flow exiting via Barrow Canyon is a combination of the northward flow through Central Channel that joins the coastal flow offshore of Icy Cape. Exiting Herald Canyon, there is a relatively narrow eastward flowing shelfbreak jet (Linders et al., 2017; Corlett and Pickart, 2017; Li et al., 2019).

As Pacific water transits the Chukchi Shelf northward, it is modified through local physical and biological processes. In summer, when sea-ice coverage is marginal or absent, water over the shallow Chukchi Shelf gains heat. A portion of this excess summer heat is advected north from the Bering Sea through Bering Strait (e.g., Woodgate et al., 2012), but the heat gained locally over the Chukchi Shelf through solar radiation can also be substantial (Tsukada et al., 2018). The modified shelf water then flows off the shelf and into the Canada Basin (Shimada et al., 2001; Steele et al., 2004; Watanabe et al., 2017; Fine et al., 2018) where it contributes to the observed accumulation of heat (Timmermans et al., 2014, 2018). Excess subsurface heat, as far west as the Chukchi Abyssal Plain (just to the west of the Chukchi Borderland), was recently identified to have a Pacific origin (Watanabe et al., 2017). Such subsurface heat anomalies can persist for years (Watanabe et al., 2017; Fine et al., 2018) and likely lead to delays in winter freeze-up and an overall decline of sea ice (Steele et al., 2008; Jackson et al., 2012; Timmermans, 2015; Serreze et al., 2016). The pathways of Pacific Water after exiting Barrow Canyon are not well known.

The basin in the vicinity of the Chukchi and Beaufort shelves is influenced by the anti-cyclonic Beaufort Gyre (Aagaard and Carmack, 1989; Regan et al., 2019), which dominates surface flow in the Canada Basin. Along the slope and beneath the Beaufort Gyre is the Arctic Ocean Boundary Current (AOBC; Woodgate et al., 2001), which moves Atlantic water cyclonically around the Arctic basin. The westward flowing Chukchi Slope Current (CSC) resides along the slope from Barrow Canyon to Herald Canyon (Corlett and Pickart, 2017; Stabeno et al., 2018; Li et al., 2019). The recently identified CSC appears to vary seasonally, with the strongest flow in the summer months and weak or even eastward flow dominating in the winter months. From earlier results, it appears to be confined to the upper ~300 m, with an eastward

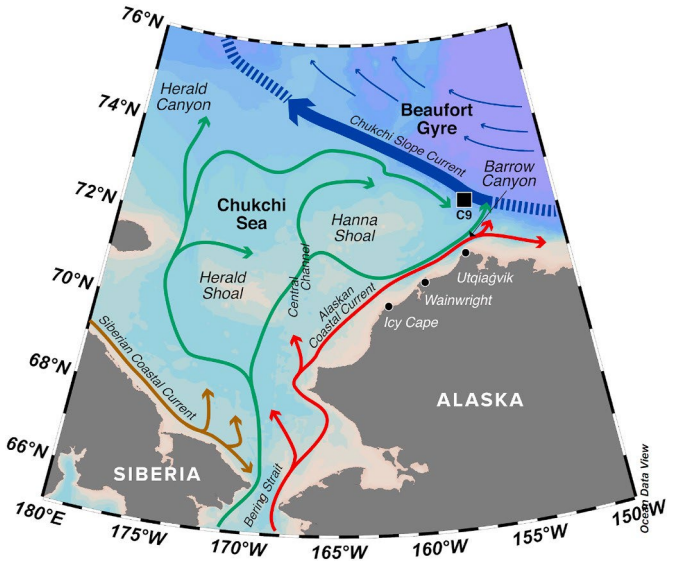

Fig. 1. Schematic map of surface flow patterns over the Chukchi Sea continental shelf and slope (adapted from Stabeno et al., 2018). The location of the C9 mooring, near the 1000-m isobath, is indicated with the black square.

reversal at deeper depths (Stabeno et al., 2018). Analysis by Corlett and Pickart (2017) indicates that it is baroclinically unstable and meanders along the slope. Satellite-tracked drifter trajectories show that the CSC extends from at least Barrow Canyon to near Herald Canyon (Stabeno et al., 2018). Watanabe et al. (2017) used observations and a high-resolution numerical ocean model to demonstrate that Pacific-origin heat gets transported in the CSC as far west as the Chukchi Borderland.

This paper concentrates on a 34-month time series of currents, temperature and salinity collected at a single mooring site on the Chukchi continental slope. A single mooring was deployed in each of three years (2014, 2015 and 2016) in the late summer, near the 1000-m isobath at a site (C9; 72.46°N, 156.55°W) north of Utqiag_ vik (previously Barrow), Alaska. The goal of these deployments was to better understand the flow along the slope and the fate of Chukchi Shelf water exiting Barrow Canyon. Data and handling methods are described in section 2. Results are presented in section 3, including: vertical structure and temporal variability of currents and temperature at C9, relationship of sea ice and winds to flow patterns, variability of Atlantic water and the strength of the AOBC. Section 4 provides a discussion of the results, summary and conclusions.

2. Data sources and methods

2.1. Atmospheric variables

Two different reanalysis products were considered in order to provide a comprehensive record of wind over our region of interest. The first is the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA5 reanalysis (https://climate.copernicus.eu/climate-reanalysis), which is the latest update to the ERA-Interim reanalysis (Dee et al., 2011). Like ERA-Interim, ERA5 solutions are based on a 4D-Var data assimilation routine, but the ERA5 model implements substantial improvements relative to ERA-Interim and includes hourly output at 31 km horizontal resolution (Haiden et al., 2017; Hersbach et al., 2018). At present, no thorough validation exists for ERA5 in the Alaskan Arctic, but we note that an Arctic-focused comparison of seven reanalysis products found that ERA-Interim was among the top-performing models for a number of key parameters (Lindsay et al., 2014). For 10-m winds, which is our focus, ERA-Interim had low biases of $\leq$0.5 m s^{-1} as well as the highest correlations ($\geq$0.85) among the seven different reanalysis models when compared to independent daily-averaged wind records measured from drifting ice stations (Lindsay et al., 2014). Belmonte Rivas and Stoffelen (2019) discuss improvements of ERA5 wind relative to ERA-Interim in comparisons with Advanced Scatterometer satellite wind on a global scale, including a 20% improvement in root mean square wind speed agreement, and reductions in divergence and curl biases; the Arctic, however, was not part of that analysis. Given the model and resolution improvements of ERA5 relative to ERA-Interim, we anticipate model skill that is at least on par with that of ERA-Interim in the Arctic.

The second reanalysis product that we considered is the National Center for Environmental Prediction (NCEP) North American Regional Reanalysis (NARR). It is an extension of the NCEP Global Reanalysis that is run over the North American Region with improvements in both resolution (~32 km) and accuracy (Mesinger et al., 2006). Stegall and Zhang (2012) reported moderate agreement between coastal land- and ocean-based wind observations in northern Alaska and the NARR winds, with correlations of 0.66 for speed and 0.71 for direction. NARR wind variance was close to observed wind variance, but NARR wind speeds were biased low (by as much as 2.5 m s^{-1}). Moore et al. (2008) and Renfrew et al. (2009) reported somewhat better performance in comparisons to buoy and aircraft measurements off southern Greenland (correlations of 0.88 for speed and $\geq$0.92 for direction with a ~1.5 m s^{-1} low bias). NARR data are available eight times daily from 1979 to present. Three-hourly winds at 10 m were obtained from the NOAA Earth System Research Laboratory, Physical Sciences Division in Boulder, Colorado, USA, from their website (https://www.esrl.noaa.gov/psd/).

For both reanalysis products, data spanning 2014–2017 were downloaded and then linearly interpolated onto desired locations or averaged over specific regions as discussed in the text. Because grid-scale noise is present in NARR wind, we first applied a two-dimensional Gaussian filter (standard deviation = 1; 5 grid points wide) to the spatial wind fields before calculating wind stress curl. We then re-gridded the smoothed NARR wind fields onto a regularly spaced 0.2° latitude by 0.6° longitude grid. Wind stress for both NARR and ERA5 was then estimated at each grid point following Large and Pond (1981), and wind stress curl was calculated using a centered-difference approach.

Comparisons with observed wind from the Barrow Atmospheric Baseline Observatory near Utqiag_ vik, Alaska, were also made. Hourly averaged meteorological data recorded at the Barrow Observatory were downloaded from the NOAA ESRL Global Monitoring Division website at https://www.esrl.noaa.gov/gmd/obop/brw/.

2.2. Sea ice

Sea-ice concentration data (2014–2017) used herein were the daily Version 3 Sea-Ice Concentrations from Nimbus-7 SMMR and DMSP SSM/I-SSMIS and were obtained from the National Snow and Ice Data Center (http://nsidc.org/data/nsidc-0079). These data are calculated using NASA's Earth Observing System AMSR-E bootstrap algorithm. Average ice concentrations in a 50 km × 50 km square around the mooring site (72.5°N, 156.5°W) were calculated.

2.3. Moorings

Moorings at C9 were deployed in three consecutive years (spanning September 2014–July 2017) in ~1000 m of water on the Chukchi continental slope northwest of Barrow Canyon (Fig. 1, Table 1). For reference, this site was ~9.8 km offshore of the seaward-most mooring (deployed during the previous year) discussed in Li et al. (2019). Because of the steepness of the slope and the interference of sea ice during deployment, actual C9 bottom depths ranged from 870 m to 970 m. The mooring design included three RCM current meters near ~900 m, ~600 m and ~300 m; an upward looking 75 kHz acoustic Doppler current profiler (ADCP) at a depth of ~300 m; and a Sea-Bird Electronics

Table 1
The duration of deployment, location and bottom depth are indicated in the first column. The instrumentation and depth of instruments are indicated in columns 2–4. MTR refers to miniature temperature recorders.

Deployment/ Recovery Info	Instrument	Measurement	Deployment Depth (m)	Comments
14C9	75 kHz ADCP	Currents	345	16-m bins

(SBE) Microcat near a depth of 400 m (actual instrument depths are listed in Table 1). Additional temperature sensors (miniature temperature recorders or MTRs, and SBE-37 which also measures conductivity) were added in the upper 300 m for the 2016 deployment. Data were collected at hourly intervals except for the ADCP deployed in 2014, which recorded data at 2 h intervals. All instruments were calibrated prior to deployment and data were processed according to manufacturers' specifications. Current meter time series were low-pass filtered with a 35 h, cosine-squared, tapered Lanczos filter to remove tidal and higher-frequency variability, and then resampled at 6 h intervals. Additional analyses were completed using other filters as described in the text (e.g., section 3.4.1). Final processed time series data are accurate to at least $\pm$0.002 °C, $\pm$0.0005 S/m and $\pm$0.5 cm s^{-1} (temperature, conductivity and currents, respectively).

Wavelet analysis was used to examine the dominant frequencies of the low-pass filtered current data. The wavelet function used here was the Morlet wavelet with non-dimensional frequency six, consisting of a sinusoid modulated by a Gaussian. The wavelet power spectra were normalized by the variance of each time series. The 95% significance levels were calculated by comparing each wavelet power spectrum to a red noise background spectrum, modeled as univariate lag-1 autoregressive (AR-1) processes generated with variance equal to that of each time series (Torrence and Compo, 1998).

2.4. Satellite-tracked drifters

From 2012 to 2018, the National Oceanographic and Atmospheric Administration's Ecosystem Fisheries Oceanographic Coordinated Investigations (EcoFOCI) program deployed 45 satellite-tracked drifters in the Chukchi Sea. Drifters were drogued at a depth of 25–35 m using a 10-m long "holey sock" drogue. Each drifter reported position and sea surface temperature via Argos approximately 14 times per day. Data were examined and spurious points were removed by inspection, as were data collected after drogues were lost (as indicated by a sensor), and after drifters grounded or entered into ice (determined from satellite maps of sea-ice extent). The resulting data were linearly interpolated to hourly intervals.

Lagrangian velocities were determined by centered differences using the hourly drifter positions. A low-pass filter (25-h running mean) was applied to the drifter location data. Spatially gridded mean velocities were then calculated following Stabeno and Reed (1994) and Stabeno et al. (2016b). In this analysis, each 2-day period within a grid area was considered an independent estimate. Each rectangular grid cell was 1° latitude by 3° longitude. In addition, three rhomboids of a similar size abutted the slope (Fig. 2).

2.5. Shipboard hydrography

In this paper, temperature and salinity data from a cruise aboard the R/V *Ocean Starr* in late summer 2017 are presented. Conductivity, temperature, depth (CTD) profiles were collected using a Sea-Bird Electronics (SBE) 911*plus* system with dual temperature, conductivity (for salinity) and oxygen (SBE-43) sensors, and single chlorophyll fluorescence (WET Labs WETStar WS3S) and photosynthetically active radiation (PAR; Biospherical Instruments QSP-200 L4S or QSP-2300) sensors. Data were recorded during the downcast, with a descent rate of

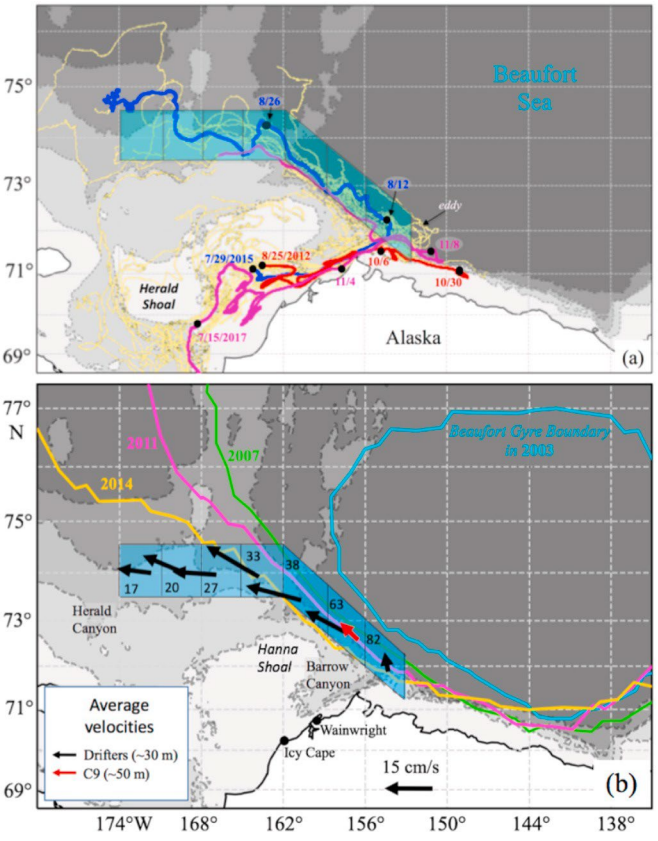

Fig. 2. (a) Drifter trajectories (drogue depth ~30 m). The yellow trajectories indicate drifters deployed in the region. Three pathways are shown in different colors: (1) eastward flow on the Beaufort Shelf (red); (2) first eastward flow and then northwestward flow (magenta); and (3) northwestward flow upon exiting Barrow Canyon (blue). Selected dates are indicated along each trajectory. (b) The position of the edge of the Beaufort Gyre during four different years (adapted from Regan et al., 2019, their Fig. 3). The mean Lagrangian velocity of the drifters in each box (black arrows), with the number of independent estimates that contributed to the mean (black numerals). The red arrow is the mean velocity at ~50 m from the three C9 mooring deployments. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

15 m min^{-1} to a depth of ~30 m, and 30 m min^{-1} at deeper depths. Salinity calibration samples were taken on approximately one-third of the 135 casts and analyzed on a laboratory salinometer. The bottle samples were then used to post-calibrate the CTD data.

In addition to the 2017 R/V *Ocean Starr* data, historical CTD profiles collected aboard a variety of other vessels that were seaward of the shelf-break, within 200 km of the C9 mooring location, and at least 400 m deep are used to describe mean water properties over the Chukchi continental slope. Those historical profiles were taken from the much larger accumulated data set provided by Corlett and Pickart (2017).

3. Results and discussion

3.1. Patterns of variability of flow in the Chukchi Slope Current

3.1.1. Spatial patterns of flow

Trajectories from satellite-tracked drifters (yellow lines Fig. 2a) provide information on general flow patterns during the ice-free season. Drifters deployed in the southern Chukchi Sea (south of 70°N), generally followed one of two trajectories, one northward through Central Channel and the other westward then turning northward through Herald Canyon. Most of the drifters did not enter onto Hanna nor Herald shoals (Fig. 2a). Stabeno et al. (2018) calculated that ~40% of the transport through Bering Strait exits through Barrow Canyon as part of the Alaskan Coastal Current (ACC). The ACC has a buoyant low salinity core, but similar to the Alaska Coastal Current in the Gulf of Alaska (Stabeno et al., 2004, Stabeno et al., 2016), it is wind driven and extends beyond the freshwater core. The strongest transport is in the summer when northward winds dominate the Chukchi Sea. Only about half of the drifters deployed in the Chukchi Sea exited the shelf. The remainder failed to reach the northern boundary before sea ice arrived or before the shifting winds weakened the northward flow. Strong wind-driven reversals are evident in the 2017 (magenta) trajectory (Fig. 2a). It must be noted that except for the low-salinity Alaskan Coastal Water, the water in the ACC is more saline and denser than the melt water that typically resides along the slope. When exiting Barrow Canyon, the ACC water sinks to ~40 m (Stabeno et al., 2018). Thus, once seaward of Barrow Canyon the drifters are not tracking shelf water.

Most of the drifters deployed over the eastern Chukchi continental shelf traveled northward through Central Channel and turned eastward south of Hanna Shoal (Fig. 2; Stabeno et al., 2018). This flow intensifies between Icy Cape and Wainwright into a narrow current (the ACC) that exits the shelf via Barrow Canyon (Stabeno et al., 2018). The trajectories of flow, once the drifters have exited Barrow Canyon, fall into three patterns (Fig. 2a): (1) a sharp westward turn and then continuing along the slope (blue); (2) an eastward turn for a short period (days) followed by a westward trajectory along the slope (magenta); and (3) eastward flow on the Beaufort shelf or along the shelf break (red). Of the 22 drifters that passed through Barrow Canyon, nine followed the first pathway and an equal number followed the second pathway traveling eastward for ~8 days (on average) before turning westward; only four followed the third pathway. The remainder of the 45 drifters that were deployed in the Chukchi Sea did not leave the shelf.

Of the satellite-tracked drifters that joined the westward flowing CSC, most continued northwestward along the slope until sea ice arrived. The remaining drifters ceased transmitting or lost their drogue before the arrival of sea ice. Mean Lagrangian velocities of all of the satellite-tracked drifters that transited along the continental slope were calculated as described in section 2.4, with an integral time scale of 48 h. Velocity was calculated in seven boxes (three rhomboids and four rectangles; Fig. 2). The outflow from Barrow Canyon dominates in the easternmost box. The velocity estimated in this box is biased, because all drifters were deployed on the shelf, so northward flow out of Barrow Canyon dominates the mean flow. The next three boxes (moving westward) all show a well-defined CSC (black arrows, Fig. 2b). Mean velocities from east to west were 14.9 $\pm$ 2.7 (mean $\pm$ standard error), 19.4 $\pm$ 2.5, and 17.3 $\pm$ 2.9 cm s^{-1}, respectively. Fewer drifters survived long enough to travel west of 165°W, and the velocities decreased from 14 $\pm$3.0 to 9.2 $\pm$ 1.6 cm s^{-1} in that region. The mean velocity (at 50 m) from the moorings (red arrow) was weaker than that calculated from the drifters for three reasons. Drogue depths were typically shallower than the uppermost ADCP bin; the Lagrangian velocities were primarily during the summer and early fall months (July–November) when the CSC is at its strongest; and the drifters only entered the CSC when the currents were westward.

The trajectories of drifters in the CSC were often characterized by meanders (wavelength ~100 km). Eddies also were apparent in two trajectories (one is illustrated in Fig. 2a) with radii of 25–50 km. The drifters remained near the slope in a ~70 km wide band, which is similar to the width of the CSC observed by Corlett and Pickart (2017).

It must be noted that the drifter trajectories reveal flow that is limited to the ice-free period. Once entering the ice field the drifters move with the sea ice. A few drifters transmitted locations sporadically during the winter, but most drifters caught in the sea ice were damaged and failed during winter or in spring/summer with the melting of the sea ice.

3.1.2. Temporal variability and vertical structure of flow at C9

Year-long deployments of each C9 mooring were made in late summer of 2014, 2015, and 2016, resulting in 34-month long velocity, temperature and salinity records at a variety of depths (Table 1; Figs. 3–5). During the first two deployments, sea ice arrived in the vicinity of C9 (50 km x 50 km box centered on the mooring site) in October and reached >80% areal ice cover within a month (Figs. 3 and 4, top panels). In the fall of 2016, sea ice arrived a month later in November, with >80% areal cover occurring ~3 weeks later (Fig. 5). Each year, the ice retreat began in June, with areal ice coverage falling below 20% from mid-July to early August.

The current meter records reveal a well-organized flow (Figs. 3–5). In the upper 100 m, the net direction ranged from 300 to 324° (Table 2), which is approximately the along-slope direction at C9. The principal axes were in a similar direction, indicating that most of the variance was also in the along-slope direction. Contours of monthly mean along-slope currents (toward 310°) reveal the mean structure of the surface-intensified CSC (Fig. 6a). During the warm months, the CSC extended to depths of approximately 200–250 m depending on the year, which is consistent with the mean geostrophic description constructed from historical hydrographic profiles by Corlett and Pickart (2017), the modeling results of Watanabe et al. (2017) and the results presented in Li et al. (2019). There was a strong seasonality in the flow, with northwestward flow most common in the warm season, and reversals occurring below 200 m in the cold seasons of 2015 and 2016. September through November of 2016 showed southeastward flow from the surface to at least 500 m (Figs. 5 and 6).

The current measurements deeper in the water column (>250 m) reveal the existence of an along-slope undercurrent that flows southeastward for at least part of the year (Figs. 3–5, Table 2). At C9, daily magnitudes of this southeastward flowing undercurrent were $\leq$10 cm s^{-1}. At ~300 m, there was a strong seasonality in the flow, with northwestward flow during spring shifting to southeastward flow in September 2015, June 2016 and July 2017 (Fig. 6b, solid line).

While the areal sea-ice concentration, and the flow in the upper 200 m and at 300 m all have annual signals, it is not clear that they are related. Depth-averaged flow in the upper 200 m ($V_{0\text{-}200}$) begins to increase before ice retreats in the summer and begins to weaken before the arrival of sea ice in the fall. The relationship between flow in the upper 200 m and at 300 m also appears to be somewhat out of phase, with northwestward flow at 300 m (Fig. 6b, solid line) tending to reverse just as the depth-averaged flow in the upper 200 m reaches its maximum.

On shorter time scales (days to weeks), variability, including flow reversals, was common in both the CSC and the flow below ~200 m (the AOBC; Figs. 3–5). The near-bottom (~900 m) flow was extremely weak during the first two deployments and not statistically different from 0

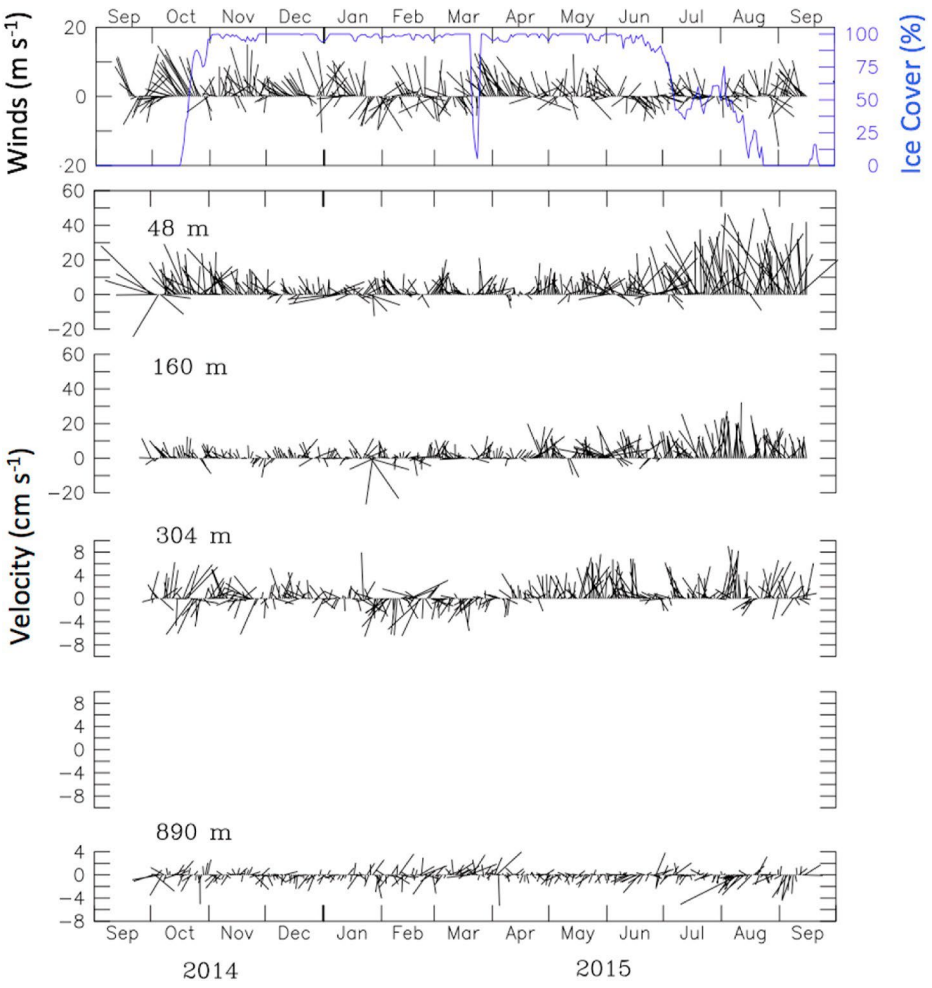

Fig. 3. (top panel) Daily ERA5 wind vectors interpolated onto the C9 mooring location and percent areal ice cover (blue) in a ~50 km x 50 km box centered on C9. (bottom panel) Low-pass filtered current velocities (daily) measured at C9 spanning September 2014–September 2015. The depths of each time series of currents are indicated. Both the wind and velocity were rotated 310° so that upward is approximately northwestward along the continental slope. Note the different velocity scales. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

cm s^{-1}. In the third deployment, the bottom instrument was almost 100 m shallower than during the first two years. During this last year, near-bottom currents were stronger and appeared to be related to the flow above (Fig. 5).

3.1.3. *Vertical variability*

To examine the vertical structure of the currents in more detail, we divide the time series into two parts—the warm (ice free) season (1 July – 31 October) and the cold (ice-covered) season (1 December – 31 May). During the warm season, currents in the upper 200 m were much stronger in 2015 than they were in either of the other years (Fig. 7a). During the cold season, the three years were all comparable (Fig. 7b). A comparison of average flows during the warm and cold seasons shows that currents in the upper 200 m were stronger in the warm season compared to the cold season, as were the reversals below 300 m (Fig. 7c). Reversals were evident below 300 m in the warm season. During the cold season, average currents below 300 m were weak and were not significantly different from zero.

The currents fall into three vertical groups: (1) 0–200 m; (2) 200–850 m; and (3) below 850 m (Fig. 8). Currents in the upper 200 m were well correlated and in phase during each deployment, and the rotation between different depths was near zero. The second vertical group was also in phase and well correlated, with a slightly larger angle of rotation among depths. Currents in groups 1 and 2 were significantly correlated at zero lag, but with a rotation angle of 15–30°. The final group consists of the bottom instrument in the first two deployments. Here the correlations between group 3 and the other two groups were weak, with significant correlation largely limited to group 2. Perhaps more importantly, there was significant rotation of ~140° counter-clockwise and a lag of 2 days between the currents at ~900 m and those at depths >200 m. The third deployment was approximately 70–100 m shallower than the other two deployments and the bottom two depths were significantly, albeit weakly, correlated and in phase with group 2.

This same vertical pattern appears in the empirical orthogonal functions (EOFs) of the along slope component (along 310°) of the time series for each deployment (Fig. 9). There were two significant modes, EOF1 and EOF2. EOF1 accounted for 69%, 51% and 62% of the variability in the 2014, 2015 and 2016 deployments, respectively, and EOF2 accounted for 17%, 33% and 22% of the variability in the 2014, 2015 and 2016 deployments, respectively. EOF1 represents the upper ~250 m of the water column, and EOF2 represents the flow patterns between ~250 and ~850 m. The bottom time series of the 2014 and 2015 deployments were not represented in neither EOF1 nor EOF2 and appeared as a mode by itself that was not statistically significant.

3.2. *Temperature and salinity at the mooring site*

Several water types are recognized on the Chukchi Shelf (Coachman et al., 1975; Gong and Pickart, 2016; Corlett and Pickart, 2017) and are indicated in Fig. 10a. Melt water (MW) results from melting ice earlier in summer. The source of fresh, relatively warm Alaskan Coastal Water (ACW), and the colder more saline Bering Sea Water (BSW) originates in the Bering Sea, entering the Chukchi Sea through Bering Strait. The cold, saline Winter Water (WW) forms locally through cooling and brine rejection during the previous winter. Remnant Winter Water (RWW)

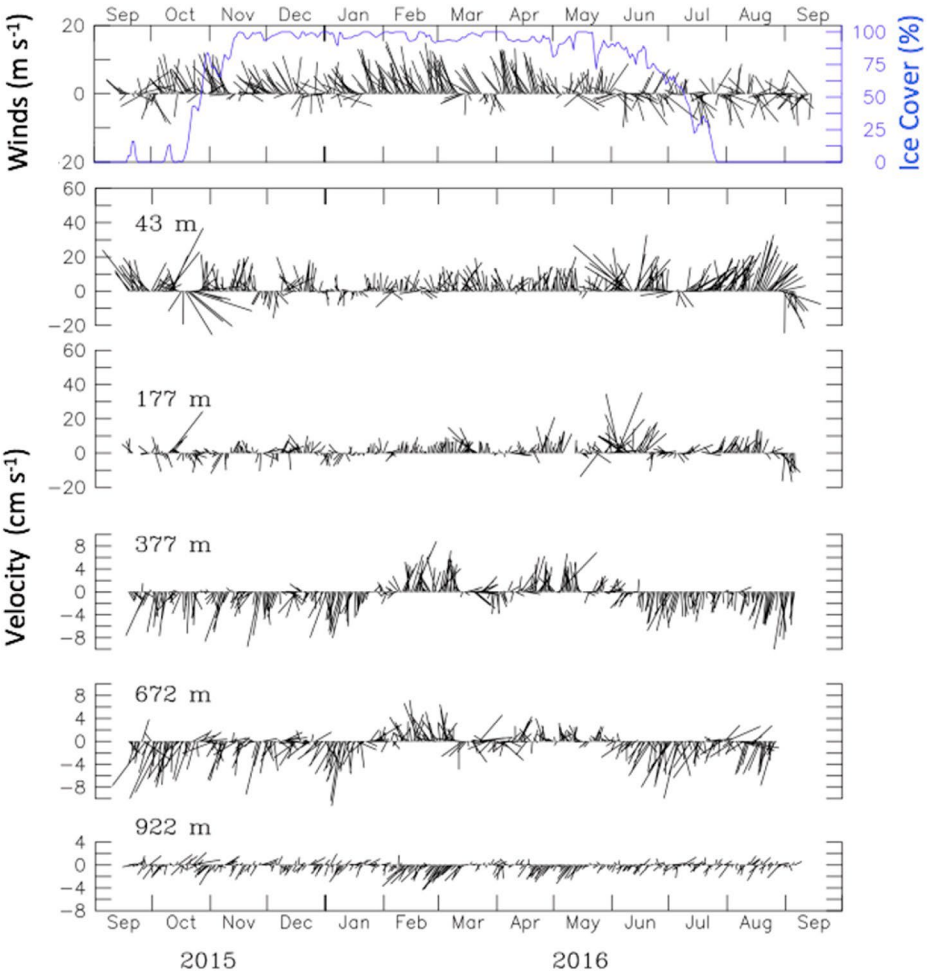

Fig. 4. Same as Fig. 3 except for September 2015–September 2016.

forms as WW warms through heating and mixing processes in the Chukchi Sea. Finally, the relatively warm and saline Atlantic Water (AW) originates in the Atlantic, as its name suggests, flowing cyclonically around the Arctic basin and, occasionally, flows onto the Chukchi Shelf via Barrow Canyon (Bourke and Paquette, 1976; Ladd et al., 2016; Wood et al., 2018; Pisareva et al., 2019).

The C9 data at 45 m in 2016 showed large variability in temperature and salinity, indicating multiple water types (MW, RWW, BSW; cyan dots, Fig. 10a). Salinity varies from <30 to >32, with the least saline water occurring in early December, almost a month after the arrival of sea ice (Fig. 11a), and likely is the result of local ice melt. So, it was not surprising that the water type for this least saline, cold (<-1 ℃) water is categorized as MW (Fig. 10a).

While measurements of salinity were limited to a few depths, in the 2016–2017 deployment 11 temperature sensors were distributed between 45 m and 460 m (Fig. 11b). In the upper 100 m, temperature ranges from −1.8 °C in winter to 3.5 °C in July 2017 after ice retreat (Fig. 10a). Between 100 m and 200 m, there was a band of relatively cold (approximately −1 °C) water. At ~200 m, the temperature begins to increase from approximately −1 °C reaching 0 °C at 258 m ± 10 m (average ± standard deviation) and continuing to warm to a depth of ~400 m. This relatively warm, saline (~0.5 °C, 34.8; Fig. 10b) water below 200 m is Atlantic Water (AW).

Atlantic Water generally inhabits intermediate depths (200–1000 m) over the continental slope in the western Arctic (Corlett and Pickart, 2017). AW contains a large amount of heat (enough to melt all the ice in the Arctic, if it came into direct contact with sea ice; Polyakov et al., 2017). At the C9 location the core of this water mass, with maximum subsurface temperature ~0.65 °C (0.57–0.80 °C) and practical salinities in the range of 34.73–34.86, was consistently found near a depth of 400 m (Fig. 10b) as expected from the historical data (Fig. 10 c–d). The C9 instrument depths varied from 345 m to 460 m dependent upon the year. The 2016 deployment was the deepest (~460 m), and the 2014 deployment was shallowest (~345 m), with the 2015 deployment falling in between (~382 m). All three time series were near the relative maximum in temperature of AW, and varied as expected along the long-term temperature-salinity line. The greatest variability was in the 2014 deployment, which was at the upper edge of the depth of the local temperature maximum. The least variability was at 460 m, while the two shallower instruments showed periods of colder temperatures.

3.3. Temporal variability in the depth of Atlantic Water

To examine the temporal variability in the depth of the warmer Atlantic Water, we chose the 0 °C isotherm (Fig. 11b). There was insufficient vertical instrumentation near 350 m, where the relative maximum of temperature occurs and the water column at the relative minimum (depth <200 m) is influenced by surface processes. The character of the isotherm varies in time. From September through March, there was much higher variability in the depth of the 0° isotherm than later during April–July. This coincides with the variability of the currents (Fig. 5, bottom). At depths shallower than 170 m, prior to mid-March, the currents were highly variable and largely southeastward. This transition was not related to sea-ice cover, since sea-ice cover was extensive (>90%) from mid-January through April (Fig. 5, top).

There are two sharp increases in the depth of the 0 °C isotherm, one

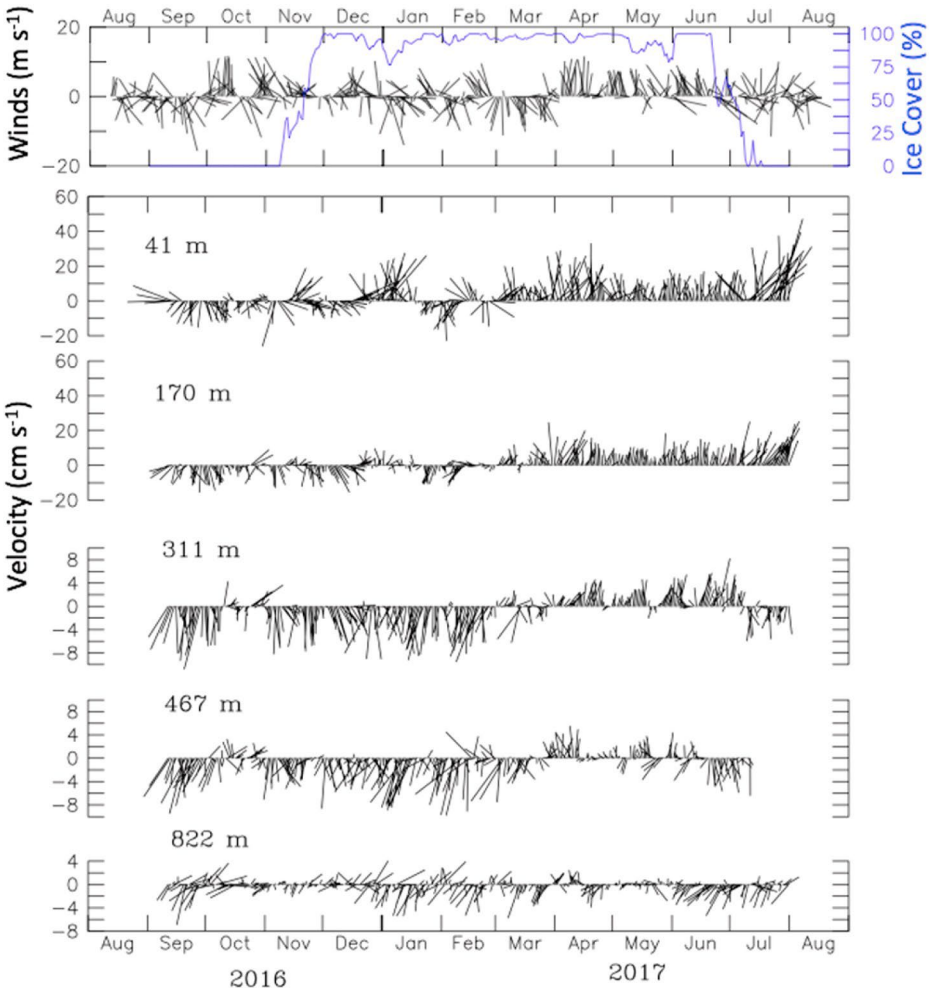

Fig. 5. Same as Fig. 3 except for September 2016–August 2017.

Table 2
Velocity statistics at selected depths distributed through the water column. Maximum speed was calculated from the hourly velocities, while net speed and principal axis were calculated from the low-pass filtered data (35-hr Lanczos).

Mooring	Depth (m)	Maximum Speed (cm s^{-1})	Net speed (Direction) (cm s^{-1} [°])	Prin. Axis (% var) (° [%])
14C9	48	72.1	10.6 (300)	302 (62)
	96	59.1	9.5 (302)	298 (62)
	192	31.1	3.4 (306)	320 (66)
	304	11.5	1.0 (291)	318 (75)
	895	11.4	0.5 (159)	359 (75)
15C9	35	58.6	8.0 (320)	306 (56)
	99	57.8	5.2 (327)	312 (58)
	195	35.9	1.7 (335)	318 (69)
	299	21.6	1.2 (129)	323 (79)
	672	17.0	1.4 (148)	330 (73)
	922	9.1	0.7 (160)	358 (75)
16C9	41	54.5	6.1 (324)	322 (70)
	105	48.7	4.7 (322)	320 (68)
	201	23.1	0.8 (10)	321 (75)
	265	17.4	1.6 (124)	320 (80)
	467	13.2	1.9 (148)	322 (77)
	822	14.4	0.8 (156)	319 (82)

in late October and the second in late December (Fig. 11b). The first event was during a period of no ice and the second during extensive ice cover. Both events had temporal scales consistent with those of longitudinal waves (3–5-day periods; Fig. 12). Interestingly, the greatest depth of the 0° isotherm in October (on the 24th) occurred when the currents were northwestward and the greatest depth of the 0° isotherm in December (on the 27th) occurred when currents were southeastward, but both were during a period of maximum wave amplitude (~20 cm s^{-1}).

Energy in the 3–5 day band is fairly common in the along slope currents at ~240 m (Fig. 13b). It does not appear to be strongly related to the presence of sea ice nor to variations in the winds. At periods >12 days there are only a couple of events in the fall of 2015 and 2016 with significant energy. In contrast, the spectra of the depth-averaged along-slope currents in the upper 200 m appears to be more energetic when sea-ice concentrations are <85% areal coverage (Fig. 13a). There are several periods (e.g. late March 2015) when a sharp decrease in sea ice is associated with an increase in energy at 1–5 days. There also is more energy in the 10- to 20-day band, but once again no significant peaks in energy are present at lower frequencies.

3.4. Forcing mechanisms

3.4.1. Wind

Given the lack of buoy measurements of wind in the Chukchi-Beaufort region, the ECMWF ERA5 reanalysis product was chosen for our analysis. While we also evaluated the NCEP NARR reanalysis,

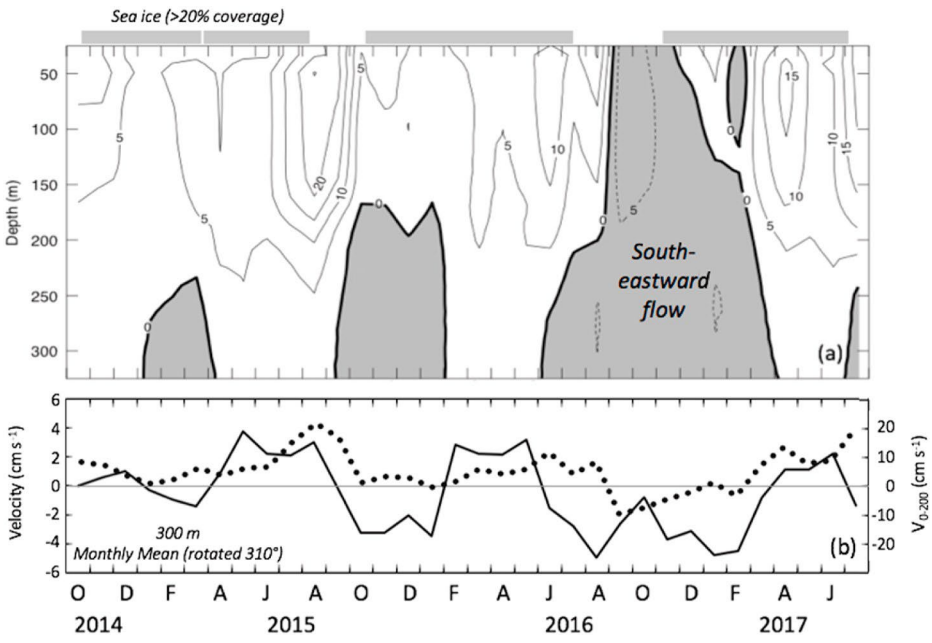

Fig. 6. (a) Contours of monthly mean currents (rotated 310°) measured by the three ADCPs deployed at C9. Positive is approximately northwestward. At the top is the areal sea-ice cover (>20%) in the vicinity of C9. The shaded region represents negative (nominally southeastward) flow. (b) Monthly mean currents at ~300 m (solid line) and depth-averaged velocity, $V_{0\text{-}200}$, in the upper 200 m (dotted line). Positive is northwestward.

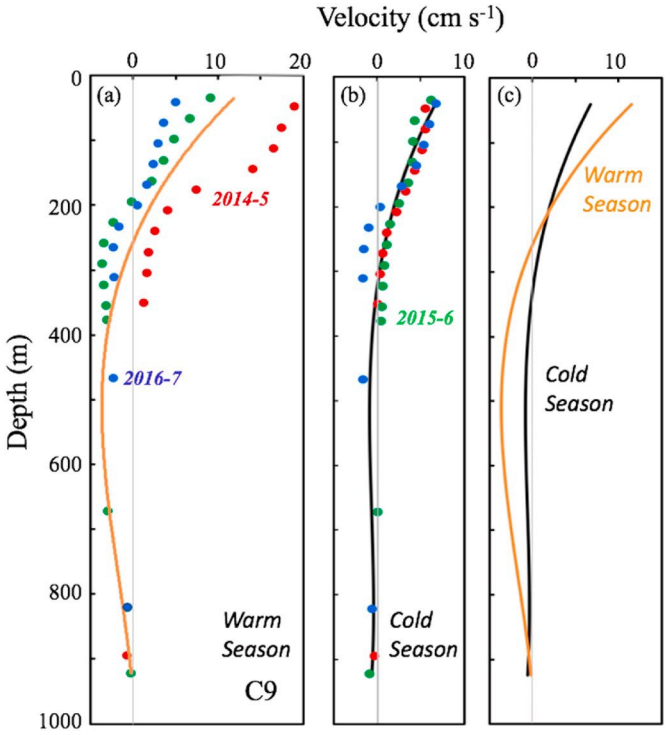

Fig. 7. Mean alongshore flow in (a) the warm season, 1 July – 31 October, and (b) the cold season, 1 December – 31 May. Positive is approximately northwestward (310°). Colored dots represent averages for different deployment years (2014 is red, 2015 is green, 2016 is blue). Solid lines in (a) and (b) represent 3-year seasonal means and are least squares fits of a third-degree polynomial. (c) The 3-year seasonal means are shown separately to facilitate comparison. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

comparisons with observed wind from the Barrow Atmospheric Baseline Observatory near Utqiag_ vik, Alaska, indicated that ERA5 more faithfully reproduced the observations. Zero-lag correlation coefficients for the east-west (north-south) components of 10-m winds spanning the 2014–2017 C9 record were r = 0.96 (0.85) for ERA5 compared to 0.90 (0.70) for NARR. Complex (vector) correlations were r = 0.94 with a 4° clockwise rotation for ERA5 wind compared to observed wind, while NARR wind had r = 0.89 with a 17° clockwise rotation relative to the Barrow observations. As is discussed later, the use of a reanalysis product such as ERA5 further allows for an examination of the spatial structure of the wind field.

We attempted a number of different lagged correlation analyses between both observed and ERA5 winds and the along-slope currents measured at the C9 mooring. For simplicity, we first chose to use currents from the shallowest ADCP bin (52 m, 36 m and 44 m depth for the 2014, 2015 and 2016 deployments, respectively). Correlations between year-long records of low-pass filtered 10-m ERA5 wind interpolated to the C9 location and the low-pass filtered near-surface along-slope current were poor, even when the current was lagged relative to the wind. The highest correlation coefficient (r = 0.36 at zero lag for the cross-slope wind component) was in 2015. This was the year with the shallowest (36 m) current data. Using observed wind or wind stress from the Barrow observatory did not markedly improve the wind-current correlations. Similarly, when we restricted the analysis to the largely ice-free summer season (or conversely to the ice-covered winter season), wind-current correlations remained poor or not significant, despite the ice-free periods generally resulting in stronger relationships. The highest correlation coefficient during an ice-free period was r = 0.46 for the along-slope wind in fall 2014. Correlations between near-surface currents at C9 and remote ERA5 winds at selected sites (e.g. in the East Siberian Sea as suggested by Danielson et al., 2014; Peralta-Ferriz and Woodgate, 2017) were generally lower than with local winds, even with lags.

We next examined wind-current correlations using successively low-frequency filters (5, 10, 15 and 30 day Hanning windows) for both the observed wind and along-slope current records. Again, highest correlations were in 2015, but the values remained low (e.g. r = 0.42 for the cross-slope component of wind with a 15-day Hanning filter applied).

Fig. 8. Complex correlations (below diagonal) and correlation angles (above diagonal) for currents for each of the three mooring deployments: (top) 2014 with 1350 data points; (middle) 2015 with 1372 data points; and (bottom) 2016 with 1200 data points. Instrument depths are in meters. The correlations are color coded from dark (high) to light (low) correlations. Shaded correlations are significant at $p < 0.01$. All lags are zero except for the 922-m record in 2014–15, and the 894-m record in 2015–16. For both of those deployments the deep current record lags the shallower records by 2 days. Divisions into three vertical groups are indicated at the left. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

Unsurprisingly, correlations between ERA5 wind and the 200-m depth-averaged along-slope current, $V_{0\text{-}200}$, over the entire 3-year record (also using 5, 10, 15 and 30-day Hanning window filters) were also poor. Thus, near-surface along-slope flows at C9 do not appear to be significantly correlated with local wind nor with ERA5 wind at select remote sites.

There are specific events, however, in the C9 200-m depth average current record, $V_{0\text{-}200}$, that appear to be in response to local wind forcing (Fig. 14c). For example, the onset of a period of sustained southeastward along-slope flow in September 2016 begins during a reasonably strong southeastward wind event (Fig. 14). Interestingly, such strong along-slope wind events are somewhat rare in the 3-year record, with the September 2016 event being the strongest during an ice-free period. Similarly, the enhancement of northwestward slope flows in April 2017 may be related to the northwestward component of winds at that time. Recall that it is evident from the wavelet analysis (Fig. 13a) that more energy is found in the currents (2–10 day band; 0–200 m average) when areal ice concentrations are <85% and wind can directly force the ocean surface. April through June 2017 was a period of relatively sustained upwelling favorable winds (Fig. 5, top) with corresponding low variability in the depth of 0° isotherm (as mentioned in the previous section; Fig. 11b) and a period of reduced 3–5 day energy in the currents (Fig. 13a). During this time, correlation between the winds and depth of 0° isotherm were significant ($r = 0.48$, $p < 0.01$) with the isotherm depth lagging the winds by 1 day with a decrease in depth of 1.8 m per 1 m s^{-1} increase in wind toward 310° (approximately northwestward). The winds were not well correlated ($r = 0.22$, $p > 0.10$) with the depth of the 0° isotherm for the first part of the record (September 2016–February 2017). We note that Li et al. (2019) also found no correlation between local wind forcing and upwelling events on the Chukchi continental slope at their nearby array site. Watanabe et al. (2017) similarly noted the lack of correspondence between local winds and the current flowing west along the Chukchi Slope in their model.

To briefly summarize, although more synoptic energy (2–10 day

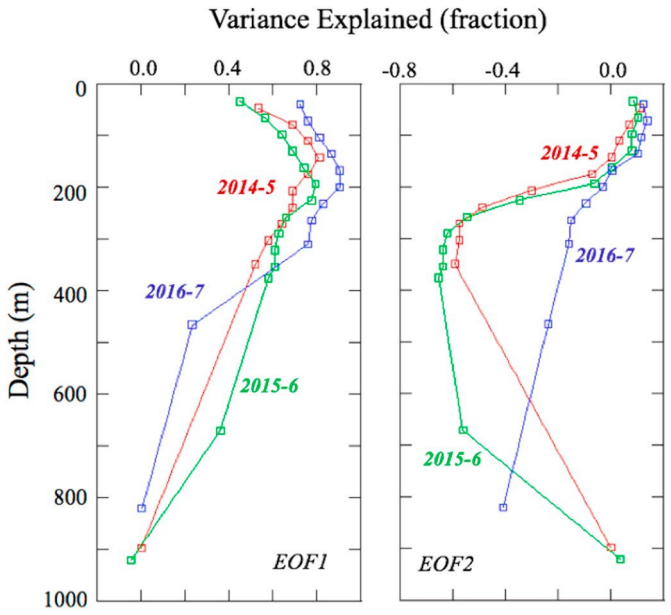

Fig. 9. The first two EOF modes of variability of the along-shelf flow (rotation of 310°) colored by deployment year. The time series were normalized by their respective standard deviations. (a) The fraction of the variance of each time series represented by the first EOF mode (EOF1). (b) The fraction of the variance of each time series represented by the second EOF mode (EOF2). Note that a negative fraction indicates negative correlations between the EOF mode and the time series and positive indicates a positive correlation.

band) is found in the upper water column currents during ice-free periods, on average, local wind does not appear to exert a primary influence on the upper water column along-slope current at the C9 site. Evidence suggests that particularly strong wind events may enhance upper water column currents over the slope, consistent with the findings of Corlett and Pickart (2017). For at least a portion of the C9 data record in 2017, wind influences were instead more readily observed in variation of the depth of the 0° isotherm.

3.4.2. Wind stress curl

Because the C9 mooring was located >100 km from shore, it is unlikely that coastal divergence of surface Ekman transport would be an important mechanism there. Wind stress curl, however, could lead to transport divergence or convergence that, in turn, could drive flow along the continental slope. Using composite averages over multiple northwestward flow events, Li et al. (2019) showed relationships between strong along-slope flows and the wind stress curl averaged over a region of the northeast Chukchi Shelf, suggesting that wind stress curl is a primary forcing agent for strong and weak states of the CSC. Although such extreme states comprised only ~23% of their record, their dominant EOF mode appeared to reflect that variability, suggesting it may be important.

To investigate whether or not wind stress curl impacts currents at C9, we plotted the time variation of mean wind stress curl calculated over a similar portion of the northeast Chukchi Sea shelf (as in Li et al., 2019, Fig. 14a) and compared it with the upper 200-m depth-averaged along-slope current, $V_{0\text{-}200}$, (Fig. 14 d,g). A few characteristics stand out. First, wind stress curl averaged over the northeast Chukchi Shelf is highly variable, often changing sign in as little as three days. On average, the mean wind stress curl is negative, although a few positive events are apparent such as in August 2015, February 2016, and January 2017. Negative wind stress curl over the northeast Chukchi Shelf would lead to flow convergence and geostrophic sea level set-up. Interestingly, high sea level over the shelf (relative to sea level offshore) would tend to force southeastward along-shelf/slope flow, which is opposite to the mean northwestward flow observed at the C9 location (Fig. 14g) and as previously observed for the CSC (Corlett and Pickart, 2017; Stabeno et al., 2018; Li et al., 2019). Thus, on average, it does not appear that the mean wind stress curl over the northeast Chukchi Shelf is itself adequate to explain the observed northwestward flowing CSC at the C9 site. Still, as with some of the wind events described earlier, and in agreement with Li et al. (2019), there is a suggestion of a relationship between portions of the wind stress curl record and the mean along slope currents. For instance, the current decreases and briefly turns southeastward in October and December 2015 when the wind stress curl is strongly negative. Similarly, the current increases to the northwest in early January 2017 when the wind stress curl is significantly positive. Other

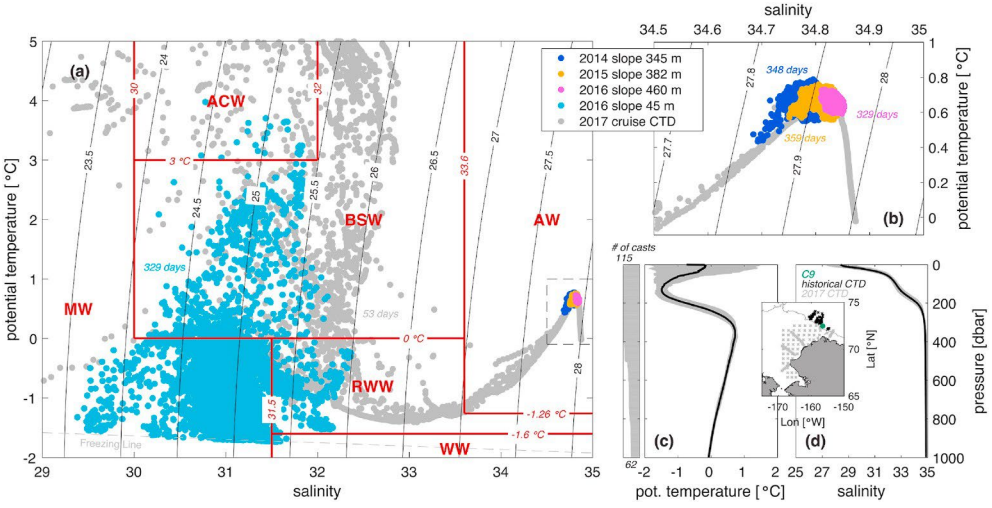

Fig. 10. (a) Potential temperature–salinity diagram, with potential density contours in black, for the Chukchi Shelf and continental slope. Red lines indicate nominal water mass boundaries (after Corlett and Pickart, 2017), and include: melt water (MW), Alaskan Coastal Water (ACW), Bering Sea Water (BSW), Winter Water (WW), Remnant Winter Water (RWW) and Atlantic Water (AW). Hydrographic data from a summer 2017 cruise are shown (gray) for context, with data (45 m) at C9 in 2016–2017 (cyan). Three years of moored data near the core depth of the AW are colored by deployment year, which is expanded in (b). The mean (c) potential temperature and (d) salinity profiles near the C9 location from historical profiles are drawn in black; gray shading represents the standard deviation. The number of profiles used to construct the means is shown to the left of (c). The inset map shows the locations of: C9 (green); the 2017 cruise data (gray) used in (a) and (b); and the historical profiles (black) used to calculate (c) and (d). (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

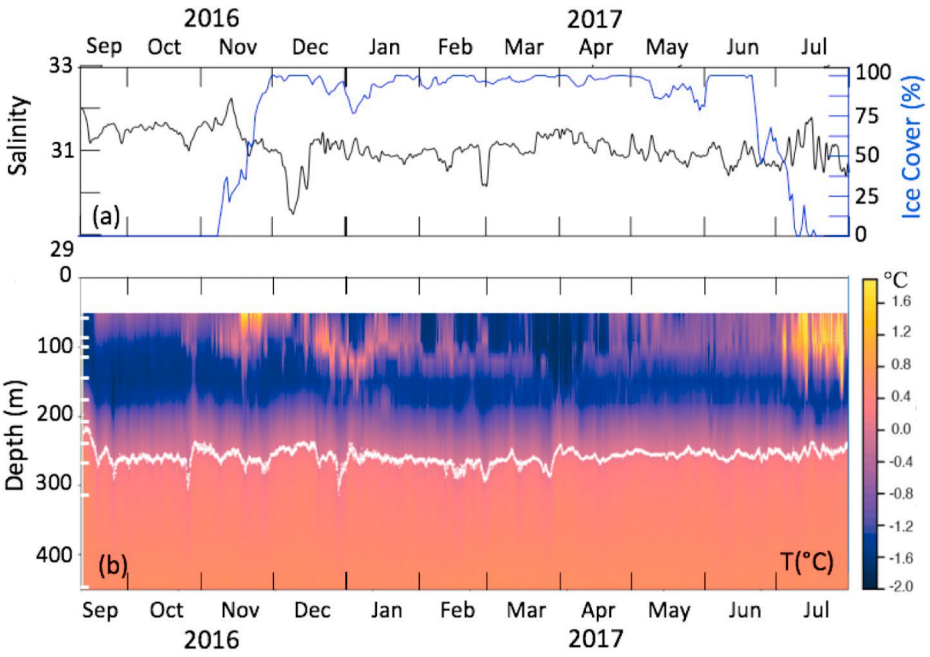

Fig. 11. (a) Time series of salinity at 45 m (black) and the daily percent ice cover (blue) in a 50 km x 50 km box centered at C9. (b) Contours of temperature at the C9 mooring spanning 50–450 m depth from September 2016 to July 2017 (color). Depth of the 0° isotherm is overlaid (white contour). Instrument depths are indicated by the white bars at the left. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

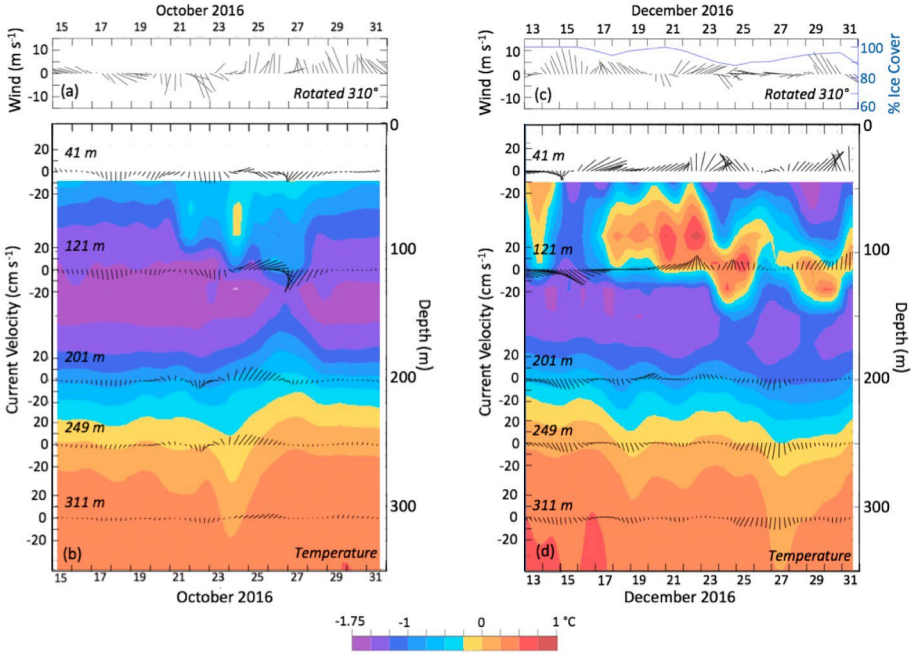

Fig. 12. (a) ERA5 winds at C9, and (b) contours of ocean temperature (color) and current velocity (vectors) at indicated depths during 15–31 October 2016. No ice was near C9 in October. (c) As in (a) during 13–31 December 2016, with percent ice cover indicated in blue. (d) As in (b) except for 13–31 December 2016. The currents are low pass filtered and rotated 310° (upward is approximately northwestward) and ice is percent cover in the 50 km x 50 km box centered on C9. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

events exist, however, that defy such a simple one-to-one explanation. The strengthening of the current in July 2015, a time when the wind stress curl over the northeast Chukchi Shelf was in opposition, is not clearly explained by shelf-average curl. Also, the positive current events spanning June–August 2016 do not appear to be related to wind stress curl over the shelf.

An examination of monthly averaged spatial patterns of wind and wind stress curl throughout the region suggests the possibility of large gradients in wind stress curl near the Chukchi continental slope (not shown); in some cases, positive/negative wind stress curl over the shelf was accompanied by negative/positive wind stress curl offshore. Thus, the induced across-slope geostrophic sea level gradient could potentially be enhanced or diminished as a result of changes in the sign of the wind stress curl across the continental slope. To test this possibility, we averaged wind stress curl over two adjacent boxes: one including a small region of the Chukchi Shelf west of Barrow Canyon parallel to the continental slope, and the other immediately offshelf including the continental slope (Fig. 14a). The difference in mean wind stress curl over these two boxes (shelf value – offshelf value) is illustrated in Fig. 14e. The mean wind stress curl difference is negative, meaning that the wind stress curl induced geostrophic sea level in the offshore box is higher than that over the shelf box (ignoring any otherwise pre-existing shelf-

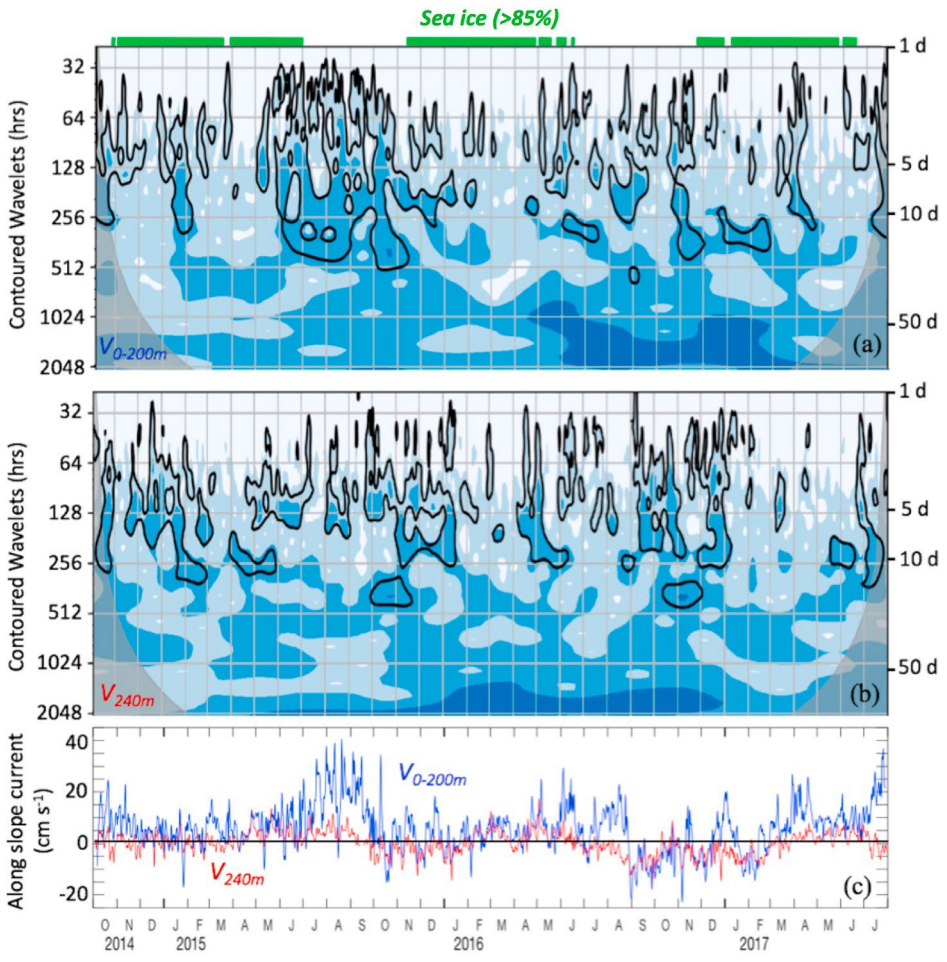

Fig. 13. Wavelet analysis for (a) along slope (rotated 310°), depth average (0–200 m) flow at C9, and (b) along-slope flow at ~240 m for October 2014–July 2017. The blue-shaded contours are quartiles. Closed black contours denote peaks of significant energy. Areal sea-ice concentration (>85%) in a 50 km x 50 km box centered on C9 is indicated in green above (a). (c) Time series used to create (a) and (b) are shown. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

slope sea level gradient), a condition that would favor the northwestward flowing CSC. There is also the suggestion of correspondence between events in the wind stress curl difference and the mean along slope currents. For example, the along-slope current is strong from August through September 2015 when the curl difference is favorable, and then decreases as the curl difference changes sign in late September 2015. A similar series of events occurred during fall 2016. Nevertheless, correlation between the shelf-offshelf curl difference and the 200-m depth-averaged current remains poor over the entire record, even when considering low-pass filtered time series (Fig. 14e, g).

3.4.3. The Beaufort Gyre

The Beaufort Gyre (BG) is a relatively shallow (~250 m), anticyclonic circulation that dominates the Canadian Basin and is driven by the Beaufort Sea High pressure system (e.g. Giles et al., 2012; Moore, 2012). The low salinity (<30) core of the BG sits above more saline Atlantic Water. It is of interest that the depth of the BG along its edge shoals to ~200 m (Doddridge et al., 2019; see their Fig. 1), which is the depth between our observed current groups 1 and 2 discussed in section 3.1.3. The size and strength of the gyre varies on seasonal through interannual time scales. Using sea surface height data from satellite altimetry during the period 2003–2014, the area of gyre and its strength were greatest in the fall and smallest in the summer (Regan et al., 2019). In addition, the size and strength of the BG increased during this time period. Although care must be taken in interpreting dynamic ocean topography near shore and complex bathymetry, it is noteworthy that the edge of the gyre extends in recent years along the continental slope from 130°W westward to the Chukchi Borderland (Fig. 2b).

The location of C9 is at the southern edge of the BG, so it could be argued that the currents measured at C9 are likely related to the BG. The largest slope of dynamic ocean topography is in the region of C9 westward to the Chukchi Borderland (Regan et al., 2019; see their Figs. 4 and 5), where the outer edge of the gyre crosses lines of latitude. This is reminiscent of a western boundary current. Here the bathymetry of the shelf crosses lines of latitude effectively reducing the strength of β, the rate of change of the Coriolis parameter (f) with latitude, to ~20% of its value at a latitude of 45°. Yang et al. (2016) suggest that even though β is small at these latitudes a western boundary current could be supported. Since the BG is driven by the large-scale wind stress curl it is possible that variability in upper 200-m depth-averaged current at C9 would also be related to variability in the basin-scale wind stress curl. A time series of wind stress curl averaged over the Canada Basin is illustrated in Fig. 14f. As with other wind metrics, correlation of this low-pass filtered quantity with low-pass filtered currents was poor ($r = 0.12$ at 37-day lag with a 30-day Hanning filter applied). We also attempted to correlate the currents with running cumulative sums of basin-averaged curl (e.g. summations over 60 days and 90 days), but this too gave similarly poor results.

3.4.4. The Alaskan Coastal Current exiting Barrow Canyon

Using both an idealized model and the year-long moored array observations of Li et al. (2019), Spall et al. (2018) found a relationship between flow in Barrow Canyon and the CSC, with monthly-averaged CSC transport lagging the transport through Barrow Canyon by roughly 2–3 months. Using the Barrow Canyon transport and velocities measured at C9, our results are more ambiguous.

The mean northeastward flow out of Barrow Canyon is ~0.5 Sv (Itoh et al., 2013; Stabeno et al., 2018), with a seasonal signal. The monthly

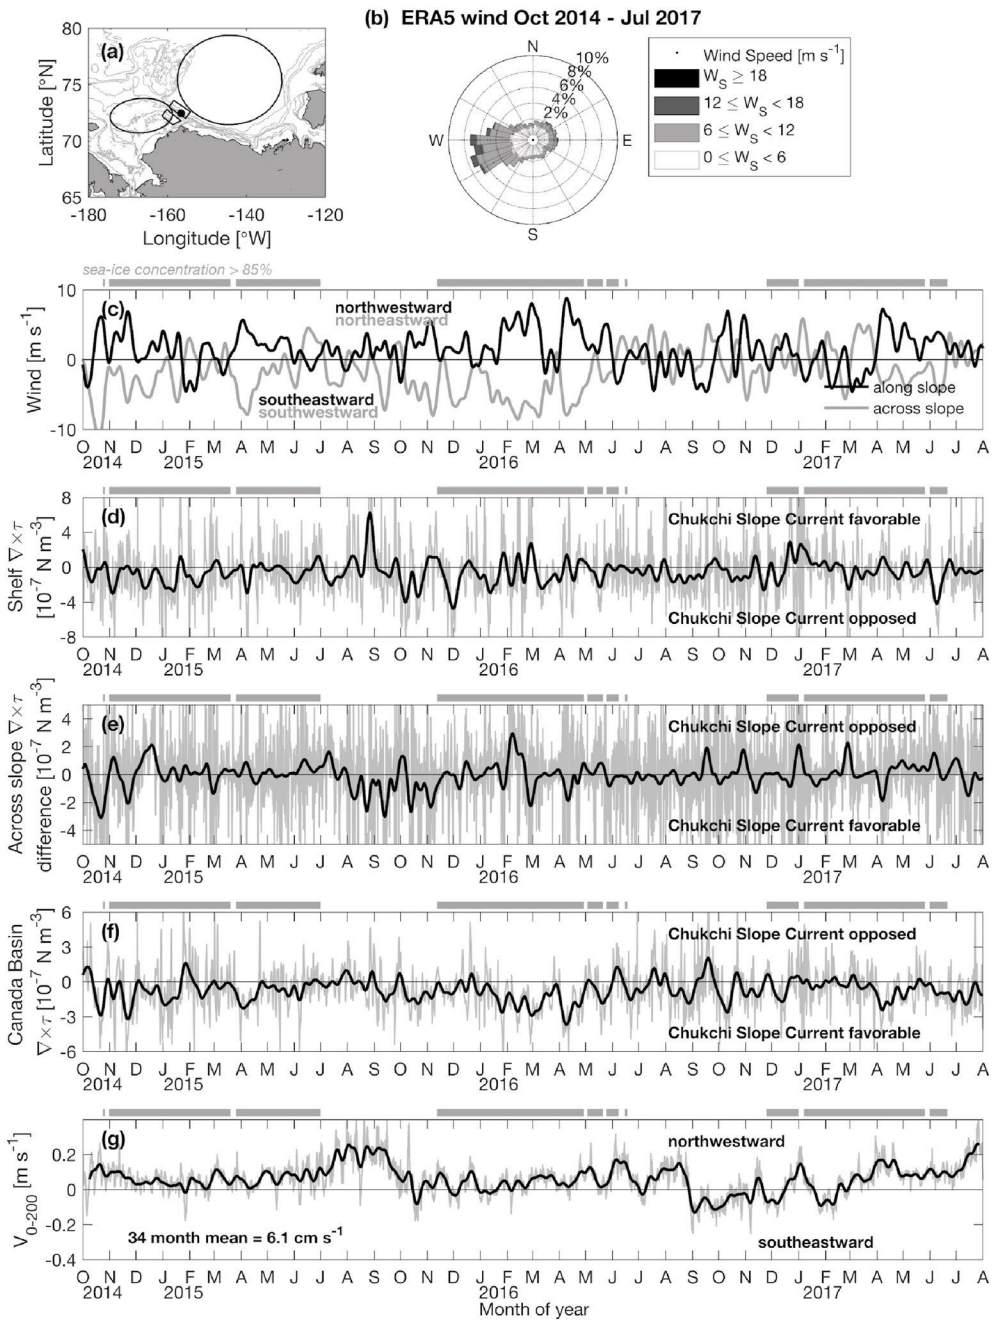

Fig. 14. (a) Map of the Chukchi Sea with the location of the C9 mooring (black dot) and the regions over which wind and wind stress curl were averaged. (b) Histogram of hourly 10-m ERA5 wind averaged over the offshore rectangle encompassing C9 in (a). Wind blows toward the direction indicated. (c) Along- and across-slope components of 10-m ERA5 winds (rotated 310°). Values were averaged over the offshore box encompassing C9 as shown in (a) and low-pass filtered with a 15.5 day Hanning window. (d) Wind stress curl (gray) calculated from the hourly ERA5 winds averaged over the ellipse spanning the northeast Chukchi Sea in (a), and low-pass filtered with a 15.5 day Hanning window (black). (e) Across slope difference of wind stress curl, as a proxy for an across slope sea-surface deformation, calculated from averages over the offshore and shelf boxes in (a). The hourly ERA5 data are gray and the 15.5-day Hanning window filtered time series is black. (f) ERA5 wind stress curl averaged over the Canada Basin as indicated by the large black circle in (a). Hourly values are gray and the 15.5-day Hanning window filtered values are black. (g) The upper 200 m depth average along-slope current measured by the C9 mooring (hourly values - gray, 15.5-day Hanning window filtered values - black).

mean transports in Stabeno et al. (2018) were calculated from hourly currents measured at three mooring sites located off Icy Cape. The number of instruments available varied from three ADCPs deployed in September 2010, 2016, 2017 and 2018 to only one instrument at the central site in 2012. Details of the calculations can be found in Stabeno et al. (2018). The monthly mean northeastward transport along the Chukchi Shelf is strongest in the summer months and weakest in the winter months. As the flow exits Barrow Canyon much of it continues northwestward in the CSC, while a smaller portion turns east forming the Beaufort shelf break current (Nikolopoulos et al., 2009). There is a significant correlation between the monthly mean transport in Barrow Canyon and the upper 200-m depth-averaged velocity, $V_{0\text{-}200}$, observed at C9 ($r = 0.5$, $p < 0.01$; Fig. 15). This significant correlation, however, is a result of six individual months during which the flow in the CSC is above average (Fig. 15a). That is, when monthly mean flow in the CSC is strong, the transport exiting the shelf through Barrow Canyon is also strong. There are even more instances, however, when the Barrow Canyon transport is just as strong yet the monthly averaged flow in the CSC is weak (<10 cm s^{-1}).

As alluded to above, we do not observe a 2–3 month lag between the peaks of monthly-averaged Barrow Canyon transport and currents at C9, although the variability in our record is substantial (Fig. 15). Given an approximate distance of 100 km from Barrow Canyon to the C9 mooring, currents leaving Barrow Canyon should pass the C9 location in 6–17 days, assuming typical speeds of ~6 cm s^{-1} from C9 (Fig. 14g) and ~15 cm s^{-1} from the drifters (drogue depth ~30 m; Fig. 2b).

Thus, using the C9 and Icy Cape current observations the flow out Barrow Canyon does not appear to drive the CSC. Once again there does appear to be an intermittent relationship between possible forcing mechanisms and the magnitude of flow at C9. While the ACC does not drive the CSC, it is a major contributor as discussed in the next section.

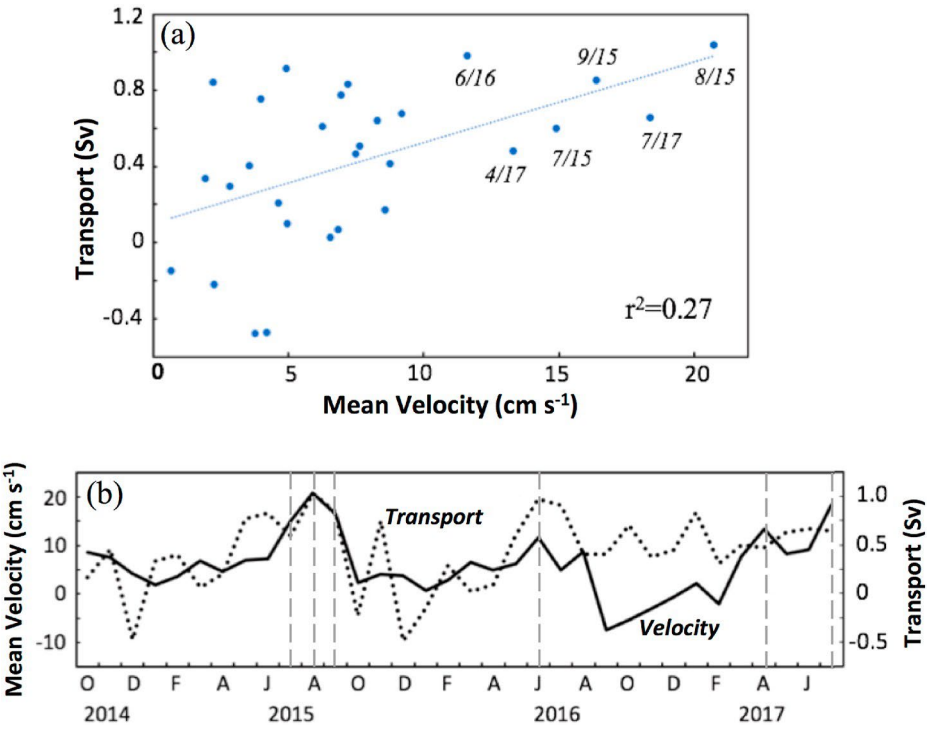

Fig. 15. (a) Monthly depth-averaged (0–200 m) velocity at C9 versus transport at Icy Cape using only data when the mean velocity at C9 was positive (toward the northwest). Best fit line and associated r^2 value are shown. (b) Time series of the depth-averaged (0–200 m) monthly mean velocity at C9 (solid line; left axis) and the monthly mean transport at Icy Cape (dotted line; right axis). The vertical dashed lines represent the timing of the strong velocity events identified in (a).

3.4.5. Volume transport in the CSC

The transport estimate for the CSC can be updated using results from Li et al. (2019) and our C9 results presented herein. Li et al. (2019) estimated transport in the CSC using three year-long moorings deployed in 2013 (spanning 163–356 m bottom depths) and covering an off-slope distance of ~30 km. Their estimate of transport over this area appears to be ~0.35 Sv (their "non-mirrored" value). As noted earlier, our C9 mooring was on the same line of moorings, and ~10 km beyond their outermost site. If we assume that the measurements at C9 are representative of the 20 km beyond the Li et al. (2019) moorings and note that the mean along-slope current in the upper 250 m at C9 was ~5 cm s^{-1}, transport in this region is estimated at 0.25 Sv (width X velocity X depth = 20,000 m X 0.05 m s^{-1} X 250 m). This is likely an under-estimation since the satellite-tracked drifter trajectories provided a width estimate of ~70 km for the CSC. If we do the same calculation assuming that the C9 average velocity is representative of 40 km instead, we obtain an estimate of 0.5 Sv. Although this is likely an over- estimation, it provides a range of transport (including the Li et al., 2019 estimate of 0.35 Sv) in the CSC of 0.60–0.85 Sv.

The mean transport at the Icy Cape moorings for September 2014–August 2017 was 0.42 Sv (following Stabeno et al., 2018). Nikolopoulos et al. (2009) estimated that the eastward transport of Pacific water exiting Barrow Canyon was 0.13 Sv, meaning that 0.29 Sv of the water exiting Barrow Canyon would flow westward. Using these values, the volume of outflow from Barrow Canyon provides between ~34% ([0.42–0.13]/0.85) to ~48% ([0.42–0.13]/0.60) of the CSC volume transport, which as a percentage is less than what was estimated by Li et al. (2019). Alternately, if we use the values explicitly measured from the mooring array, Li et al. (2019) estimated 0.28 Sv of Pacific water in the CSC (their "non-mirrored" value), which is essentially identical to our 0.29 Sv that exits Barrow Canyon and turns westward.

4. Discussion and conclusions

Three years of moored current meter and water property data confirm a well-defined, seasonally varying northwestward surface-intensified flow (the CSC) along the northern Chukchi continental slope. This flow was best defined in the upper 200–250 m of the water column. Below this surface layer was an undercurrent (the AOBC) that flowed predominantly southeastward. Temperature and salinity in this undercurrent (~200 m–~850 m) classified it as Atlantic Water. Vertical correlations among current time series in the AOBC were strong, as were correlations among current time series in the CSC. Only temperature was measured at 900 m in the 2014 and the 2015 deployments, and the average potential temperature at 900 m (below the AOBC) was ~0.0 °C (standard deviation of 0.03 °C), which is typical of Arctic deep water in the Canada Basin.

The C9 mooring site was unknowingly positioned on the southern boundary of the BG (Regan et al., 2019). The BG intensified from 2003 through 2012, reaching a maximum in 2013 and 2014 the end of the analysis period described by Regan et al. (2019). In recent years, the geostrophic transport in the vicinity of C9 has stabilized (Armitage et al., 2017; Zhang et al., 2016), although there remains strong monthly variability in the system, particularly in the fall (Regan et al., 2019). Northwestward velocity appears to be largest in the fall (Regan et al., 2019), but variability also appears to be strongest at that time. In contrast, the flow in the upper 200 m at C9 increased from June through September and then appeared to weaken in the fall. It is unclear whether this apparent disagreement is a result of temporal variability in the system or other mechanisms. For instance, C9 was a single mooring, making it difficult to differentiate between spatial oscillations, such as cross-slope meanders, and temporal variability in the current system. As noted in section 3.1.2, meanders in the system are apparent in the satellite-tracked drifter trajectories. The northwestward trajectory of the drifters followed the trajectory of the southern edge of the BG in 2013 and 2014 (Regan et al., 2019).

The appearance of the CSC has been most evident to the west of Utqiag_ vik, AK (Corlett and Pickart, 2017; Stabeno et al., 2018; Li et al., 2019). According to the analysis by Regan et al. (2019) this is also the region of greatest slope of dynamic ocean topography. Evidence for a

similar current flowing along the Beaufort continental slope is currently lacking. However, we note that the ~1400 m depth mooring of Nikolopoulos et al. (2009) did capture a weak (~2 cm s^{-1}) mean northwestward near-surface flow. Interestingly, the Beaufort mooring array analyzed by Nikolopoulos et al. (2009) was deployed in 2002–2004 before the recent expansion and increase in strength of the BG (Armitage et al., 2017; Regan et al., 2019). It remains unknown whether a more recent mooring array would detect a similar relatively weak northwestward flowing current off the Beaufort continental slope. It should also be noted that the model fields of Watanabe et al. (2017) showed northwestward flow all along the Beaufort continental slope. That the strength of the CSC varied substantially over the three years of our deployment is not surprising, in that the strength and size of the BG also varies interannually (Armitage et al., 2017; Regan et al., 2019).

Recent updates to the freshwater content volume in the BG region indicate that 2015–2017 have the largest total freshwater content volumes on record, with particularly large spatial gradients near the Chukchi continental slope (Proshutinsky et al., 2019; see their Figs. 4 and 5). Thus, our three years of observations at C9 were during a period where the BG was particularly strong.

Li et al. (2019) built upon the results of Corlett and Pickart (2017) by suggesting that wind stress curl over the shelf, rather than westward winds alone, primarily drive variability in the CSC. Our findings indicate that while this may be true in an episodic sense, it is generally not the case over our three-year C9 record. The along-slope currents at C9 were not significantly correlated with local winds, except at depths <40 m. There are several possibilities for this.

One potential explanation for the lack of strong correlations between winds and currents at C9 could be meandering of the current. As mentioned, from a single mooring location, it is difficult to distinguish between temporal variability in currents and inherent spatial changes such as cross-slope meandering of the current.

Secondly, the winds were typically weak, often <10 m s^{-1} (Fig. 14b and c). At present, we remain uncertain about how skillfully the ERA5 reanalysis reproduces the true wind stress curl. Belmonte Rivas and Stoffelen (2019) suggest improvements in ERA5 relative to its predecessor model, but additional ground-truthing is needed, particularly in the Arctic where data for assimilation is sparse.

Remote forcing could provide another possible explanation for the lack of correlation between currents and winds or between the depth of the 0° isotherm and local wind during the first part of the 2016–17 record. Recall that there was significant energy in the currents in the 2–10 day energy band. This energy is likely generated elsewhere, and thus could obscure any correlation between currents and local winds. While we tested for relationships with remote winds at select sites without significant results, a more complete investigation of remote versus local forcing on the Chukchi continental slope is left for future analyses.

Finally, the C9 location is approximately 120 km from the coast north of Utqiag_ vik, AK, where the coastline abruptly changes direction by ~90°. Wind at C9 is usually oriented northeast-southwest, roughly parallel to the Chukchi Sea coast (Fig. 14b; Stabeno et al., 2018), so that it often blows across, rather than along, the continental slope. This general lack of alignment of the wind and continental slope could potentially help explain the lack of correlation between the wind and observed along-slope currents at C9. In contrast, wind blowing along Alaska's Beaufort coastline, where the shelf is much narrower, appears to be effective at forcing along-slope flows (Nikolopoulos et al., 2009). Any oceanic response, however, to changes in wind forcing on the Beaufort continental slope would propagate east in the direction of coastal-trapped waves, rather than toward the C9 site. Finally, the BG is forced by basin-wide winds (the Beaufort High) and modified by the accumulation of freshwater stored in the BG (Armitage et al., 2017; Regan et al., 2019; Petty et al., 2016), so it is not surprising that the CSC at C9 is not locally wind-forced. Although we also found poor correlations between basin-averaged wind stress curl and currents at C9, the fact that the region of highest sea-surface height gradient exists along the Chukchi continental slope from Barrow Canyon to the Chukchi Borderland (Regan et al., 2019) suggests a relationship between the CSC and the BG.

We hypothesize that this northwestward flowing CSC is forced by the edge of the Beaufort Gyre. Corlett and Pickart (2017), while admitting that a dynamical connection could exist, argued that the CSC was not a manifestation of the Beaufort Gyre, citing the relatively strong currents observed on the Chukchi Slope, lack of a similar current off the Beaufort Slope and the presence of Chukchi Shelf water properties in the CSC as evidence. Spall et al. (2018) similarly suggest that the CSC is distinct from the Beaufort Gyre owing to its Bering Strait source and unique water properties. Nevertheless, the fact that the CSC flowed west in the model of Spall et al. (2018) was a result of the basin-scale circulation associated with the BG (their Fig. 16). The body of evidence indicates that the fact that the CSC flows northwestward is a result of the BG dynamics. We suggest that water exiting the Chukchi Shelf via Barrow Canyon is entrained into the western boundary current of the BG flowing northwest along the Chukchi Slope, consistent with the model results of Spall et al. (2018). Dynamically, we expect that the lateral pressure gradient associated with the BG in the region north of, and extending west from, Utqiagvik (Figs. 4 and 5 of Regan et al., 2019) presents an effective "wall" that is more than sufficient to overcome the Coriolis force acting on the flow emanating from Barrow Canyon, resulting in the CSC flowing northwestward along the continental slope.

The shelf-slope system from Barrow Canyon to the Chukchi Borderland is a complex region. The exit of warm, saline water out of Barrow Canyon during summer is a source of subsurface heat to the Arctic Ocean basin (Aagaard and Carmack, 1989; Stabeno et al., 2018; Woodgate et al., 2012). In contrast, the Atlantic Water can enter the Chukchi Shelf via Barrow Canyon (Bourke and Paquette, 1976; Ladd et al., 2016; Wood et al., 2018). An array of moorings across the Chukchi Slope would provide insight into the variability in the boundary of the BG, its strength and the pathways of the outflowing Pacific Water. Clearly, additional observations are required to understand the system.

ABSTRACT

The Chukchi Sea consists of a broad, shallow (<45 m) shelf that is seasonally (November–July) covered by sea ice. This study characterizes the seasonal patterns of near-bottom primary production using moored instruments measuring chlorophyll fluorescence, oxygen, nitrate, and photosynthetically active radiation. From 2010 to 2018, moorings were deployed at multiple sites each year. Instruments were restricted to within 10 m of the seafloor due to ice keels, which can reach 30 m below the surface in this region. Near-bottom blooms were common at all mooring sites. The bloom onset directly followed ice retreat whereas the end of the bloom followed loss of light in September. The intensity of light at the seafloor (~40 m deep) was similar to levels observed under 1–2 m thick ice floes in the spring/early summer, and was sufficient to support photosynthesis near the seafloor, utilizing nitrate and producing oxygen. We hypothesize that the near bottom bloom originated from aggregates of ice algae that sank during ice retreat. As a consequence of climate warming and earlier ice retreat, we predict that the near-bottom bloom onset will occur earlier, but the timing of the end of the near-bottom bloom will remain the same pending a sufficient nutrient supply. The Chukchi Sea is highly productive even though the growing season is short. This production is promoted by a shallow seafloor, which allows multiple production layers (surface open water, bottom of the mixed layer, under-ice algae, and disassociated ice algae which settles near the seafloor). We term this the Multiple Production Layers (MPL) hypothesis.

1. Introduction

The Chukchi Sea consists of a broad shallow shelf, extending >800 km northward from the Bering Strait to the shelf break and the Arctic basin. It is characterized as an inflow shelf for the Arctic (Carmack and Wassmann, 2006) and is the sole source of Pacific water to the Arctic Ocean. The flow through Bering Strait provides heat, freshwater, and salt, including nutrients, to the Chukchi Sea and the Arctic Basin. The northward flow divides into two primary branches — the western branch flows into the Arctic basin through Herald Canyon and the eastern branch flows through Barrow Canyon (Coachman et al., 1975). Sea-ice algae are a major source of carbon to the benthic ecosystem (Grebmeier, 2012; Koch et al., 2020) with an estimated production during spring of 1–2 g C m^{-2} (Gradinger, 2009). Production of ice algae is primarily limited by light (Michel et al., 1988; Welch and Bergmann, 1989) and nutrients (Cota et al., 1987; Castellani et al., 2017).

The spring plankton bloom likely initiates under and within the sea ice (Hill and Cota, 2005; Arrigo et al., 2012; Lowry et al., 2018; Tedesco et al., 2019). Seasonal ice retreat favors the export of aggregates of under-ice algae directly to the benthos (Ambrose et al., 2005; Boetius et al., 2013; Katlein et al., 2015; Koch et al., 2020). This, together with benthic microalgae, support the Chukchi's rich, benthic-dominated ecosystem (Dunton et al., 2014).

There has been a dramatic loss of sea ice in the Chukchi Sea during the last 15 years (Wood et al., 2015, 2018; Serreze et al., 2016; Frey et al., 2015), with earlier ice retreat in the spring/summer and later ice arrival in the fall. This loss of sea ice (including multi-year ice) has increased the atmospheric heat-flux into the Chukchi Sea (Danielson et al., 2020). Earlier ice retreat also impacts the timing of export of ice algae to the seafloor and the timing of open water phytoplankton production (Arrigo et al., 2008; Hill et al., 2017), and favors open water phytoplankton primary production that benefits a pelagic ecosystem (Grebmeier et al., 2006, 2015; Moore and Stabeno, 2015). A longer open-water season is predicted to alter the composition and distribution

of phytoplankton communities (Tremblay et al., 2009; Neeley et al., 2018).

The focus in this paper is to examine the relationship among chlorophyll fluorescence, arrival and departure of sea ice, and photosynthetically active radiation (PAR). We utilize a variety of data sources, including hydrographic casts, pop-up buoys (a newly developed technology that measures properties underneath the ice), and a variety of time series collected on moorings. Chlorophyll fluorescence, PAR, oxygen, and nitrate were measured near the seafloor at multiple mooring sites on the U.S. Chukchi Shelf over a 9-year period (Fig. 1). These instruments were all deployed within 8 m of the seafloor to avoid the deep ice keels that can occur on this shelf.

Preliminary analysis indicated that the large export of ice algae to the seafloor coincides with ice retreat (Berchok et al., 2015). In their analysis, an increase in percent oxygen saturation and/or decrease in nitrate concentration were often associated with this export event, suggesting that net primary production due to ice algae continues at depth. We contend that this continued production is not due to subsurface phytoplankton, which lie shallower, but rather near-bottom disassociated ice algae. We present evidence to support this distinction in the results and discussion.

Our objective was to test the multiple production layer or MPL, 'maple', hypothesis that ice algae fall to the seafloor as ice retreats and continue to photosynthesize for weeks or longer (Fig. 2). According to this hypothesis, this near-bottom layer of continued photosynthesis by disassociated ice algae adds to the other layers of primary production (i.e. sympagic algal production, and surface and sub-surface phytoplankton blooms) that together account for the high primary productivity found on the Chukchi Shelf (Hill and Cota, 2005; Arrigo et al., 2012; Codispoti et al., 2013; Hill et al., 2017).

2. Data and methods

2.1. Moorings

Moorings (Fig. 1) were deployed at 8 sites (C1–C8) on the Chukchi Shelf during late summer and recovered the following summer, when new moorings were usually deployed. Listed in Table 1 are the deployment years at each site, mooring locations and instrumentation. All moorings were short, taut wire moorings. During winter and spring, sea-ice keels can be as deep as 30 m below the surface (Stabeno et al., 2018). To avoid these ice keels, each mooring was <10 m tall, keeping the upper float at least 30 m below the surface. This height limitation resulted in two moorings being deployed at each site, because of the limited amount of vertical wire space. Instruments on the moorings collected hourly measurements of the following variables: temperature (SeaBird SBE-37, SBE-39, SeaCat); currents (Acoustic Doppler Current Profiler, RCM-9); salinity (SBE-37, SeaCat); chlorophyll fluorescence (Sea-Bird/WET Labs FLSB ECO Fluorometer); nitrate (Sea-Bird/Satlantic ISUS or SUNA; at selected sites); and PAR (Biospherical Instruments QSP2300). Excluding the ADCP that was deployed at the top of the mooring, the rest of the instruments were deployed 4–8 m above the bottom. All instruments were prepared according to manufacturers' specifications and calibrated prior to deployment (except for calibration of the nitrate sensors which is discussed below). While chlorophyll samples were taken at the mooring sites on deployment and recovery of the moorings, there were insufficient data to improve the conversion of fluorescence to chlorophyll.

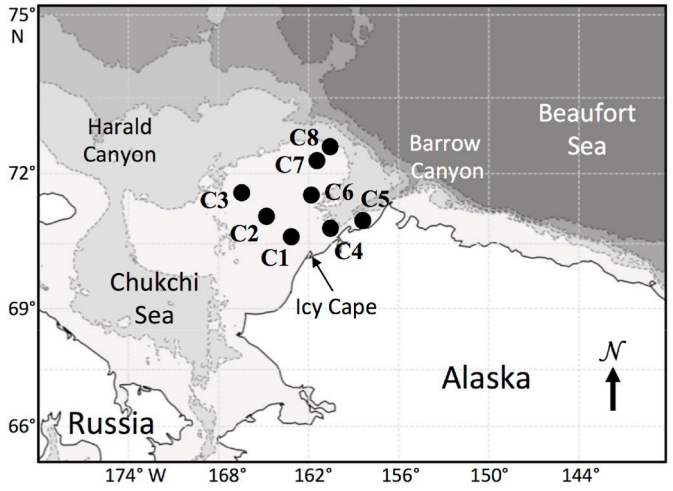

Fig. 1. Map of the Chukchi Sea shelf with bathymetry and place names. The eight shelf mooring sites (C1–C8) are indicated by black dots. The periods of deployments are listed in Table 1.

To reduce biofouling, optical wipers on the Eco Fluorometer and SUNA were engaged prior to each hourly set of measurements, and the ISUS sensors were plumbed into the outflow of a Sea-Bird Scientific SBE-16 with anti-fouling agents mounted on either side of the ISUS flow cell. See Mordy et al. 2020 for further details of data processing of nitrate sensors.

2.2. Hydrography

The conductivity-temperature-depth (CTD) instrument package consisted of a Sea-Bird 911plus with dual sensors measuring temperature, conductivity and oxygen, and single sensors measuring, pressure, and chlorophyll fluorescence. Hydrographic casts were done at each mooring site upon deployment and/or recovery of moorings. While the optical nitrate sensors (ISUS and SUNA) have a reported accuracy of ~2 μM, they must be calibrated with discrete samples. At the depth of the nitrate sensor, discrete samples for nutrients were collected from Niskin bottles and filtered through 0.45 μm cellulose acetate filters. Samples were frozen for analysis at our laboratory in Seattle, WA. See Mordy et al. 2020 for details of the analysis.

On July 18, 2015, aboard the USCGC Healy cruise HE1501, a GoPro camera was attached to the top of the CTD frame and a movie was taken simultaneously with the CTD downcast near the C2 mooring (164.3°W, 71.2°N). Three representative frames were selected from this movie and presented herein, and a short video segment is included in the supplemental material (Supplemental Video).

2.3. Pop-up buoy

During the last four years, pop-up buoys have been developed at the Pacific Marine Environmental Laboratory (Langis et al., 2018). The purpose of this effort was to develop an inexpensive, expendable buoy to make under-ice measurements that could be deployed in summer or fall and rise to the surface in the following winter or spring on a prearranged day. Eventually, when the ice melted, the buoy surfaced and transmitted data back to the laboratory. The instruments collect data during three unique periods: (1) on the seafloor; (2) on the vertical profile as it rises to the surface; and (3) under the ice.

The buoy presented in this manuscript is Generation 3. It consisted of a spherical float (30 cm in diameter). The upper ~5 cm of top had been cut off, and a flat plate (cap) attached at the top. One thermistor (±0.01 °C) was located on the top-cap and a second one at the bottom of the float. A fluorometer (±2%) was located on the bottom of the float facing downwards, while the PAR sensor (±3%) and pressure sensor (±0.21 m) were located on the top-cap. The camera (UCAM III Low-Resolution Digital Camera) was tilted upward at 45° and positioned ~10 cm from the bottom of the ice.

2.4. Sea ice

The Advanced Microwave Scanning Radiometer (AMSR-E) data

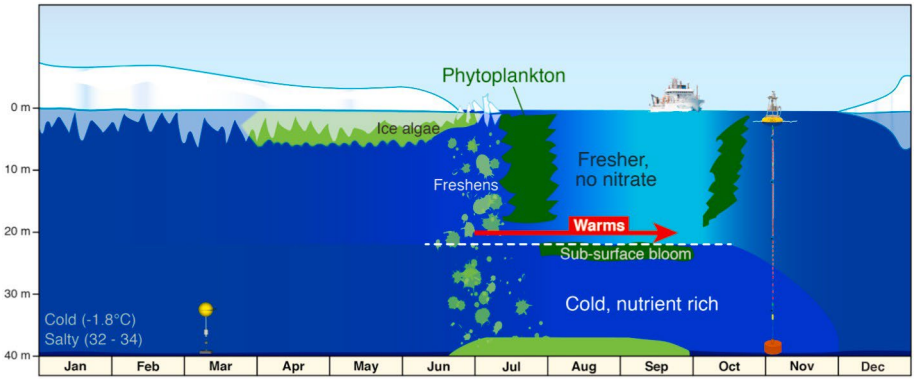

Fig. 2. Seasonality of the lower trophic level of the ecosystem on the northeastern Chukchi Sea Shelf. Ice algae bloom occurs beneath the ice in spring, and with ice melt it is exported to the bottom, where there is sufficient light and nutrients to support further production. With ice retreat/melt the water stabilizes with a relatively warm, low salinity surface layer overlaying a colder, more saline bottom layer. With this stabilization, a surface phytoplankton bloom can occur consuming the remainder of surface nutrients and support a subsurface bloom. With surface mixing in late summer a fall phytoplankton bloom may occur (Adapted from Fig. 136, Berchok et al., 2015).

Table 1
List of moorings (with depth in parentheses) and instruments deployed between 2010 and 2017. F indicates the fluorometer functioned correctly providing data for the entire deployment. Similarly, N is a nitrate sensor, O an oxygen sensor and P a PAR sensor. Bold indicates that the instrument recorded data for only part of the deployment cycle. "Yes" indicates that there was production in the near bottom; "No" indicates that there was no production; and "-" indicates that there were insufficient data to decide. In addition to the variables listed below, currents were measured at most sites. The depths of each instrument were 4–8 m above the bottom.

(available from the National Snow and ice Data Center, http://nsidc.org/data/amsre/) were used in this manuscript. AMSR is a dataset of sea-ice extent and areal concentration consisting of daily ice concentration data at 12.5 km resolution. Time series of percent areal coverage were calculated in 50 km × 50 km boxes around each mooring site (C1–C8).

2.5. Data analysis

Time series of sea-ice coverage (percent) values were used to determine the timing and duration of the ice-free period in summer. These records were plotted, and the retreat and return dates were assigned (Table S1, Fig. S1). Ice retreat was considered to have occurred when areal sea-ice cover fell below 15% for the first time during each year. Ice return was considered to have occurred when areal ice cover increased above 15% for the last time during each year. The duration of the ice-free period was computed as the difference in days between ice retreat and ice return.

PAR values near the seafloor for each mooring and year were examined to determine the time and duration of the photic period in summer. These records were plotted and the onset, end and maximum value of PAR were assigned (Table S1, Fig. S1). Onset and end of the PAR period were considered to have occurred when the PAR value crossed a threshold of 0.1 μE m^{-2} s^{-1} (Hancke et al., 2018). PAR duration was computed as the difference in days between PAR end and PAR onset.

Chlorophyll values near the seafloor for each mooring and year were examined to determine the time and duration of the bloom in summer (herein we use "bloom" to indicate increased chlorophyll fluorescence). These records were plotted and the onset, end and maximum value of the summer bloom were assigned (Table S1, Fig. S1). Onset and end of the near-seafloor summer bloom ('bloom end') were considered to have occurred when the concentration of chlorophyll crossed 1 μg l^{-1} (Arrigo and van Dijken, 2011). Bloom duration was computed as the difference in days between bloom end and bloom onset.

Annual values of ice retreat, ice return, PAR onset, PAR end, bloom onset, and bloom end were plotted by year and mooring using box plots and the R package 'ggplot2'. The relationships between values (e.g. between bloom onset and ice retreat) were plotted by year and mooring using the R package 'ggplot2' scatter plots. Their relatedness was examined by computing Pearson correlation coefficients *r* (e.g., between bloom onset and ice retreat) and the statistical significance of the *r*-values were estimated using the R package 'Hmisc'.

3. Results

3.1. Sea ice

Typically, ice cover was at or near 100% during winter for most mooring sites (Fig. 3a, Fig. S1). The exceptions were the three most coastal moorings—primarily C4 and C5 and, to a lesser extent, C1. At these sites, winter and spring sea-ice cover was usually reduced when strong winds were out of the east and/or northeast (referred to as a wind-driven polynya) or when warm Atlantic water surfaced (referred to as a sensible heat polynya) (Ladd et al., 2016; Hirano et al., 2016). At these coastal moorings, areal ice concentration during winter was smallest in 2013, 2014, and 2016 (Fig. 3a). The greatest variability in areal ice cover was at C4 and C5, the two moorings nearest the shelf break (Figs. 1 and 3b). At all the mooring sites discussed herein, sea ice eventually retreated in summer, and returned in late summer or fall (Fig. S1).

The timing of sea-ice retreat varied among years with later retreats in 2012–2014 and earlier retreats in 2010–2011 and 2015–2017 (Fig. 4a). The median day of ice retreat was approximately day 170 (mid-June) for 2010–2011, day 205 (late July) for 2012–2014, day 190 (early July) for 2015–2016, and day 135 (mid-May) for 2017. This pattern of two years of early retreat, three of late, two of mid-range, and finally one year of early ice retreat largely occurred regardless of location, with some exceptions. For example, ice retreat at C7 and C8 in 2010 was similar to the later ice retreat observed in 2012–2014. At C4, the early ice retreat in 2012 reflects a brief period of low ice followed by a return of sea ice lasting several weeks (Fig. S1).

The timing of sea-ice return varied less than sea-ice retreat, with most returns occurring between days 300 and 330 (November; Fig. 4d). The range of sea-ice return was much narrower (~50 days, day 294–345) than the range of sea-ice retreat (~100 days, day 133–232) (Table S1). Thus, variability in the duration of the ice-free period was dictated more by ice retreat than ice return and ranged from 67 to 203 days. The median duration of the ice-free period was 127 days.

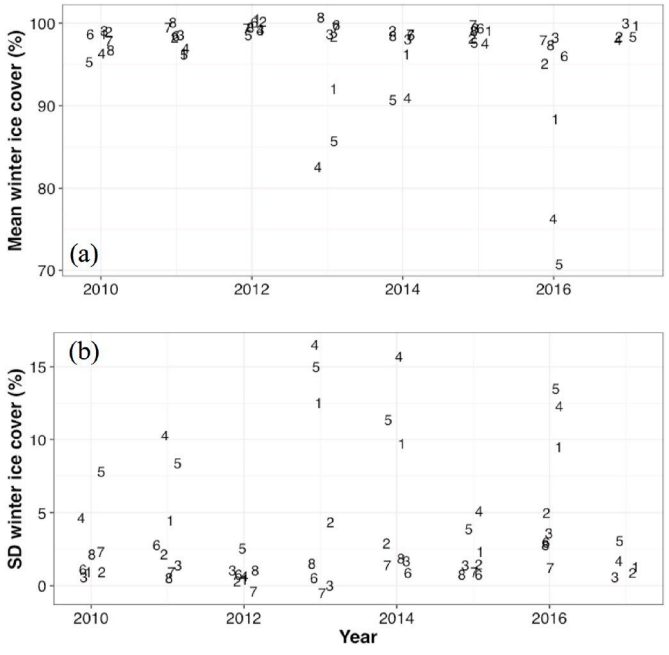

Fig. 3. (a) The mean winter (January–March) ice cover at each mooring site as a function of year. (b) The standard deviation of the mean winter ice cover shown in (a). The individual moorings are indicated by number, so "4" refers to the mooring site C4. The points are randomly offset to reduce overlap. The coastal moorings C1, C4, and C5 had periods of low ice cover and the greatest variability.

3.2. Ice algae

3.2.1. Under-ice data from pop-up buoy

An under-ice (water-ice interface) bloom was observed during spring 2019 from a pop-up buoy that floated to the surface and came to rest at the bottom of an ice floe for approximately two months (May and June). The pop-up buoy was deployed in August 2018 near the C2 mooring (71.2°N, 164.3°W). It remained anchored to the sea floor until April 30, 2019, when the pop-up buoy was released (as designed) and rose to the surface underneath a large (~20 km long) ice floe (Fig. 5a). This distinctive floe was tracked *via* satellite images until 20 June, when the ice floe began to break apart. The floe traveled a distance of ~400 km over a period of 60 days (blue line, Fig. 5b). During this period, the pop-up buoy successfully collected hourly temperature, PAR and fluorescence data just below the bottom of the ice. The top of the buoy rested immediately below the ice at a depth of ~1.5 m (an indication of ice thickness) during the first ~25 days and then began to shoal (an indication of ice thinning) (Fig. 5c).

Chlorophyll fluorescence near the ice-seawater interface began to increase on ~14 May and the bloom continued through early June (Fig. 5d). This bloom occurred under low light conditions (max 2–3 μE m^{-2} s^{-1} prior to 27 May); PAR increased reaching 4–8 μE m^{-2} s^{-1} in early June. In mid-June, the fluorescence disappeared and PAR increased to 20 μE m^{-2} s^{-1}. It was unlikely that the disappearance of the bloom was related to photoinhibition because Cota and Horne (1989) found that, even for ice algae adapted to low light, photo inhibition does not occur until ~40 μE m^{-2} s^{-1}. While nutrient depletion and grazing cannot be discounted, the expectation is that the bloom sank toward the sea floor once the ice substrate began to erode (Fig. 5c), which is consistent with loss of color in the under-ice images (Fig. 5f and g) (Riebesell et al., 1991; Ambrose et al., 2005; Boetius et al., 2013; Ferna´ndez-M´endez et al., 2014; Katlein et al., 2015).

The pop-up buoy remained in the vicinity of moorings C2 and C3 for ~25 days (Fig. 5b). This provided simultaneous time series of fluorescence underneath the ice and near the seafloor (Fig. 6). While in the vicinity of C2 (red line Fig. 6a), the under-ice chlorophyll fluorescence was near-zero as was the near-bottom chlorophyll fluorescence. As the buoy came closer to C3, under-ice fluorescence began to increase (green line). The near bottom fluorescence began to increase at C3 ~20 days after it began to increase at the ice-water interface (green line in Fig. 6b). This lag is consistent with estimates of settling rates of ice algae (0.4–2.7 m d^{-1}, Michel et al., 1993).

3.2.2. Water column data from CTD and video

Vertically, there can be multiple layers of significant chlorophyll fluorescence in the Chukchi Sea (Martini et al., 2016). This multilayer pattern was evident in a hydrographic cast done in 2015 (Fig. 7, left), when a camera was attached to the CTD frame (photos in Fig. 7, right). This CTD cast (164.3◦W, 71.2◦N on July 18, 2015) was taken near C2, approximately 3 days after the ice retreated. Two increases in chlorophyll fluorescence are evident in the cast data, a relatively small one at ~15 m and a larger one below 20 m. The photos show the different quality of the blooms. The photo of the upper water column appears fairly clear (Fig. 7, photo A); the middle photo shows a diffuse chlorophyll peak and likely represents a subsurface phytoplankton bloom associated with the pycnocline (Fig. 7, photo B), while the bottom photo (Fig. 7, photo C) has larger aggregates of cells and extends over ~10 m depth (Fig. 7, left). As the CTD passed the halfway point through the lower layer of fluorescence (~28 m), PAR was fully attenuated. These aggregates are better viewed and clearly visible by video (Supplementary Video), and consistent with reports of sinking aggregates of disassociated ice algae (Riebesell et al., 1991; Ambrose et al., 2005; Boetius et al., 2013; Ferna´ndez-M´endez et al., 2014; Katlein et al., 2015; Koch et al., 2020).

Identifying these aggregates as disassociated ice algae at our moorings is supported by observations at a nearby sediment trap deployed on

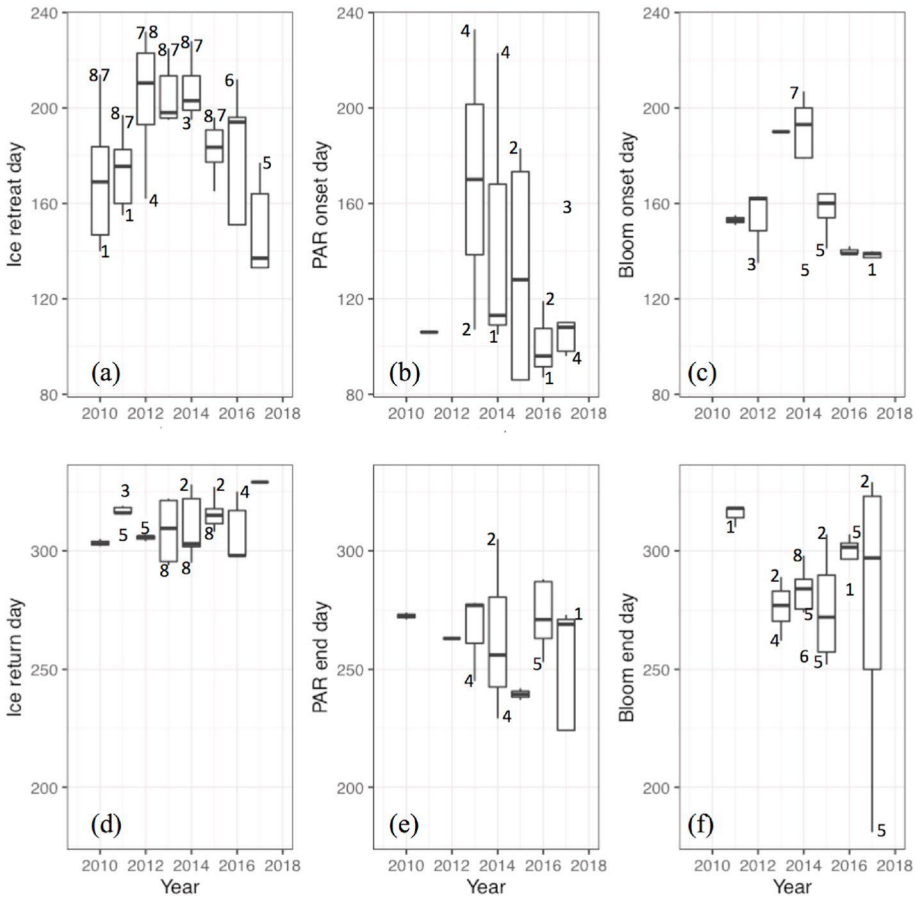

Fig. 4. Box plots indicating (a) day of ice-retreat, (b) day on which the onset of PAR > 0.1 μE m^{-2} s^{-1}, (c) day of bloom onset, (d) day of ice-return, (e) day on which PAR falls below 0.1 μE m^{-2} s^{-1}, and (f) day of bloom end day, all versus year of mooring deployment. The data shown herein are from S1. The numbers in each panel indicate the mooring sites (e.g. "4" refers to C4) that are outside the interquartile range.

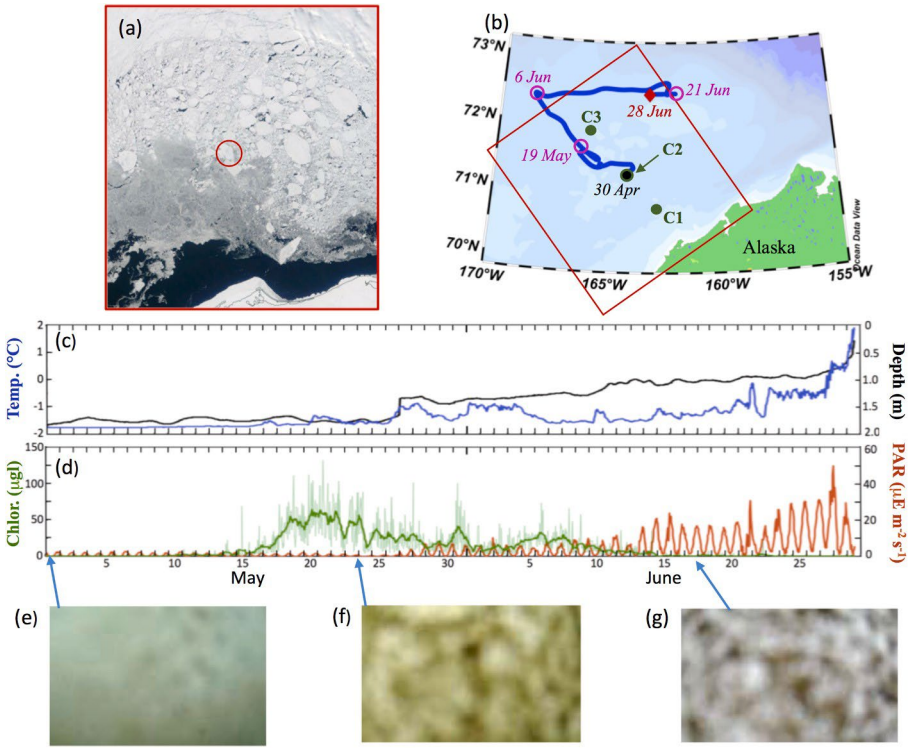

Fig. 5. (a) Satellite image of sea ice on April 30, 2019 when the pop-up buoy surfaced. The red circle indicates the location of where the pop-up buoy was deployed. (b) The trajectory of the ice floe from 30 April to 28 June when it broke apart and the buoy began to transmit location and data (red dot). Selected dates are indicated in purple. Mooring locations are shown and color-coded. The red box is the area shown in (a). (c) Time series of temperature beneath the sea ice and the depth of buoy. The depth of buoy is effectively the thickness of the sea ice at that point because the buoy sits immediately beneath the ice. (d) Time series of chlorophyll fluorescence and PAR measured below the ice by instruments on the pop-up buoy. (e–g) Photos of the water column. Fig. 6. (a) Low-pass filtered time series of chlorophyll fluorescence measured by pop-up buoy under the ice. It is color coded with red indicating when the buoy was in the vicinity of C2, green in the vicinity of C3, and black in the vicinity of no mooring. (b) Low-pass filtered time series of near-bottom chlorophyll fluorescence measured at C2 (red) and C3 (green). (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

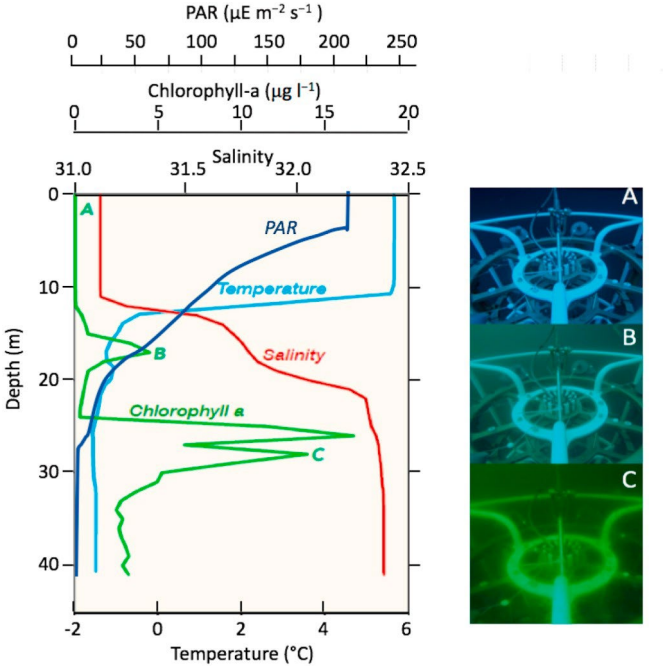

Fig. 7. (left) Hydrographic cast in 2015 near C2 showing multiple subsurface chlorophyll maxima. A smaller subsurface maximum was observed just below the pycnocline, and a larger maximum was observed in the bottom layer. (right) Photos of the water column (taken from a video in the supplemental material): upper layer of relatively clear water; first chlorophyll maximum below the pycnocline; and at the top of the large maximum. The letters A, B, and C correspond to the appropriate depth shown on the left.

the northern Chukchi Shelf in 2016 (Koch et al., 2020). Koch et al. (2020) found that as ice retreated, the flux of sea-ice exclusive diatoms (*Nitzschia frigida* and *Melosira arctica*) increased from ~2 million cells m^{-2} d^{-1} in early June to ~ 30 million cells m^{-2} d^{-1} in early July. This was accompanied by a 10-fold increase in the flux of lipids that are specific to sympagic organisms (from ~100 to 1000 ng m^{-2} d^{-1}). The timing of this flux was concurrent with the increased concentrations of chlorophyll observed at two nearby moorings, C2 (60 km away) and C4 (80 km) (Fig. S1).

3.2.3. Near-bottom data from mooring C2 in 2018

The fate of these sinking aggregates can be seen in the time series (oxygen, nitrate, PAR and fluorescence) collected at the moorings. For example, in 2018 at mooring C2, the ice retreated in mid-May (Fig. 8a), an early date for ice retreat, and there was a sharp increase in chlorophyll fluorescence in the near-bottom water (30–40 m below the surface; Fig. 8b). Accompanying this increase in fluorescence was a sharp increase in the percent saturation of oxygen, from ~90% to >120%, and, at the same time, a decrease in nitrate from ~15 μM to near 0 μM

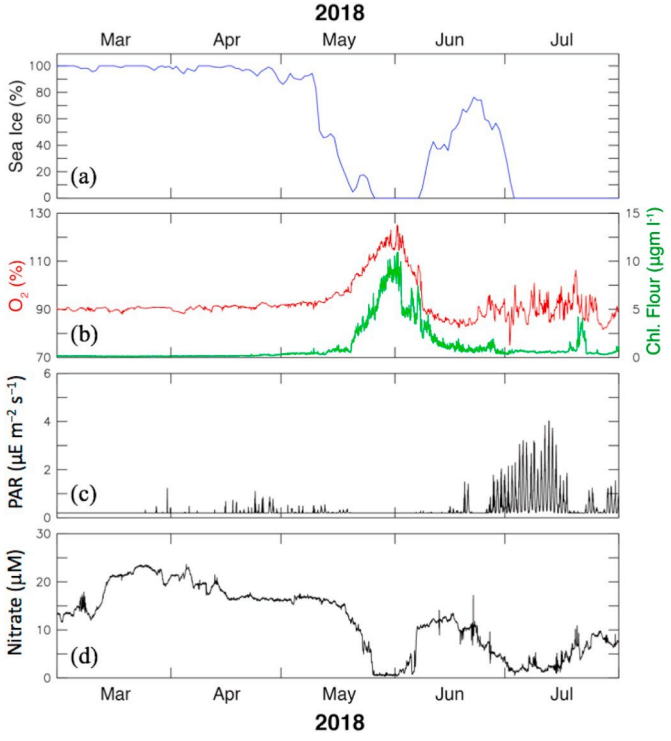

Fig. 8. Time series of: (a) percent ice cover in 50 km × 50 km box centered on C2; (b) percent oxygen saturation (red) and chlorophyll fluorescence (green); (c) PAR; and (d) nitrate. Except for (a), all time series were measured on mooring at C2 within 8 m of the bottom. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

(Fig. 8d) consistent with active photosynthesis in the bottom waters. Light (PAR) was very weak (<2 μE m^{-2} s^{-1}), but measurable through mid-May, decreasing to near zero during the period of high chlorophyll fluorescence; it increased markedly in early July with the disappearance of fluorescence. We suspect that the decrease in PAR to near zero in mid-May was a result of disassociated ice algae descending as a mass through the water column, and the resulting shading prevented most of the light from reaching the seafloor. Such a shading (sharp decrease in PAR) effect was also evident in Fig. 7a, when the CTD entered the region with high chlorophyll. The highest PAR values (Fig. 8c) occurred in July when near-bottom chlorophyll concentrations were low and ice was absent. Vertical mixing in the bottom ~8 m during late May - early June likely exposes the ice algae to sufficient light to continue production; that is, sometimes cells are at the top of the layer and exposed to sufficient light and then mixed downward in this bottom mixed layer.

Near the seafloor, chlorophyll fluorescence began decreasing between 1–6 June, perhaps due to nutrient limitation or grazing (Fig. 8b, d). On 7 June, sea ice returned, and there was a sharp increase in nitrate, and reductions in chlorophyll fluorescence and oxygen saturation (<90%), results consistent with advection of water past the mooring (Mordy et al., 2020) and net respiration. When the ice retreated for the second time in early July, the highest PAR was recorded and yet there was no clear evidence of active photosynthesis as chlorophyll fluorescence remained low and oxygen saturation, while variable, was <100%. Finally, in mid-July there was a small pulse of chlorophyll fluorescence that once again shaded near-bottom waters (low PAR), was coincident with a 5 μM drop in nitrate, and resulted in a short period of >100% oxygen saturation.

3.3. Near-bottom chlorophyll and its relationship to sea ice and light level

Continued fluorescence and photosynthesis near the seafloor following ice retreat was common in our time series. This pattern (described in the previous section for mooring C2 in 2018) of ice retreat, increased fluorescence, increased oxygen (by >20%) and/or decreased nitrate dominates at the mooring sites over the years (2010–2018), occurring 22 out of 23 times (96%) when there are sufficient data to detect this pattern (Table 1). Each of these locations is shallow (<48 m) with measurable light (PAR) reaching the bottom. In MPL, we have hypothesized that the increased fluorescence was likely due to continued photosynthesis by disassociated ice algae near the seafloor, as evidenced by accumulation of sea-ice exclusive diatoms in a sediment trap (Koch et al., 2020) and increasing percent oxygen saturation and/or decreasing nutrients (Fig. 8). In the next few paragraphs, we explore the relationship among the timing and duration of the chlorophyll fluorescence bloom, ice retreat and duration, and the magnitude of PAR.

The timing of PAR onset (>0.1 μE m^{-2} s^{-1}) was earlier for 2011, variable and often later for 2013–2015, and earlier for 2016–2017 (Fig. 4b). The median of PAR onset was approximately days 95–130 for all years except in 2013, when the median was about day 170. Unlike the timing of PAR onset, the timing of PAR end was similar regardless of the year. In general, the range of PAR end (~80 days, day 224–305) was much narrower than the range of PAR onset (~150 days, day 86–233) (Supplemental Table S1). Thus, the duration of the PAR period was dictated more by the timing of PAR onset than the timing of PAR end, ranging from 6 (C4 in 2014) to 200 days. The median duration of the PAR period was 151 days (Table S1).

The timing of the algal bloom onset was earlier for 2011–2012, later for 2013–2014, and earlier for 2015–2017 (Fig. 4c). The median day of bloom onset was approximately day 160 for 2011–2012, 190 for 2013–2014, and 150 for 2015–2017. The timing of bloom end was later for 2011, earlier for 2013–2015, and mid-range for 2016–2017 (Fig. 4f). The median day of the end of the bloom was about day 320 for 2011, 280 for 2013–2015, and 300 for 2016–2017. The median duration of the bloom was 128 days and the range was 41–190 days (Table S1). One unusual observation was mooring C5 in 2014, which had a much earlier bloom onset (approximately day 130) than that year's median (approximately day 190). This bloom began during a period of variable ice cover, but the ice was not so reduced that it reached the 15% threshold that defined ice retreat (Fig. S1).

Comparing the timing of ice, light and the bloom provides evidence that the near-bottom bloom onset occurs at, or prior to, ice retreat, whereas the end of the bloom followed the loss of light in September (Fig. 9). The timing of bloom onset was related to ice retreat ($r = 0.54$, $p = 0.007$) and weakly related to PAR onset ($r = 0.51$, $p = 0.065$) (Fig. 9). The timing of bloom end was weakly related to PAR end ($r = 0.46$, $p = 0.098$) and unrelated to ice return ($r = 0.26$, $p = 0.199$) (Fig. 9). Based on these results, we computed an alternate index of the growing period, the interval between ice retreat and PAR end. We termed this interval the ice retreat-PAR end duration and found that bloom duration is strongly related to ice retreat-PAR end duration ($r = 0.72$, $p = 0.013$) (Fig. 10).

3.4. Annual fluorescence variation during summer

The growing season near the seafloor typically began with the following sequence: ice retreat, a slight increase in PAR, followed by a reduction of PAR concomitant with an increase in near-bottom chlorophyll fluorescence (e.g. Fig. 8). As the ice melted, ice algae were released from the underside of the ice and dropped to the bottom. During the period of the near-bottom bloom (high fluorescence), PAR was particularly low due to self-shading of the bloom. In addition, open-water phytoplankton blooms in the surface layer or below the surface mixed layer (subsurface), common on the northern Chukchi Shelf (Martini et al., 2016), likely contributed to shading of the water column. Another good example of this sequence of events is mooring C2 in 2013 (Fig. S1), where ice cover decreased to 50% in early July and was quickly followed by increased near-bottom chlorophyll concentration. PAR increased concomitant with declining chlorophyll.

As discussed above, sea-ice return did not determine the end of the growing season. Instead the near-bottom bloom was terminated by the seasonal reduction in light during early fall that preceded ice return during our sample years. The usual sequence at the end of the growing season was: PAR becoming undetectable around days 250–270; the near-bottom bloom ending around days 270–300; and ice returning around days 300–320 (Fig. 4).

The near-bottom bloom onset followed directly on ice retreat whereas the end of the bloom followed loss of light in September. As a result, the growing season (bloom duration) near the seafloor was significantly related to the duration of the period between ice retreat and PAR end. In fact, because there was relatively low variability in the ice return day, the PAR end day, and the bloom end day (Fig. 4), the durations of the bloom, PAR, and the ice-free periods were dictated by the timing of their onsets and not their ends.

3.5. Earlier blooms, polynyas and ice-cover variability

Areas of open water during winter and spring occurred in some years. Most often, this happened at mooring sites C1, C4, and C5 (2010, 2011, 2013, 2014, and 2016; Fig. 3). Each of these moorings is near the coast where the Chukchi polynya occurs (Ladd et al., 2016). Intrusion of warmer, saltier Atlantic Water can contribute to or even cause this polynya (Ladd et al., 2016). Earlier blooms were more common in the Chukchi polynya area (C1, C4, and C5) than outside this area. Using the median bloom onset day (day 154) as a threshold to differentiate "early" from "late" bloom onset, 8 of 12 bloom onsets were early in the Chukchi polynya area and only 4 of 12 bloom onsets from this area were late.

Ice retreat is primarily a result of ice melt or of advection forced by local winds and local currents, or a combination of melt and advection (Ladd et al., 2016). The timing of ice retreat (defined here as the first occurrence of areal ice concentration <15%) varied among the five primary moorings (C1–C5 for the period 2001–2016), with earliest

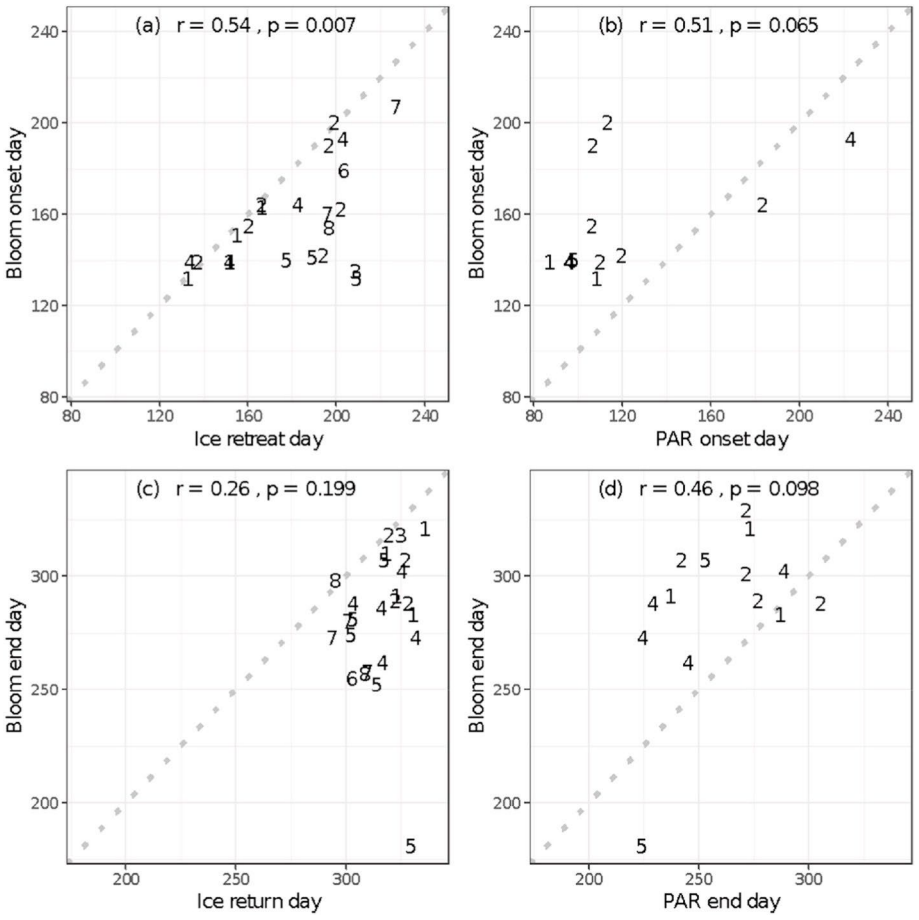

Fig. 9. Scatter plots of the timing of: (a) bloom onset versus ice retreat; (b) bloom onset versus PAR onset; (c) bloom end versus ice return; and (d) bloom end versus PAR end based on near-bottom measurements. The dashed grey line is the 1:1 line.

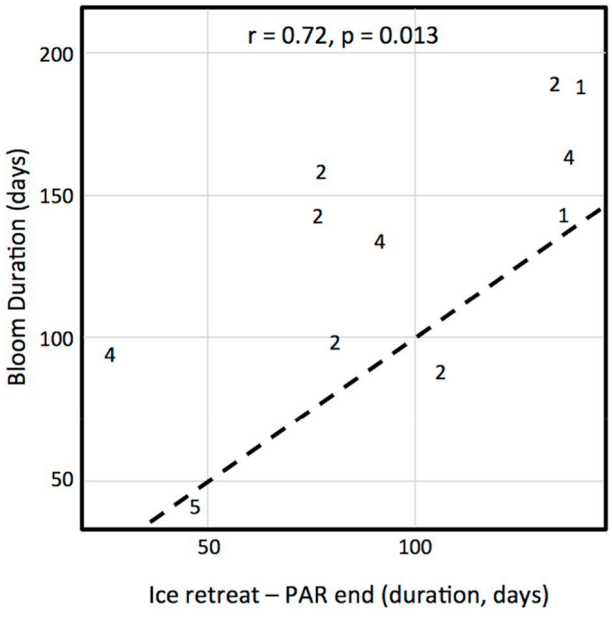

Fig. 10. Scatter plot of the duration of the bloom versus the length of time between ice retreat and PAR end based on near-bottom measurements. The dashed grey line is the 1:1 line.

mean retreat occurring at C1 followed by C4, C2, C3 and, finally, C5. The date of retreat among these five moorings was related with the highest correlation ($r = 0.86$, $p < 0.01$) between the coastal moorings C1 and C4 and the weakest, but still significant, between C1 and C5 ($r = 0.71$, $p < 0.01$). Noting this relationship, the expectation (Fig. 9a) would be that blooms occur earliest at C1 and latest at C3 and C5. Unfortunately, directly examining the timing of the blooms is difficult, because of the limited number of concurrent time series.

Bloom onset was early during years when ice retreated earlier (Fig. 9a) or was episodic in nature. Occasionally ice retreated early, partially returned and then retreated fully for the summer (e.g. mooring C1 in 2012). In this case, a bloom began with the initial ice retreat and continued during the partial return. In other years (e.g. mooring C2 in 2018; Fig. 8) the bloom began with ice retreat and stopped when ice returned. In some years, ice cover was variable during winter and spring (e.g. 2016), PAR increased early (April) and the spring bloom occurred after the early PAR increase (Fig. S1).

Even if ice retreat occurred earlier, an associated chlorophyll maximum was not guaranteed. The earliest observed chlorophyll maxima were during May. For example, a May bloom followed early ice retreat at mooring C5 in 2014 and 2015 (Fig. S1). This can be seen in the 2016 time series; ice cover was irregular in April at moorings C1, C2, and C4, yet substantial fluorescence increases did not occur until May. The lack of a bloom may indicate that either little ice algae were present or the sea ice was advected away (taking its ice algae with it) as opposed to melted.

4. Discussion

4.1. Primary production continues at the seafloor through summer

We found that primary production continued at the seafloor through summer, adding to the primary productivity of the Chukchi Sea, which together with the Chirikov Basin (the region of the northern Bering Sea northeast of St. Lawrence Island) are the most productive regions in the Pacific Arctic (Hill and Cota, 2005; Arrigo et al., 2012; Codispoti et al., 2013; Hill et al., 2017). Virtually all the moorings that successfully measured chlorophyll fluorescence, and either oxygen or nitrate, showed a clear signal of continued production near the seafloor during the summer (Table 1).

We propose that this near-bottom production is due to disassociated ice algae. In most regions with seasonal sea ice, ice algae descend below the photic zone, and thus discontinue to photosynthesize (e.g. Boetius et al., 2013; Rapp et al., 2018). In contrast, much of the Chukchi Sea Shelf is less than 45 m deep and lies within the photic zone. The magnitude of PAR at the Chukchi seafloor was comparable to what was measured beneath the sea ice (Figs. 5d and 8c). Because ice algae can photosynthesize at low levels (Hancke et al., 2018), it is not surprising that photosynthesis by disassociated ice algae may continue near the seafloor. This conclusion is consistent with Koch et al. (2020) who identified disassociated ice algae species together with chlorophyll fluorescence for several months at the seafloor. In addition, the concentration of nitrate in spring and summer is variable, but nitrate usually is sufficient to support some production (see Figs. 2 and 5 in Mordy et al., 2020. With both light and nutrients, the contribution of continued primary production on the seafloor can be substantial and should be considered in estimating primary production in the Chukchi Sea.

4.2. MPL hypothesis

Our results support the hypothesis that continued photosynthesis by disassociated ice algae at the seafloor provides another source of primary production in addition to the spring phytoplankton bloom in the surface mixed layer (Arrigo et al., 2012; Lowry et al., 2014, 2018), the subsurface phytoplankton blooms in the nutrient rich water beneath the surface mixed layer (Lowry et al., 2015; Martini et al., 2016), and the sympagic algal bloom (Gradinger, 2009; Poulin et al., 2011). There is also evidence of a late summer phytoplankton bloom, when summer/fall storms entrain water from the nutrient-rich lower layer (Hill et al., 2017; Ardyna et al., 2014). Together, the various blooms form Multiple Productive Layers that we term the MPL Hypothesis. The MPL hypothesis explains why the Chukchi Sea is highly productive even with a short growing season.

The Chukchi Sea is an inflow shelf (Carmack and Wassmann, 2006). The Arctic Marine Pulses Model describes the Chukchi Sea ecosystem as being dominated by various pulses from the Bering Sea into the Chukchi Sea and from the Arctic basin onto the Chukchi Shelf (Moore et al., 2018). On monthly time scales, inflow through Bering Strait is typically weak in the winter, but in summer this changes with a strong northward flow ($>1 \times 10^6$ m^3 s^{-1}) of relatively warm nutrient-rich, Bering Sea water into the Chukchi Sea (Coachman et al., 1975; Mordy et al., 2020. With the melting of sea ice, a strong pulse of carbon (e.g. ice algae) is exported to the benthic community—an important pelagic-benthic coupling that supports the rich benthic community of the Chukchi Sea (Grebmeier, 2012; Koch et al., 2020). Herein, we add that while there is a sudden pulse of ice algae to the bottom with sea ice melting; in the Chukchi Sea, this near-bottom water remains productive for weeks to months.

4.3. Comparison of Chukchi and Bering Seas

The relationship between the onset of the growing season and ice retreat for the Chukchi Sea also occurs in the northern Bering Sea, but not in the southeastern Bering Sea (Sigler et al., 2014). In the southeastern Bering Sea, the timing of the spring bloom (ice algae and phytoplankton) is dependent on ice and winds (Sigler et al., 2014). If ice retreats early (prior to March 15) or is not present at all, storms continue to mix the upper water column, and the spring bloom commences only after surface waters have warmed enough to stratify the vertical structure. This bloom is only composed of phytoplankton. If ice retreat is late, melt water stabilizes the water column and promotes an early spring, under-ice algal bloom, as well as an open-water phytoplankton bloom near the ice edge. The latter pattern is what occurs in the northern Bering Sea, at least until 2018 (Stabeno and Bell, 2019; Stabeno et al., 2019). In 2018, the lack of sea ice in the northern Bering Sea (mooring M8; 62.2°N, 174.7°W) resulted in a late (June) open water bloom, similar to what occurs in the southeastern Bering Sea during years when there is no ice on the southern shelf after 15 March. While subsurface blooms are uncommon in the southeastern Bering Sea, the northern Bering Sea is similar to the Chukchi Sea, with subsurface blooms being common (Stabeno et al., 2012).

The timing of the spring bloom in the southeastern Bering Sea affects the zooplankton species of the ecosystem, a phenomenon described as the Oscillating Control Hypothesis (OCH) (Hunt et al., 2002, 2011; Stabeno and Hunt, 2002). This control likely is spatially determined and related to the location of the ice edge (Siddon et al., 2013; Sigler et al., 2016). The region where the OCH is effective appears to be moving north as climate warms. For example, the entire eastern Bering Sea Shelf was largely ice free in the winter of 2017–2018, a radical change that was not predicted to occur for at least a few decades (Stabeno et al., 2012; Stabeno and Bell, 2019). The lack of ice had widespread effects on the survival of large crustacean zooplankton and juvenile walleye pollock (Duffy-Anderson et al., 2017). Whether and when the OCH region will move into the Chukchi Sea remains to be examined.

Continued productivity of ice algae that has sunk to the seafloor is probably much greater for the Chukchi Sea Shelf than the eastern Bering Sea Shelf, because the latter's bottom depth is mostly below the photic zone. The eastern Bering Sea Shelf deepens from east to west and the mid-shelf is 50–100 m deep whereas the eastern Chukchi Sea Shelf is predominantly shallower than 45 m. Thus, in the Bering Sea, primary production is limited to under-ice algal blooms, surface mixed layer phytoplankton blooms and subsurface phytoplankton blooms, while in the Chukchi Sea, there is evidence of additional disassociated ice algal production near the seafloor.

4.4. What are the consequences of a shorter ice season?

Sea ice in the Chukchi Sea has been arriving later and retreating earlier for ~30 years (Wood et al., 2015; Serreze et al., 2016; Stroeve et al., 2014) and this pattern is expected to continue (Wang et al., 2018). How changes in ice arrival and retreat will impact primary production in the Chukchi ecosystem is dependent upon how other ecosystem characteristics change. Consider two scenarios (from Berchok et al., 2015). As ice retreats earlier, there will be an earlier export of ice algae to the benthos, but the timing of the spring phytoplankton bloom depends upon wind conditions. If winds are strong, then the water column will be well mixed and the spring phytoplankton bloom will not set up until after winds weaken and water becomes stratified. In contrast, if winds are weak the water column will stratify with a warm, fresher (from ice melt) surface layer. This would support an earlier spring phytoplankton bloom. The first scenario will result in weaker stratification than the second scenario, allowing more short summer blooms supported by input of nutrients during wind events. The complexity of the system makes it difficult to predict how this ecosystem will react to changing ice conditions, but there is consensus on some changes.

With climate warming, there will be a decrease in the duration of sea ice over the Chukchi Sea (Wang et al., 2018). Earlier ice retreat will result in earlier export of ice algae to the seafloor, where there should be sufficient nutrients and light to support a near bottom algal bloom

(Tedesco et al., 2019). The one caveat to this scenario is: can the sea-ice retreat occur "too early". Considering that from our analysis there is insufficient light after the fall equinox to support algal production on the seafloor, it is likely that any ice algae dropping to the seafloor before the spring equinox, also will be non-productive. Ice retreat prior to the spring equinox, however, is not predicted to occur prior to 2050 (Wang et al., 2018). In contrast to earlier ice retreats, delayed ice return will have little impact on near-bottom algal blooms, since they are largely controlled by the availability of light.

Ice algae, however, is only one component in primary production in the Chukchi Sea. Changes in phytoplankton blooms in spring (upper mixed layer), in the summer (sub-pycnocline) and fall (near surface) have been discussed by others. In open water, phytoplankton production may increase, because of a longer growing season (Arrigo and van Dijken, 2015; Arrigo et al., 2008; Brown et al., 2015), although nutrients could be limiting. Once nutrients are consumed in the surface layer, a bloom often forms below the surface mixed layer (e.g. Martini et al., 2016; Lowry et al., 2015). This bloom can be substantial, providing more than a third of primary productivity in the Beaufort Sea (Martin et al., 2013). Churnside et al. (2020) suggest that with reduction in sea ice, the occurrence of these subsurface blooms could increase. These subsurface phytoplankton blooms would likely compete for nutrients with the near-bottom algal blooms and may reduce near-bottom algal production through shading.

5. Summary

The Chukchi Sea is highly productive even though the growing season is short. We provide evidence of production at multiple layers and hypothesize that near-bottom production is a result of disassociated ice algae near the seafloor. On the basis of this evidence, we propose the MPL hypothesis, where high production is promoted by a shallow seafloor, which allows multiple production layers (surface, sub-surface, sympagic ice algae, and disassociated ice algae near the seafloor; Fig. 2). High production occurs because the amount of light near the seafloor in mid-spring to early fall is similar to that measured beneath a 1.5-m thick ice floe. With sufficient light near the seafloor (~40 m deep), ice algae continue to photosynthesize, utilizing nitrate and producing oxygen through summer; a unique feature that pertains to this shallow shelf.

Bloom onset occurred in summer following ice retreat, whereas the end of the bloom occurred in September following loss of light. While this is a complex system, with multiple feedbacks and thus difficult to predict, our results do suggest certain possibilities. Even in a changing system with ice retreating later and arriving earlier, the primary change will be the timing of the export of ice algae to the bottom. Thus, the duration of near-bottom primary productivity will lengthen, because bloom onset occurs earlier.

Introduction: The Pacific Arctic marine ecosystem is rapidly changing due to ocean warming, sea ice loss, and increased advection via the Bering Strait. These physical changes are expected to impact the distributions of Arctic fish communities, and while climate-mediated range shifts of juvenile and adult fish populations are a major topic under study, less is known about how the early life stages (larvae) are responding.

Methods: In this study, we analyzed time series data of larval fish distributions sampled in the late summer (Aug-Sep) of 2010-2019 relative to ocean conditions in the northern Bering (NBS) and Chukchi Sea region (>60°N).

Results and Discussion: Multivariate analyses revealed the presence of 3 distinct multi-species assemblages in the region across all years: 1) a warmer water (≥7.4°C), lower latitude assemblage dominated by Yellowfin Sole (*Limanda aspera*); 2) a colder water (<4.6°C), higher latitude assemblage dominated by Arctic Cod (*Boreogadus saida*), Bering Flounder (*Hippoglossoides robustus*), and other common Arctic species; and 3) a mixed assemblage (4.6-7.4°C) comprised of the dominant species from the other two assemblages. We used partial least squares models to examine links between oceanographic and climate parameters and the areal coverage and center of distribution of each assemblage. We found that the areal coverage of the warmer water assemblage expanded further into the Chukchi Sea in years with higher NBS sea surface temperature (SST), strong Bering Strait northward advection, and increased southerly winds, while the colder water assemblage retracted its areal coverage in those years. Conversely, the colder water assemblage expanded in years with lower Chukchi Sea SST and greater sea ice area and extent. Additionally, we observed a general northward latitudinal shift of all NBS-Chukchi larval fish assemblages in recent warm years (2018-2019) characterized by strong northward winds and advection. Species-level abundance responses to temperature in the northeast Chukchi Sea varied such that lower latitude larval fish species increased in abundance in response to Arctic warming, whereas higher latitude species decreased in abundance (Fig. 1). Mid-latitude species responses to warming conditions varied, but were far less extreme than high-latitude and low-latitude Arctic species. These findings suggest that Arctic warming is most

significantly driving density changes in the leading and trailing edges of the larval fish community. Further, the patterns observed over the past decade in the region document how quickly larval fish communities track environmental change and suggest that climate warming and associated oceanographic processes could be leading toward a borealization of the Arctic by a warmer-water, lower latitude larval fish assemblage.

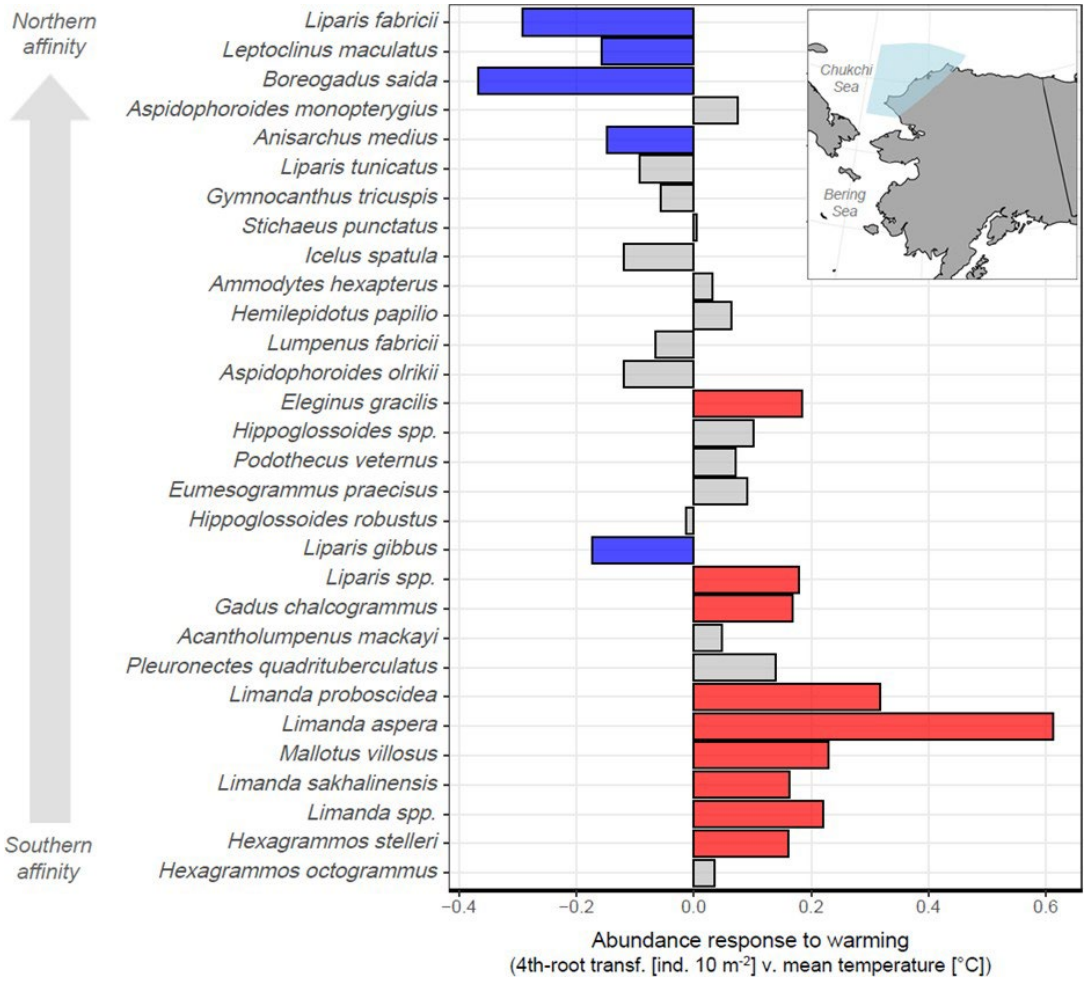

Fig. 1. Mean species-level relationships between the abundance (fourth-root transformed ind. 10 m^{-2}) of all 30 larval fish taxa examined in this study and temperature (°C) for all years pooled (2010-2019) during late summer in the northeast Chukchi Sea (calculated region shown in the blue polygon on the inset map). Spearman correlation coefficient values are given for each species' abundance and temperature pairing; positive correlations are displayed in red (indicating a significant increase in abundance in response to higher water temperatures), negative correlations in blue (indicating a significant decrease in response to warming), and grey indicates no significant response (correlations with $p \geq 0.05$). Taxa are sorted based on their mean latitudinal distribution in cold years (i.e., 2012-2013; proxy for average baseline Arctic conditions).

Abstract

Spatial and temporal patterns of primary productivity in the Arctic are expected to change with warming-associated changes in ice cover and stratification, yet productivity measurements are historically spatially and temporally limited. An established method to estimate net community production (NCP) rates involves measurement of dissolved oxygen/argon gas ratios (O_2/Ar) from a vessel's underway seawater system. An emerging method that may provide comparable NCP estimates involves measurement of oxygen/nitrogen ratios (O_2/N_2) with a gas tension device (GTD) and optode. The GTD/optode combo has several advantages: it is small, inexpensive, and suitable for autonomous deployments; however, the dissimilarity in solubility between O_2 and N_2 makes this tracer pair less favorable than O_2/Ar. We conducted a side-by-side comparison of a GTD and EIMS during the 2019 Arctic Integrated Ecosystem Survey OS1901-L1 in the Pacific Arctic. NCP from these two approaches were generally consistent throughout this cruise, with median NCP from O_2/Ar and O_2/N_2 of 7.33 ± 2.43 and 9.43 ± 2.73 mmol O_2 m^{-2} day^{-1} in comparable regions, respectively. While O_2/Ar and O_2/N_2 tracked each other in patterns, there were small deviations due to different sensitivities to physical drivers, which included a section in the Bering Strait where wind induced bubbles were the primary driver, followed by a period where both temperature and wind were thought to drive the differences between O_2/Ar and O_2/N_2. These results suggest that the GTD/optode can be used to enhance spatial and temporal coverage of NCP measurements. However, the GTD/optode approach is reliant on well-calibrated oxygen observations, a potential challenge if the GTD/optode is autonomously deployed. Uncertainty in the GTD/optode approach makes it well-suited to regions with strong gradients in NCP, while regions near equilibrium may result in unacceptably high uncertainty.

Chapter 12: Loss of sea ice alters distributions, abundance, and diet carbon sources of young Arctic forage fish in the Chukchi Sea

Abstract

Loss of sea ice can alter habitat for forage fish and copepods that function as important energetic links between primary producers and higher trophic levels, potentially impacting spatial distributions and diets with consequences to Arctic marine food webs. To address the impacts of loss of sea ice on pelagic lower trophic level taxa, we focus on the early life stages of two species of forage fish (polar cod: *Boreogadus saida* and saffron cod: *Eleginus gracilis*) and two copepod taxa (*Calanus* spp. and *Pseudocalanus* spp.) in the Chukchi Sea with differing reliance on sea ice environments. We assess distributions throughout years of varying sea ice extent (2010-2013, 2015, 2017-2018) and diets during two unprecedented warm years (2017-2018) using stable isotope analyses [bulk $\delta^{13}C$ and $\delta^{15}N$ and $\delta^{13}C$ compound-specific isotope analysis of amino acids]. *Calanus* spp. and polar cod were found primarily in northern Chukchi Sea in close proximity to recent sea ice, whereas saffron cod were rare and *Pseudocalanus* spp. were more evenly distributed. Spatial patterns in $\delta^{13}C$ stable isotopes were latitudinal but also showed inshore-offshore gradients in regions where ocean current converge suggesting shifts in baseline isotope values as well as the potential for water mass-associated changes in carbon sources. When sea ice was entirely absent from the Chukchi shelf during 2017, all taxa were broadly dispersed but *Calanus* spp. abundance was low, polar cod had a reduced isotopic (diet) breadth, and diet carbon sources for both saffron cod and polar cod differed from those of 2018 when sea ice was also low but not absent. Changes in distributions and diet associated with lack of sea ice in the summer indicate shifts in pelagic habitats that are likely to reverberate up Arctic marine food webs.

Introduction

The Arctic is warming at an accelerated rate compared to lower latitudes, leading to loss of sea ice and feedbacks that amplify the impacts of climate change (Serreze and Barry 2011). Warmer temperatures and an extended ice-free season have multiple impacts on Arctic marine ecosystems such as altering species distributions (Frainer et al. 2017) as well as the phenology

and magnitude of algal blooms (Ji et al. 2013) that impact marine food webs (Griffith et al. 2019). For high latitude taxa that function as important links between primary producers and higher trophic levels, loss of sea ice and changes in primary production may impact pelagic habitats and alter species' distributions and diets with consequences that ripple throughout Arctic food webs.

To better understand the impacts of loss of sea ice and ocean warming on high latitude ecosystems and species that are adapted to sympagic habitats, we focus on important zooplankton taxa and the early life stages of forage fish that are closely tied to changes in primary producers. Specifically, we assess: 1) distributions and abundance of Polar cod (*Boreogadus saida*) and saffron cod: (*Eleginus gracilis*) during years of differing ice extent, 2) spatial variability in $\delta^{13}C$ and $\delta^{15}N$ stable isotopes in anomalously low-ice extent years for Polar and saffron cod as well as co-occurring *Calanus* spp. and *Pseudocalanus* spp. copepods (henceforth *Calanus* and *Pseudocalanus*), and 3) whether loss of sea ice alters carbon sources for forage fish that are important linkages to higher trophic levels.

Methods

We assess spatial distributions from the years 2010-2018 of two forage fish species (Polar cod: *Boreogadus saida* and saffron cod: *Eleginus gracilis*) during the pelagic larval life stage, and two copepod taxa (*Calanus* and *Pseudocalanus*) using a combination of historic and recent survey data collected in the Chukchi Sea available through the National Oceanic and Atmospheric Administration Eco-FOCI Program. Spatial and between-year patterns in diet were determined using stable isotope analyses during two unprecedented warm years (2017 and 2018) using two approaches: bulk stable isotopes and compound-specific isotope analysis of amino acids (CSIAA).

Bulk stable isotope values were measured to address variability in $\delta^{13}C$ and $\delta^{15}N$ due to baseline variation and shifts in diet and trophic position. Copepod and fish isotopic niches, indicative of diet breadth, were assessed for years with low (2018) and no (2017) summer ice by calculating convex hull and standard ellipse areas from bulk $\delta^{13}C$ and $\delta^{15}N$ stable isotope values. Lipids are depleted in ^{13}C compared to other tissues (Post et al. 2007), so bulk $\delta^{13}C$ values were corrected to account for lipids in the tissue samples following (Marsh et al. 2017) using equation (1) for fish that was derived from a combination of aquatic animal whole tissue samples and samples with solely muscle tissue (Post et al. 2007) and equation (2) for copepods (El-Sabaawi et al. 2009):

$$\delta^{13}C_{cor} = \delta^{13}C_{measured} - 3.32 + 0.99 * C{:}N \quad (1)$$

$$\delta^{13}C_{cor} = \delta^{13}C_{measured} - 1.85 + 0.38 * C{:}N \quad (2)$$

Where $\delta^{13}C_{cor}$ (henceforth referred to as $\delta^{13}C$) is the lipid-corrected value, $\delta^{13}C_{measured}$ is the measured value from bulk isotope analyses, and C:N is the carbon to nitrogen ratio for each fish or copepod sample. Several methods were employed to determine interannual variability in isotopic niche. Convex hulls and standard ellipses both incorporate variability in $\delta^{13}C$ and $\delta^{15}N$, but standard ellipse calculations were performed using Maximum Likelihood with a correction for small sample size (SEA_C) as well as a Bayesian framework (SEA_B) to account for bias associated with sample sizes and to allow for comparison among unbalanced datasets (Jackson et al. 2011). Isotopic niche analyses were performed using the R package SIBER (Jackson et al.

2011). Survey and sample coverage differed among study years, therefore the samples included in the analyses were truncated based on the latitudinal extent of the sample collection for each species during the year with the smallest spatial coverage. Specimens collected far from land were also excluded for *Pseudocalanus* in 2018 because no isotope samples were obtained from the region in 2017. Total area of the truncated sample region (excluding land) was calculated for each species and year to compare with isotope niche (SEA_B).

Focusing on forage fish, variation in $\delta^{13}C$ was also assessed using CSIAA to better understand the drivers of variability in baseline carbon sources and potential differences in food web dynamics between years and species. CSIAA has advantages over bulk analyses because essential amino acids (AA) can only be synthesized by bacteria, fungi, and photoautotrophs. Essential AAs therefore show minimal trophic fractionation throughout the food web because they are routed from the diet directly into the tissue of the consumer, thereby minimizing the need for isotopic baseline measurements (McMahon et al. 2010).

Results

High abundances of Polar cod and *Calanus* spp. were generally found farther north in closer proximity to recent sea ice, whereas saffron cod larvae were rare and *Pseudocalanus* spp. were more evenly distributed throughout the Chukchi Sea (Fig.1). For all taxa and years, regardless of sea ice extent, there were consistent regions of aggregation in the northern Chukchi sea near Barrow Canyon (Fig. 1). Based on carbon stable isotope analyses ($\delta^{13}C$: bulk stable isotopes and CSIAA), diet carbon sources were broadly similar for all taxa during the two warm years (Figs. 2 and 3A), but showed some minor difference within species among years (Figs 2B and 3B, C). Spatial patterns in stable isotopes indicated that there were latitudinal and inshore-offshore gradients in bulk $\delta^{13}C$ (Fig. 2A). When late summer sea ice was entirely absent in 2017, basal carbon sources in Polar cod and saffron cod diets were almost indistinguishable (Fig. 3A) and isotope niche breadth was reduced for Polar cod compared to 2018, primarily due to reduced breadth of $\delta^{13}C$ but not $\delta^{15}N$ (Table 1, Fig. 2B).

Discussion

Spatial patterns in distributions and carbon sources suggest interactions between sea ice extent during the summer months and ocean currents that advect warm southerly water northward across the Chukchi shelf, impacting the distributions of copepods and forage fish as well as the composition of primary producers consumed by key taxa in Arctic food webs. Of the four focal taxa, Polar cod and *Calanus* spp. are more ecologically-linked to sea ice habitats than saffron cod and *Pseudocalanus* spp. (Søreide et al. 2010; Leu et al. 2011; Kohlbach et al. 2017; Bouchard and Fortier 2020), implying that these taxa may be more sensitive to shifts in sea ice extent. Indeed, distributions of both taxa were often restricted to the north near recent sea ice and concentrated in regions where ocean currents converge such as Barrow Canyon (Danielson et al. 2017). While *Calanus* spp. and *Pseudocalanus* spp. taxonomic resolution for this study likely includes multiple species, comparisons of distributions among the four taxa suggest that sea ice likely impacts the southerly extent of Arctic species that are closely tied with sympagic habitats, which is not evident for taxa that are less tightly coupled with sea ice ecosystems and sea ice algal blooms.

Polar cod diet breadth and carbon sources shifted between low ice years to a greater degree than other taxa, suggesting that even the impacts of small changes in ice extent on pelagic conditions may affect basal carbon sources and feeding for a key species in Arctic food webs. Polar cod eggs hatch under the ice during the spring (Bouchard and Fortier 2008) and small larvae prey on copepod nauplii that feed on sea ice algae (Kohlbach et al. 2017). As they growth, larval Polar cod transition to broader diets that also include larger prey items such as lipid-rich *Calanus glacialis* copepods (Michaud et al. 1996). During a year with no summer sea ice, Polar cod diet breadth was more restricted and basal carbon sources from CSIAA were almost indistinguishable from saffron cod. In contrast, during 2018 when ice was minimal but present at some sampling stations (*personal observation*), Polar cod diet breadth was greater. Notably, bulk $\delta^{13}C$ values diverged from north to south, suggesting that shifts in diet breadth could be driven by both changes in advection and associated water mass composition as well as loss of sea ice that impacts primary producers. However, carbon source variation based on CSIAA also indicated slight shifts in diet between low ice years, suggesting alterations in baseline carbon sources for Polar cod. Such shifts highlight the sensitivity of Polar cod to changing conditions in the Arctic and suggest that lack of sea ice may force young fish to diverge from ice-associated carbon sources that typically contribute to Arctic food webs. Changes in distributions coupled with altered trophic relationships suggest broad consequences and potentially the borealization of Arctic ecosystems that could impact trophic structure and pelagic food web length and composition.

Manuscript in preparation for Geophysical Research Letters

Based on year-round measurements of nutrients from summer 2017-2018 from the Anadyr Strait, we use a combination of year-round mooring-based in situ measurements and salinity-nutrient relationships established at Anadyr Strait are used to estimate Pacific-to-Arctic fluxes of nitrate, phosphate, and silicate for each month spanning 1998-2018. Annually averaged fluxes are 16 ± 5, 1.6 ± 0.5, and 30 ± 10 kmol s^{-1} for nitrate, phosphate, and silicate, respectively, and inter-annual variability can reach ±30% of the means. Maximum fluxes occur in April, exceeding the annual average by ~50%, while minimum fluxes occur in December. Due to biological uptake, the seasonality of nutrient fluxes is more closely tied to nutrient concentration than transport, which peaks in June. Our annually averaged estimates are ~ 50% higher than prior estimates, which may be rooted in methodological differences. We find significant ($p < 0.05$) increasing trends in phosphate and silicate fluxes over 1998-2018 that are associated with increasing transport. In contrast, nitrate exhibits no significant long-term trend, suggesting different nutrient composition ratios between surface and deep waters. Our data, taken from the core of the Anadyr current, will be valuable for assessing biogeochemical model performance at a globally important oceanic chokepoint and can contribute to studies that seek to understand the future trajectory of the Arctic ecosystem.

1 Introduction

The Arctic Ocean is experiencing rapid and accelerating change due to an anthropogenically altered climate (Zhang et al. 2005; Polyakov et al. 2020), including reduction of sea ice extent volume (Comiso et al. 2006, Frey et al. 2015, Wang et al. 2018), and altered growing conditions (e.g., changes in timing, temperature, and light availability) for marine phytoplankton (Arrigo et al. 2008, Codispoti et al. 2009, Neeley et al. 2018, Lewis and Arrigo, 2020). Consequently, the Arctic marine ecosystem may exhibit changes even to the character of the ecosystem services that it provides (Huntington et al., 2020), including critical habitat for marine mammals and seabirds, subsistence harvests vital to indigenous communities, and its globally important role in carbon export and sequestration.

The Arctic has limited connectivity to the rest of the world's oceans. Bering Strait is the only link to the Pacific ocean, and is relatively narrow and shallow, ~ 85 km across, with an average depth ~ 50 m, and an annual average throughflow of about 1.0 Sv (10^6 m^3s^{-1}) (Woodgate, 2018). The Anadyr Current (Fig. 1a) delivers approximately 80% of the Bering Strait transport through Anadyr Strait (Overland and Roach, 1987; Muench et al., 1988; Danielson et al., 2014). The two straits are separated by less than 250 km and the advective time scale is as little as 10 days (Coachman, 1993). Due to characteristically low nutrient concentrations on the eastern Bering shelf (Danielson et al. 2011), the Anadyr Current delivers the vast bulk of nutrients that are advected into the Arctic through Bering Strait. This nutrient-rich flow is thus singularly responsible for maintaining the remarkably high levels of pelagic and benthic biological productivity found downstream in Chirikov Basin and the Chukchi Sea (Grebmeier et al., 2015).

Relatively little work has evaluated Arctic-bound nutrient fluxes directly at Bering Strait. Torres-Valdes et al. (2013) used data from a single cross-strait transect from summer of 2005 in combination with modeled currents to estimate annually averaged fluxes into the Chukchi Sea. They found poleward fluxes of 9.0±0.8, 1.3±0.1, and 20.9±2.4 kmol s^{-1} for nitrate, phosphate, and silicate, respectively. Zhao et al. (2021) used a coupled physical and biogeochemical numerical model to estimate ~10 kmol s^{-1} of nitrate through Bering Strait. Downstream in the Chukchi Sea, Mordy et al. (2020) found considerable variability in winter nitrate flux (ranging between 0-10 kmol s^{-1} during 2010-2018). Here, we seek to build upon these results and provide an updated set of observation-based nutrient flux estimates by using a year of mooring-based measurements from Anadyr Strait (2017-2018) and long term mooring observations in the Bering Strait (1998-2018).

2 Data

2.1 Shipboard Hydrography

Nutrient and CTD hydrographic data from several ship-based observation programs that sampled in the Northern Bering and Southern Chukchi seas are used to characterize the regional nutrient distribution. All cruises took place between April and September (Fig. 1a) and in aggregate the collection includes over 500 vertical profiles (spanning 2004-2018). See supplementary Table A2 for more information on these cruises.

2.2 Moorings

2.2.1 Anadyr Strait Mooring

A subsurface mooring (N2) was deployed in 46 m of water in Anadyr Strait (Fig. 1a) from 12 June 2017 to 9 June 2018. At 64.1545 °N, 174.5260 °W. N2 was equipped with the following: three conductivity-

temperature-depth (CTD) sensors, a fluorometer, an acoustic Doppler current profiler (ADCP), submersible ultraviolet nitrate analyzer (SUNA), and an Aqua Monitor to collect bag samples for nutrient analysis. The SeaBird Electronics CTDs were mounted at 25 m (SBE-16, 120 minute sampling), 35 m and 41 m (SBE-37s with 15 minute sampling) depths. The WetLabs AFL fluorometer was mounted at 25 m depth (120 minute sampling). The upward-looking 300 kHz Teledyne RDI ADCP was mounted at 41 m depth (30 minute ensembles of 1-m bins). The SUNA V2 was mounted at 35 m depth (120 minute sampling). The Green Eyes Aqua Monitor discrete water sampler was mounted at 35 m depth. Between 12 June 2017 and 09 June 2018, twenty five 500 mL water samples were collected, each prepared with 400 μL of saturated mercuric chloride solution to halt microbial growth. Upon recovery, samples were analyzed for nitrate (NO_3), nitrite (NO_2), ammonium (NH_4) phosphate (PO_3) and silicate (SiO_4). All records were subjected to quality assurance protocols that are described in the archived datasets.

Immediately following mooring deployment, the Aqua Monitor collected four samples spanning 45 minutes to estimate repeatability and thereafter once every 9-31 days (averaging once every 17 days, see Supplementary Table S1).

2.2.2 Bering Strait Mooring

At Bering Strait, we employ monthly estimates of salinity and transport (Woodgate et al. 2015, Woodgate 2018) based on measurements from the long-term A3 mooring (Fig. 1a), which has been site of continuous monitoring from 1997 to the present and is representative of the Bering Strait through-flow (Woodgate 2015). Our estimates do not include contributions from the Alaskan Coastal Current (ACC), which contributes ~ 10% of the net transport but is generally nitrate-deplete (Danielson et al., 2017).

3. Results

3.1 Nutrient Biases and Corrections

Niskin bottle nutrient samples from the N2 mooring deployment and recovery cruises provide a means to correct both the SUNA and Aqua Monitor data for offsets and drift (e.g. Daniel et al., 2020). The Niskin samples (not shown) exhibit a well-mixed water column within ± 10 m of the Aqua Monitor at deployment, with average $NO3_{CTD}$=17.7±0.5, $PO4_{CTD}$=1.80±0.02, and $SiO4_{CTD}$=28.1±0.8 μM from 6 samples (± indicates standard deviation). Upon deployment, Aqua Monitor concentrations were as follows: $NO3_{AM}$ = 15±2, $PO4_{AM}$=1.9±0.1, and $SiO4_{AM}$=24±3. These samples suggest initial Aqua Monitor biases of about -3, +0.1, and -4 μM, and measurement uncertainties of ±2, ±0.1, and ±3 μM (nitrate, phosphate, and silicate, respectively). Upon recovery one year later, CTD profiles suggest the water column was well mixed within ±5 m of the Aqua Monitor, with average $NO3_{CTD}$=12.9±0.3, $PO4_{CTD}$=1.75±0.05, and $SiO4_{CTD}$=27±1 μM from 5 samples, where a single Aqua Monitor sample measured $NO3_{AM}$=12.9, $PO4_{AM}$=1.9, $SiO4_{AM}$=23.6. These samples suggest final Aqua Monitor biases of approximately 0, +0.1, and -3 μM (nitrate, phosphate, and silicate, respectively). We assume a linear drift between the deployment and recovery biases over the yearlong deployment, and adjust Aqua Monitor nutrient concentrations accordingly. Similarly, the bias at deployment (recovery) for the SUNA nitrate was 4.1 μM (deployment) and 0.3 μM (recovery), and concentrations were again adjusted assuming linear drift. Post corrections, the two measures of NO_3 at mooring N2 (Aqua Monitor and SUNA) are strongly correlated over the year-long deployment (root-mean-square-difference=2.3 μM, r=0.87 and $p<0.01$, Fig. 2e). The offset between SUNA and Aqua Monitor nitrate does not have a significant temporal trend, and the good agreement between these independent data provide evidence of the proper functioning of both instruments.

3.2 Salinity-nutrient relations

Ship-based hydrography from across the northern Bering Sea shelf and continental slope exhibit a nearly monotonic relationship between salinity (S_{HYD}) and nitrate ($NO3_{HYD}$) for measurements collected >100 m (Fig. 2a, dark grey dots), corresponding to parameter ranges of about S_{HYD}=33-34 and $NO3_{HYD}$=25-45 μM. Extrapolation of this mixing line to full nitrate depletion at salinity ~ 31 PSU closely approximates the maximum observed nitrate concentration for all salinities in the range of 31-34 (Fig. 2a), suggesting that in absence of nitrate draw-down due to biological production, mixing between the nitrate rich slope waters and the nitrate deplete shelf waters (upper 10-20 m throughout the southern Bering Sea) primarily regulates nutrient concentration. While it is not clear exactly what range of depths the Anadyr Current draws its source waters from, near-bottom observations of nitrate up to 30 μM in Anadyr Strait (Walsh et al., 1989) and typical vertical profiles from the slope region (Fig. 1c) suggest that the core of the Anadyr Current must draw slope waters from at least 100 m depth. In the absence of mixing, water from 100 m at the slope would provide a salinity of ~ 33.1 and NO_3 of ~ 28.2 (based on 14 samples taken from 100 m depth over the Bering slope with salinity and nitrate ranges of 33.0-33.3 and 24.5-30.4, respectively). If the Anadyr Current waters mix with lower-salinity shelf waters during their transit to Anadyr Strait, the mean source depth could be even greater.

In the aggregate, nutrient estimates from the Aqua Monitor near 35 m depth at N2 are not tightly coupled with *in situ* salinity (S_{N2}) from the co-located SBE37 instrument but significant relationships emerge when the data are partitioned seasonally (Fig. 2a-d), according to expected nutrient drawdown or regeneration. We divide the mooring data into three intervals, each with different environmental conditions: 1) January to April (cold, ice-covered, dark), 2) May to August (warming, ice-free or declining sea ice conditions, high light availability), and 3) September to December (warm, ice-free, decreasing light availability). The moored S_{N2} data is strongly correlated with $NO3_{AM}$ from January-April (orange) ($r=0.99$, $p<0.01$, $N=6$) and September-December (pink) ($r=0.97$, $p< 0.01$, $N=5$), but the relationship breaks down even at this sub-pycnocline depth for May-August (green) ($r=0.50$, $p=0.10$, $N=13$). The offset between the fall and winter regression lines is attributed to the fall season being at the end of the growing season where nutrients not yet fully replenished from the summer biological drawdown. The winter samples all fall close to the "upper limit" bounding mixing line between high-salinity, high-nitrate slope waters (e.g., salinity=33, nitrate = 30) and low-salinity, low-nitrate shelf waters (e.g., salinity=31, nitrate = 0). These results show that for the weakly stratified fall and winter seasons, salinity is a allows for a potentially useful estimate of nitrate in the Anadyr Current.

While it is possible to modestly improve the salinity-nitrate correlations with different grouping strategies (e.g. finer monthly partitioning), here we seek to avoid over-fitting to the individual year of data collection in favor of a coarser strategy that is generalizable to different years. Using detrended (Section 3.1) Aqua Monitor nitrate and SBE salinity at mooring N2, we perform linear least squares regressions to parameterize nitrate concentration ($NO3_{EST,N2}$) based on a known salinity (S_{N2}), such that

$$NO3_{EST,N2} = C_1 S_{N2} + C_2 \qquad \text{Eq. 1}$$

C_1 and C_2 are coefficients calculated for each of the three seasonal time frames described previously (Fig. 2b).

Table 1. Summary of trawling effort in the Chukchi Sea included in this study.

Year	Months	Trawl type (model)	Mouth opening	Max. mesh (mm)	Min. mesh (mm)	No. stations	Chukchi Sea Region
2010	Sep.	Large-mesh benthic (DT 27.1/24.4)	16.2 m horiz.	80	10	38	Western
2012	Aug. - Sep.	Large-mesh benthic (83-112)	17.0 m horiz.	100	31	71	Eastern
2012	Aug. - Sep.	Small-mesh benthic	2.1 m horiz.	7	4	40	Eastern
2017	Aug. - Sep.	Surface	18 m horiz. X 24 m vert.	1620	12	17	Eastern
2017	Aug. - Sep.	Midwater	7.5 m horz. X 7.9 m vert.	64	30	33	Eastern
2017	Aug. - Sep.	Small-mesh benthic	2.1 m horiz.	7	4	60	Eastern
2018	Aug. - Sep.	Large-mesh benthic (DT 27.1/24.4)	16.2 m horiz.	80	10	54	Western
2019	Aug. - Sep.	Surface	18 m horiz. X 24 m vert.	1620	12	10	Eastern
2019	Aug. - Sep.	Midwater	7.5 m horz. X 7.9 m vert.	64	30	42	Eastern
2019	Aug. - Sep.	Small-mesh benthic	2.1 m horiz.	7	4	49	Eastern
2019	August	Large-mesh benthic (DT 27.1/24.4)	16.2 m horiz.	80	10	79	Western

Table 2. Prey-specific relative index of importance (PSIRI) for prey taxa by trawl type for Pacific cod small juveniles collected in the eastern Chukchi Sea in 2017. Only prey items with PSIRI greater than 3 are listed.

Trawl Type	Prey Taxa	Prey Group	PSIRI
Small-mesh benthic	Polychaeta	Annelid worm	13.57
Small-mesh benthic	Eurytemora herdmandi	Calanoid copepods, <2.5 mm Total length	13.55
Small-mesh benthic	Nematoda parasite	Unidentified	10.55
Small-mesh benthic	Euphausiidae juv/adult	Euphausiids, j+a	10.00
Small-mesh benthic	Decapoda	Decapoda	8.83
Small-mesh benthic	Cistenides spp.	Annelid worm	5.59
Small-mesh benthic	Margarites spp.	Gastropod	4.41
Small-mesh benthic	Argis spp.	Carideans	3.21
Small-mesh benthic	Paguridae juv/adult	Anomuran crab	3.06
Midwater	Calanoida (<2.5 mm)	Calanoid copepods, <2.5 mm Total length	17.68
Midwater	Actinopterygii	Fish	17.48
Midwater	Caridea	Carideans	17.01
Midwater	Gadiformes	Fish	12.89
Midwater	Cirripedia cypris	Barnacle	8.72
Midwater	Centropages abdominalis	Calanoid copepods, >2.5 mm Total length	8.09
Midwater	Brachyura megalopa	Brachyuran crab	6.80
Midwater	Paguridae zoea	Anomuran crab	6.04
Surface	Centropages abdominalis	Calanoid copepods, >2.5 mm Total length	31.41
Surface	Calanoida (<2.5 mm)	Calanoid copepods, <2.5 mm Total length	31.28
Surface	Decapoda	Decapoda	13.45
Surface	Crustacea	Crustacean	8.33
Surface	Pseudocalanus spp.	Calanoid copepods, <2.5 mm Total length	7.34
Surface	Brachyura megalopa	Brachyuran crab	5.73

Table 3. Comparison of Catch per Unit Effort (CPUE) in this and other studies from Alaskan waters using a similar 3-meter beam trawl based on the design of Gunderson and Ellis (1986). Where noted, the trawls were based on the modified design of Abookire and Rose (2005).

Large Marine Ecosystem	Area	Year	Trawl Design	Mean Pacific cod km^{-2}	Reference
Chukchi Sea	20-29m depth range	2017	Abookire and Rose (2005)	6,200	This study
Chukchi Sea	30-39m depth range	2017	Abookire and Rose (2005)	2,800	This study
Chukchi Sea	20-29m depth range	2019	Abookire and Rose (2005)	0	This study
Chukchi Sea	30-39m depth range	2019	Abookire and Rose (2005)	1,800	This study
Bering Sea	Alaska Peninsula <50m depth	2012	Abookire and Rose (2005)	2,200	Hurst et al., 2015
Gulf of Alaska	Kachemak Bay	1994	Gunderson and Ellis (1986)	100	Abookire et al., 2001
Gulf of Alaska	Kachemak Bay	1995	Gunderson and Ellis (1986)	48,700	Abookire et al., 2001
Gulf of Alaska	Kachemak Bay	1996	Gunderson and Ellis (1986)	0	Abookire et al., 2001
Gulf of Alaska	Kachemak Bay	1997	Gunderson and Ellis (1986)	50,300	Abookire et al., 2001
Gulf of Alaska	Kachemak Bay	1998	Gunderson and Ellis (1986)	200	Abookire et al., 2001
Gulf of Alaska	Kachemak Bay	1999	Gunderson and Ellis (1986)	600	Abookire et al., 2001

Figure 1. Map of the study area in the Chukchi and northern Bering Seas and the surrounding area.

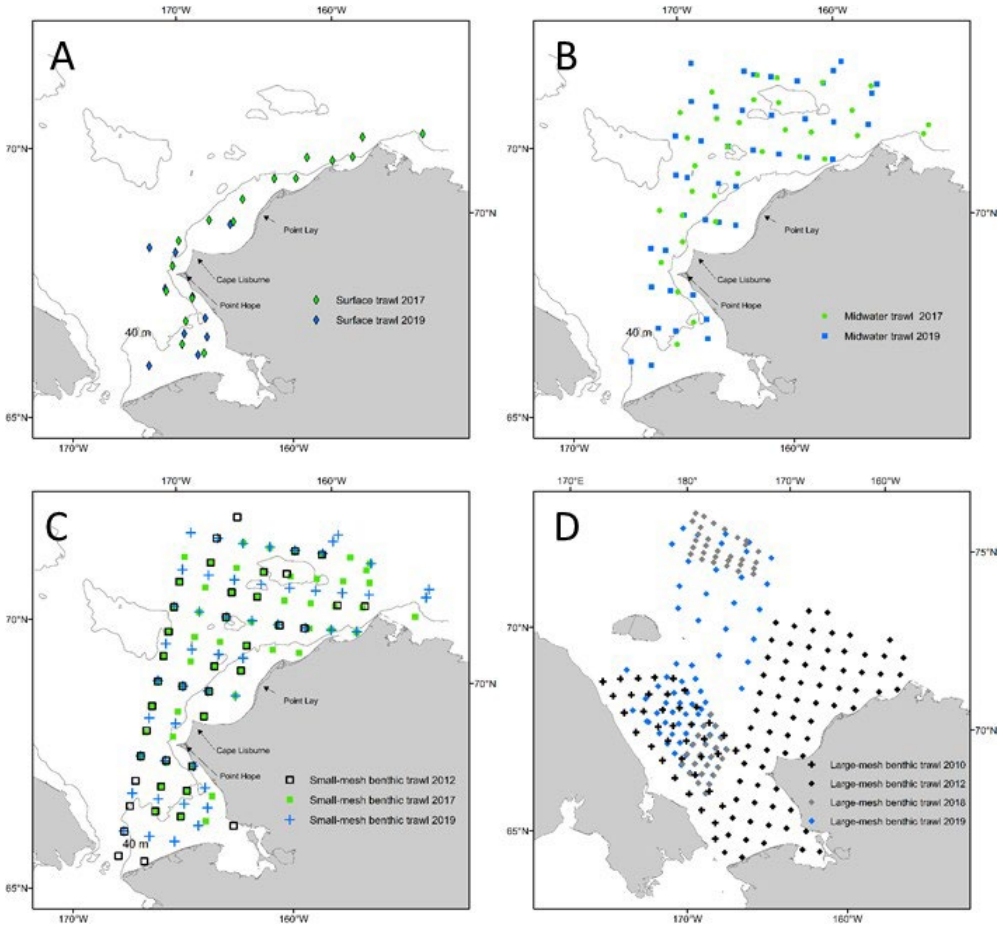

Figure 2. Maps of trawl sampling effort by trawl type and sampling year for A) surface trawl, B) midwater trawl, C) small-mesh benthic trawl, and D) large-mesh benthic trawls.

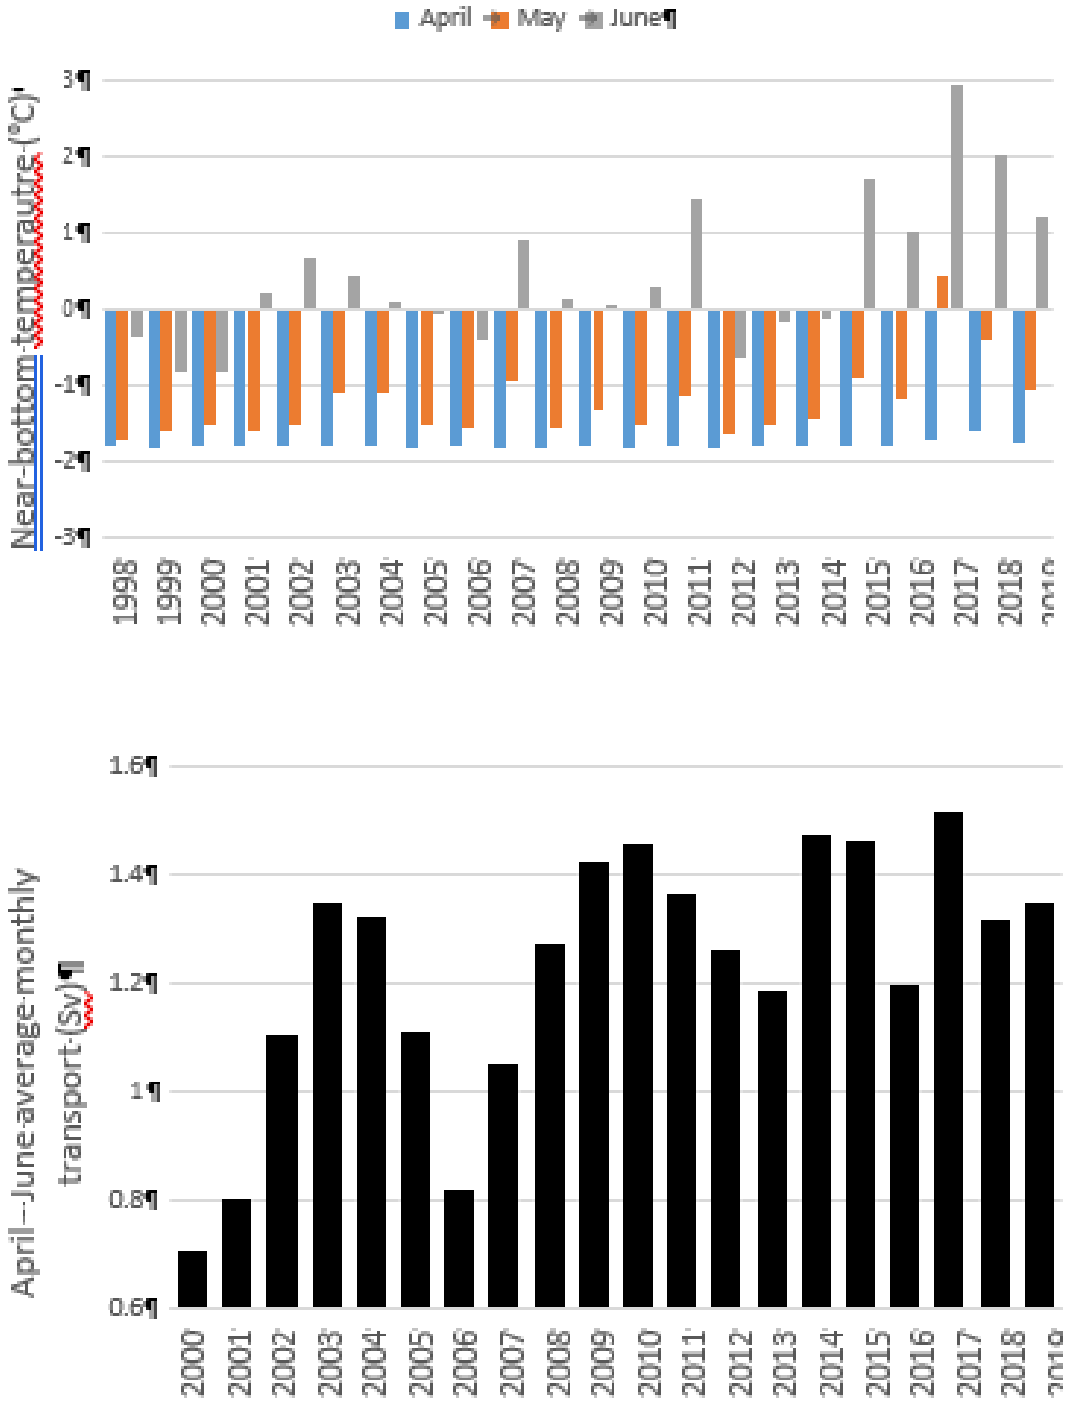

Figure 3. Environmental measurements from the A3 mooring north of the Bering Strait. Monthly-averaged near bottom temperatures in April – June from 1998 through 2019 (Top panel) and mean of average monthly northward transport from April – June in 2000 – 2019 (Bottom panel).

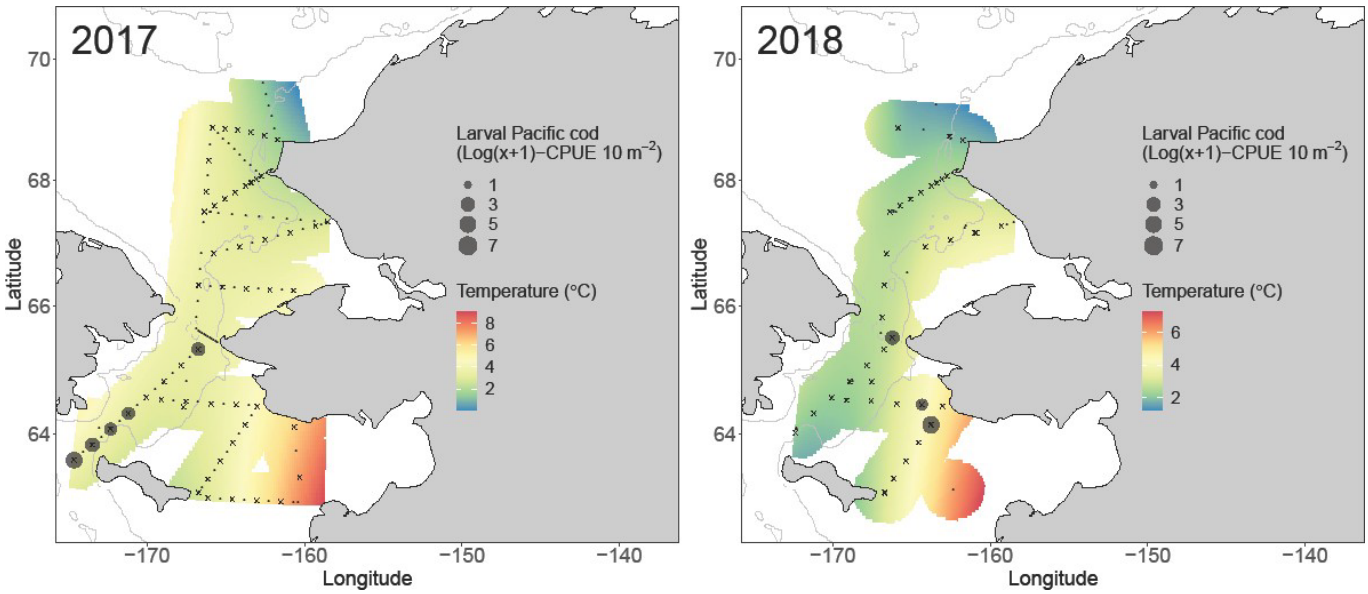

Figure 4. Pacific cod larval distributions and interpolated mean water column temperature in the Northern Bering and Chukchi Seas in June 2017 and 2018. “X” indicates zero catch.

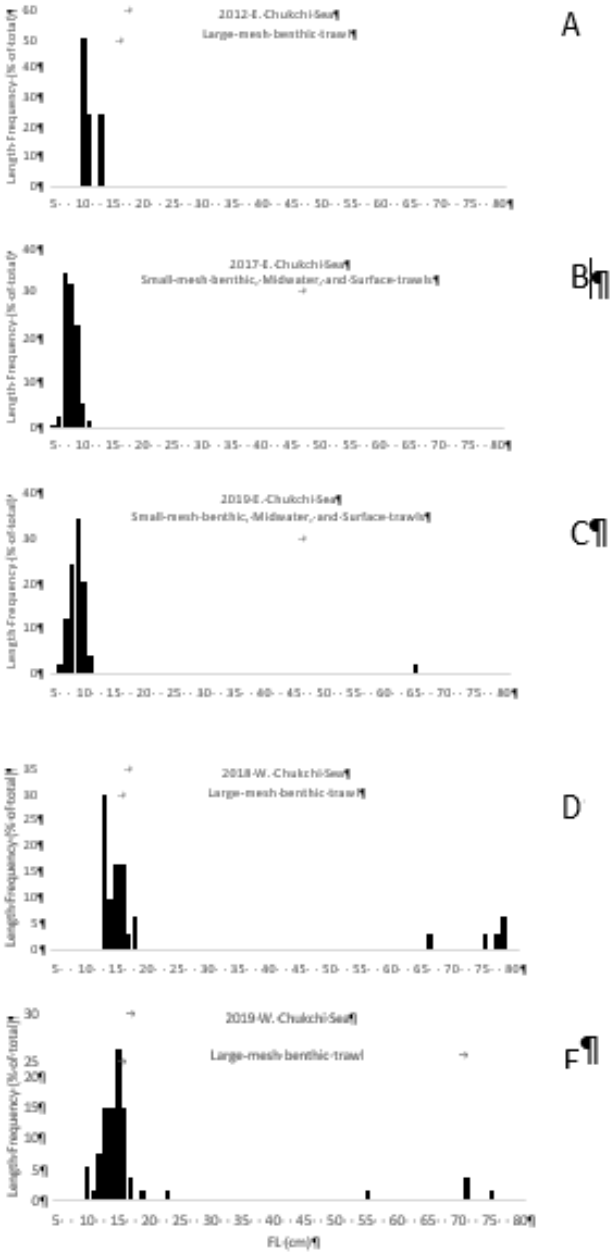

Figure 5. Length frequency distributions for Pacific cod caught in the Chukchi Sea in: A) 2012 in a large-mesh trawl in the eastern Chukchi Sea, B) 2017 in three trawls (small-mesh benthic trawl, midwater trawl, and surface trawl) in the eastern Chukchi Sea, C) 2019 in three trawls (small-mesh benthic, midwater, and surface) in the eastern Chukchi Sea, D) 2018 in a large-mesh benthic trawl in the western Chukchi Sea, and E) 2019 in a large-mesh-benthic trawl in the western Chukchi Sea.

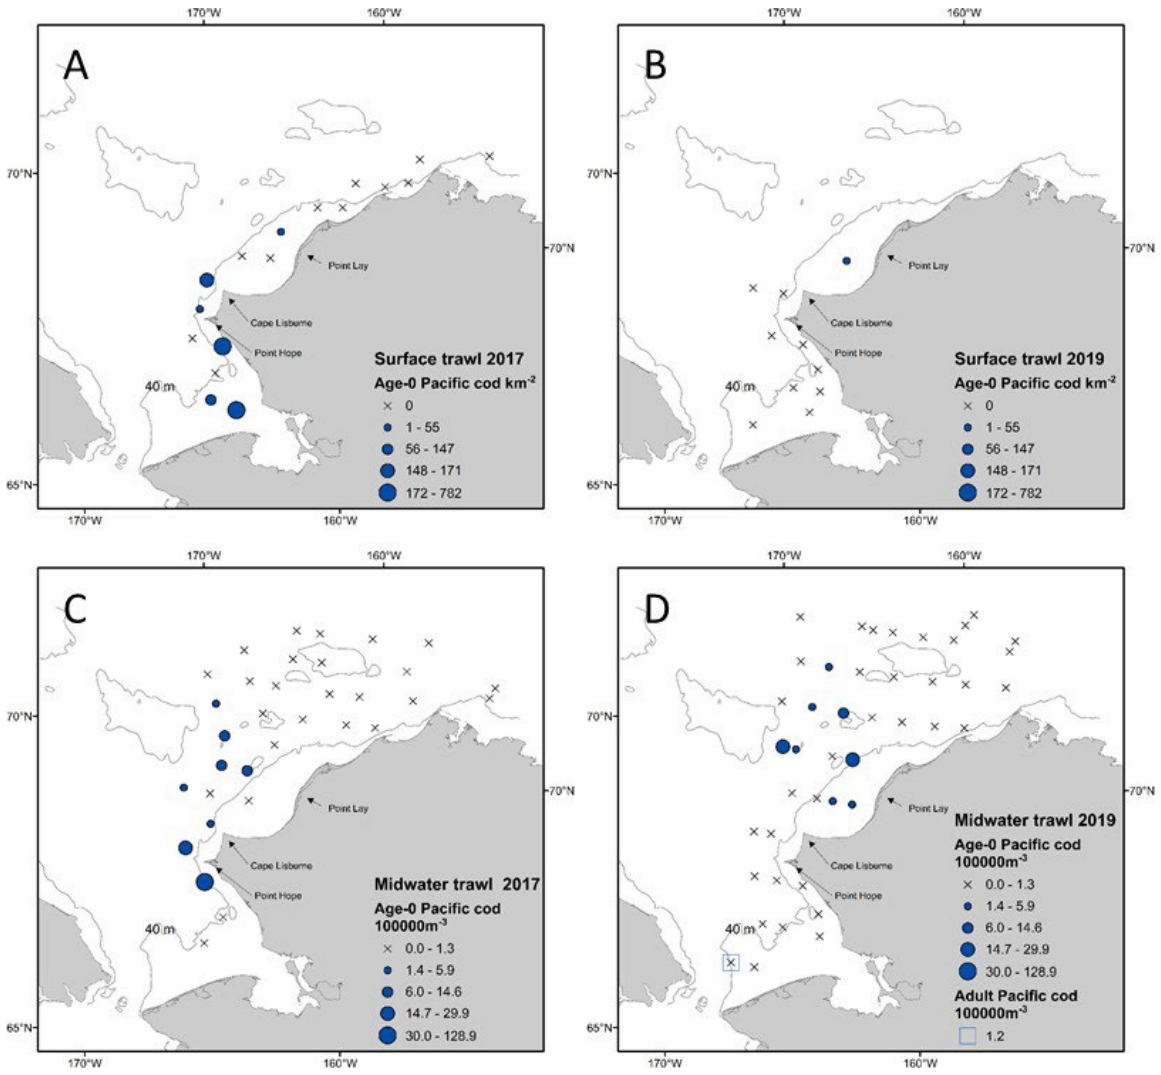

Figure 6. Distribution and catch per unit effort of Pacific cod caught in: A) the surface trawl in 2017; B) the surface trawl in 2019; C) the midwater trawl in 2017; D) the midwater trawl in 2019.

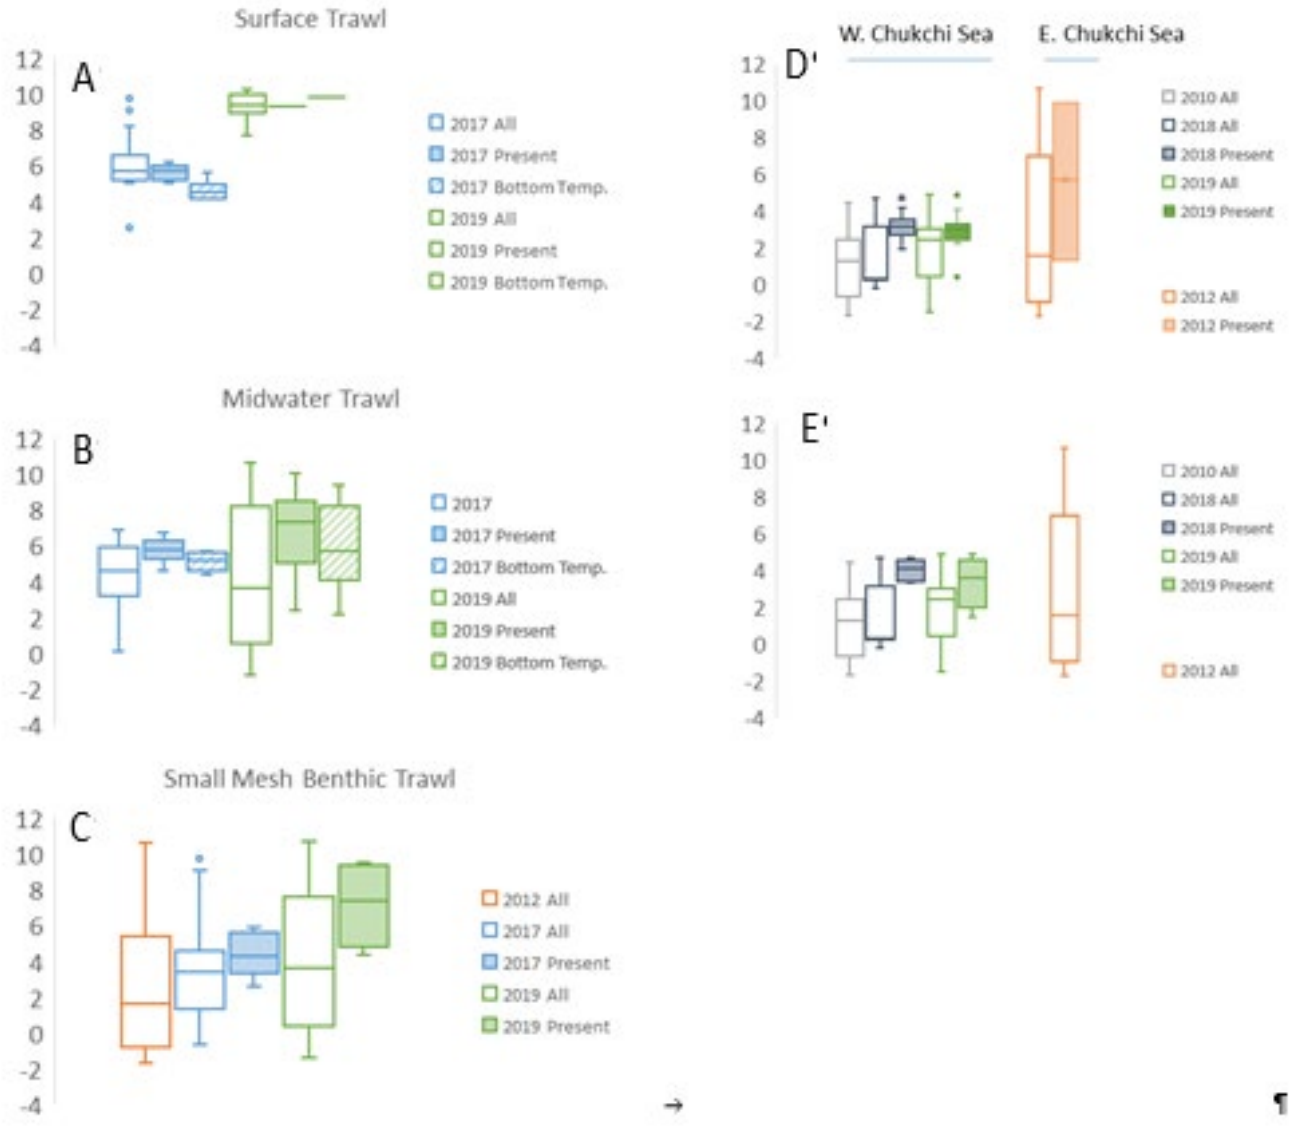

Figure 7. Boxplots of water temperatures at trawl stations in the Chukchi Sea by trawl type and year: A) surface trawl for age-0 Pacific cod sampling, B) midwater trawl for age-0 Pacific cod sampling, C) small-mesh benthic trawl for age-0 Pacific cod sampling, D) Large-mesh benthic trawl for age-1 Pacific cod sampling and E) Large-mesh benthic trawl for adult Pacific cod sampling. Open boxplots represent gear temperatures at all sampled stations. Filled boxplots represent gear temperatures at stations with Pacific cod presence. Striped boxplots represent bottom temperatures at stations where Pacific cod were present in pelagic (surface and midwater) trawls.

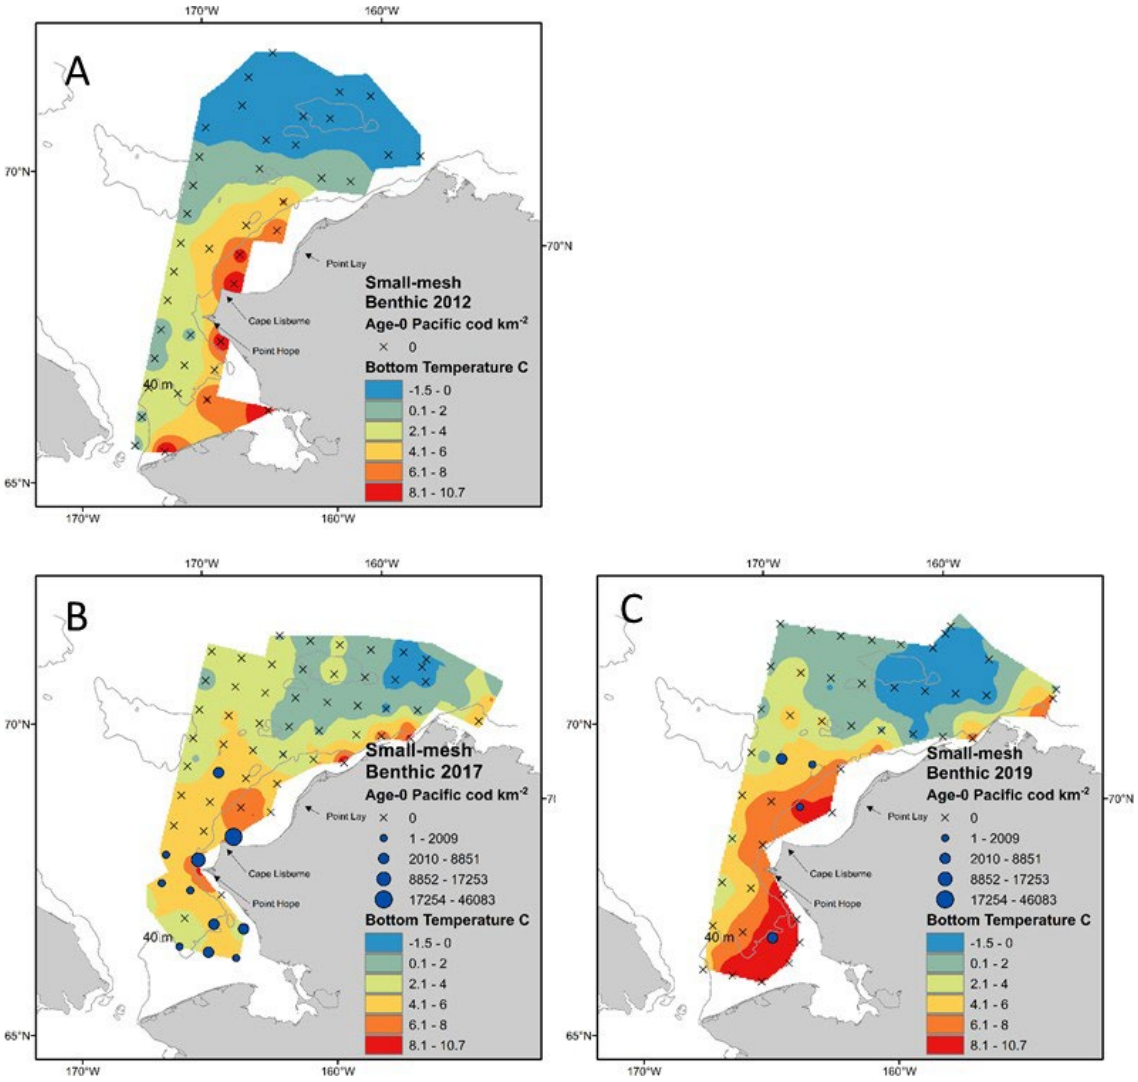

Figure 8. Maps of catch per unit effort of age-0 Pacific cod caught in the small-mesh benthic trawl and interpolated bottom temperatures for three survey years: A) 2012; B) 2017; and C) 2019.

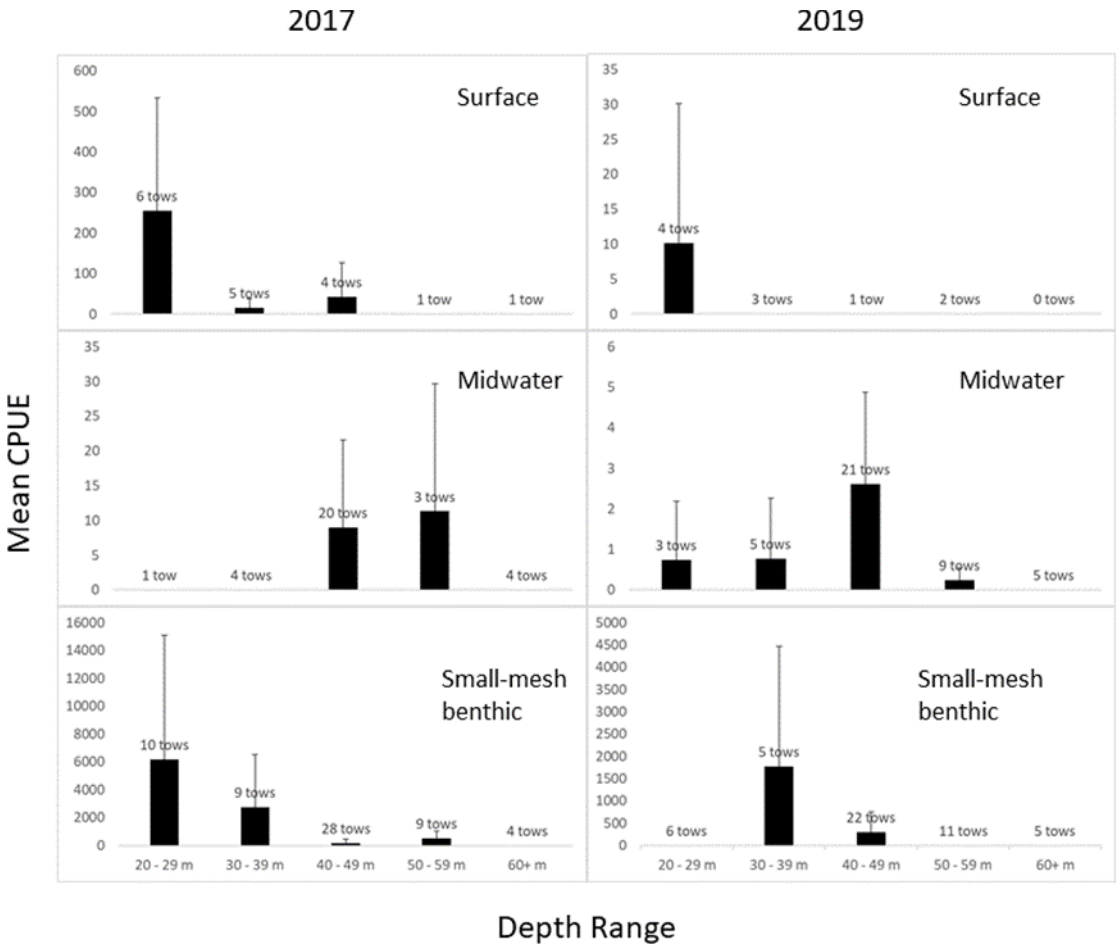

Figure 9. Mean catch per unit effort (CPUE) of age-0 fish by bottom depth range for each gear type in 2017 and 2019. CPUE units are number of fish per km^2 for the surface and small-mesh benthic trawls, and number of fish per 100,000 m^3 for the midwater trawl. Error bars represent 95% confidence interval.

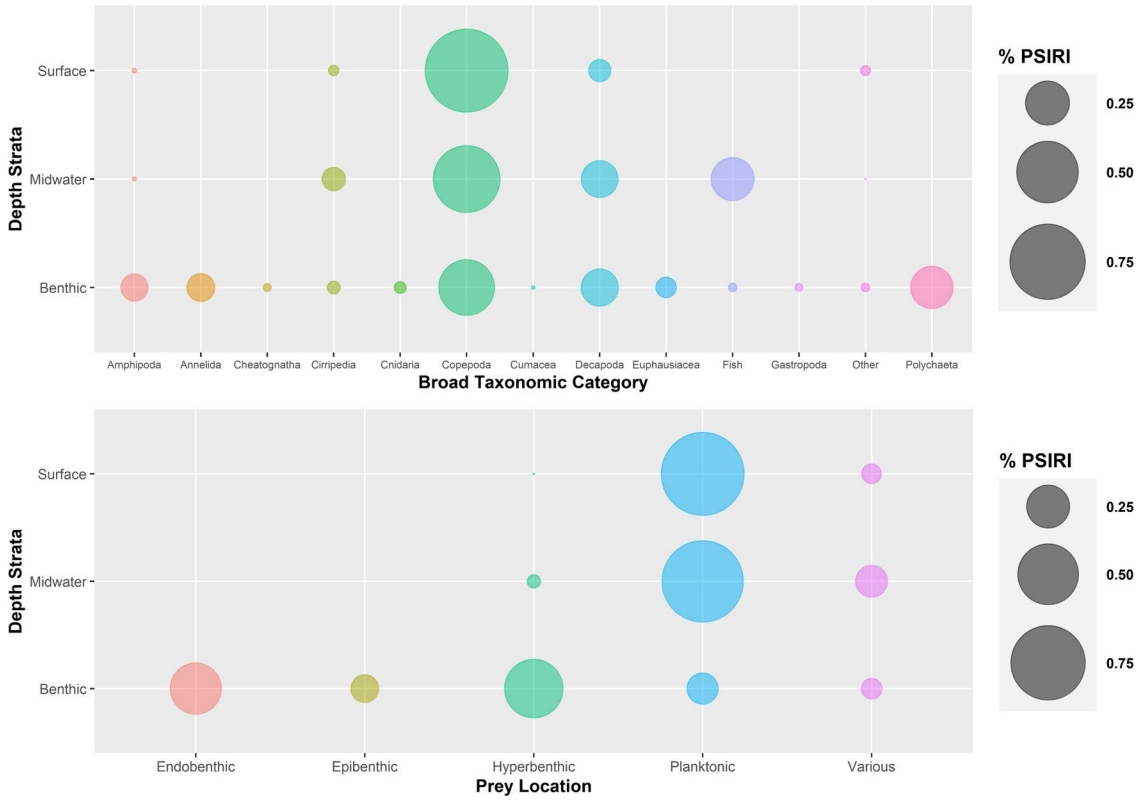

Figure 10. Prey specific relative index of importance (PSIRI) of prey items in the diet of small juvenile Pacific cod caught in 2017. Top panel depicts PSIRI by prey taxonomic groups, and bottom panel depicts PSIRI by prey general habitat classification.

CHAPTER 14 - Response of Pink salmon to climate warming in the northern Bering Sea

Objective 4: Establish the relative abundance, size, and condition of juvenile salmonids that utilize the coastal regions of the PAR.

Farley, E.V., Jr., J.M. Murphy, K. Cieciel, E.M. Yasumiishi, K. Dunmall, T. Sformo, P. Rand. Response of Pink salmon to climate warming in the northern Bering Sea. Deep-Sea Research II https://doi.org/10.1016/j.dsr2.2020.104830.

Abstract

Life-history and life-cycle models of Pink salmon (*Oncorhynchus gorbuscha*) are developed to provide insight into production dynamics of northern Bering Sea Pink salmon. Arctic ecosystems, including freshwater and marine ecosystems in the northern Bering Sea, are warming at a rapid rate. Due to their short, two-year life cycle, Pink salmon are well known to respond rapidly to ecosystem change and can provide unique insight into ecosystem impacts of warming Arctic conditions. Life-cycle models suggest a lack of density-dependence for adult Pink salmon spawners in the Yukon River and potential for some density-dependence for adult Pink salmon spawners in the Norton Sound region. Life-history models identify a positive and significant relationship between the abundance index for juvenile Pink salmon and average Nome air temperature during their freshwater residency (August to June). This relationship supports the notion that warming air temperatures in this region (as a proxy for river and stream temperatures) are contributing to improved freshwater survival or increased capacity of freshwater habitats to support Pink salmon production. Life-history models also identify the number of adult Pink salmon returning to Norton Sound and the Yukon River is significantly related to the juvenile abundance in the northern Bering Sea. This result indicates that much of the variability in survival for northern Bering Sea Pink salmon occurs during early life-history stages and that juvenile abundance is an informative leading indicator of Pink salmon runs to this region.

Introduction

The Pacific Arctic Region (PAR), that is, the northern Bering Sea, and the Chukchi Sea to the East Siberian and Beaufort seas, is experiencing significant warming and extremes in seasonal sea ice extent and thickness (Frey et al., 2014; Baker et al., 2020; Danielson et al., 2020). Over the past two decades, record summer sea-ice minima (2007, 2011, 2012; 2017 and 2018) have occurred, and climate models project that the southern Chukchi Sea will be sea-ice free for 5 months (July to November) within a decade or two (Overland et al., 2014). In the northern Bering Sea, sea ice is projected to be less common during May, but will continue to be extensive through April (Stabeno et al., 2012). However, recent events during 2017 and 2018 in the northern Bering Sea indicate that open water in this region during winter is already occurring (Stabeno and Bell, 2019). The presence of sea ice during winter and into spring is known to influence summer bottom temperatures; however, climate models project that the loss of seasonal sea ice during spring and into fall months is currently resulting in, and expected in the future to lead to, increased sea surface temperatures during summer months in both the northern Bering Sea and Chukchi Sea (Wang et al., 2012). In addition, the reduction in seasonal sea ice is likely contributing to increased primary and secondary production (Arrigo and van Dijken, 2011) that could shift the ecosystem to a more pelagic state (Grebmeier et al., 2006).

These shifts in the PAR ecosystem are likely to have large impacts on the ecology of upper trophic level species such as fishes, birds, and mammals (Sigler et al., 2011). For instance, the community structure of some upper trophic level species already show evidence of changes in the Chukchi Sea, such as the shift from predominantly piscivorous seabirds to planktivorous seabirds in recent decades (Gall et al., 2017).

Large scale distributional shifts of walleye pollock (*Gadus chalcogrammus*) and Pacific cod (*G. microcephalus*) in response to reduced cold pool extent in the northern Bering Sea were also found (Stevenson and Lauth, 2018). Other ecosystem consequences of continued warming have been described elsewhere, such as the Barents Sea, and include changes in zooplankton community structure as well as shifts in species distributions and relative abundances (Hop and Gjøsæter, 2013; Orlova et al., 2013; Fossheim et al., 2015). Because the upper trophic level species are typically top predators, they must adapt via biological responses to physical forcing and thereby are "sentinels" of ecosystem variability and reorganization (Moore et al., 2014). As such, there will likely be fishes that do better under climate warming and those that may not.

The most common salmon species in the PAR include Pink (*Oncorhynchus gorbuscha*) and Chum (*O. keta*) salmon (Nielsen et al., 2013; Carothers et al., 2013; Stephenson, 2006). Of these two salmon species, Pink salmon are the most abundant in the North Pacific Ocean (Ruggerone and Irvine, 2018) and have the broadest distribution in the PAR from the Yukon River to small steams from Point Hope to Point Barrow (Craig and Haldorson, 1986). Vagrants have also been found upstream in the Mackenzie River to Fort Good Hope, Northwest Territories (Dunmall et al., 2018), as far east in the Canadian western Arctic as Paulatuk, Northwest Territories (Dunmall et al., 2013) and Kugluktuk, Nunavut (Dunmall et al., 2018), and along the east coast of Greenland (Dunmall et al., 2013). Spawning Pink salmon have also been documented along the Chukotka Peninsula coastline from the northern Bering Sea, into the Chukchi Sea and as far east as the Kolyma River (Radchenko et al., 2018).

Pink salmon production around the North Pacific Ocean has increased over the last decade (Radchenko et al., 2018). While some authors have expressed concern that Pink salmon may be exerting top-down control on the food web (Batten et al., 2018) and affecting growth and survival of other species reliant on the marine food web (Ruggerone et al., 2016; Oka et al., 2012; Springer et al., 2018), others have illustrated no evidence of Pink salmon abundance on marine production (Radchenko et al., 2018). While Pink salmon abundance in northern regions of their range is still quite low in relation to stocks farther south, there is evidence that the abundance of some northern stocks is increasing during this period of warming.

Pink salmon have a short 2-year life-cycle that include freshwater and marine environments (Radchenko et al., 2018). Adult Pink salmon in the northern regions return to rivers during July to September and their eggs hatch during late winter and into spring. Fry enter the marine environment during late May through June (Howard et al., 2017) and they spend the summer as juveniles in near coastal regions before migrating offshore into the North Pacific Ocean for the winter. After winter, they migrate back to their natal spawning grounds. The 2-year life-cycle creates separate even and odd year brood lines that do not overlap on spawning grounds (Radchenko et al., 2018).

Conditions in both freshwater and marine environments are important to the survival of Pink salmon. In northern regions of Pink salmon distribution, cold river and stream temperatures in the freshwater environment are believed to limit salmon production (Dunmall et al., 2016); however, continued warming air and stream temperatures, and longer periods of ice-free conditions may benefit salmon survival within this environment (Nielson et al., 2013). Two critical periods in the marine environment are believed to be important to marine survival of salmon. The first critical period is during their early marine residence where rapid growth is believed to reduce predation (Parker, 1968). The second critical period is during their first winter at sea where juvenile salmon that attain sufficient size and energy reserves (lipids) during their first summer at sea have higher probability of survival (Beamish and Mahnken, 2001). Both critical periods are linked to ecosystem function (i.e. optimum sea temperatures for growth, quantity and quality of prey resources) during their first summer at sea as juveniles and there is evidence in the PAR that warmer sea temperatures benefit juvenile Pink salmon early marine growth (Moss et al., 2009; Andrews et al., 2009; Wechter et al., 2017). Thus, the expectation is that Pink salmon in the PAR will respond positively to the rapid warming in both freshwater and marine environments.

To better understand Pink salmon dynamics in this region, we examine the total life-cycle productivity for the Yukon River and Norton Sound area (total number of adult returns per spawner; R/S) based on models that relate abundance estimates for adult returns to the number of spawners two years earlier. We include Nome air temperatures as a proxy for river and stream temperatures and estimates of summer sea surface temperature taken from satellite measurements in the northern Bering Sea in the life-cycle productivity models to explore whether temperature in these environments is affecting production. Next, we use surface trawl survey data to examine early marine life-history periods and conditions in these environments that may impact Pink salmon survival. Juvenile Pink salmon caught during the surface trawl survey are most likely from spawning populations (previous year) in this region (Farley et al., 2005); the juveniles return as adults the following summer to western Alaska rivers. For freshwater and early marine effects, we relate juvenile Pink salmon relative abundance to the total number of spawners to the Yukon River and Norton Sound region and to Nome air temperatures as a proxy for river temperature. Strong positive relationships would suggest that the number of spawners along with warmer freshwater temperatures lead to increased relative abundance of juvenile Pink salmon in the northeastern Bering Sea region. Finally, we examine the relationship between the indices of adult Pink salmon returns to the Yukon River and Norton Sound region with the juvenile Pink salmon relative abundance, body size, and summer sea temperatures from satellite estimates. Strong positive relationships would suggest higher numbers of juveniles along with warmer temperatures and increased size lead to greater numbers of adult Pink salmon the following year.

Materials and methods

Life-cycle models

A time series (1995 to 2018) of adult Pink salmon return indices (harvest and spawners) and spawner indices to the Yukon River and Norton Sound were derived from a number of sources. The time series for the number of Yukon River and Norton Sound region Pink salmon returns are from Estensen et al. (2018) and Menard et al. (2020). For the Yukon River, the number of adult Pink salmon spawners is indexed from estimates of passage past the Pilot Station Sonar in the lower river (JTC, 2019), escapement past the East Fork Andreafsky River weir downstream of the sonar (Conitz, 2019), and total harvest of this species in the Yukon River (Estensen et al., 2018). While some lower river escapement of Pink salmon occur in systems downstream of the East Fork Andreafsky River weir and Pilot Station Sonar, a majority of total number of Pink salmon spawners in the Yukon River is accounted for by these assessment projects. For Norton Sound, the adult Pink salmon spawner index includes rivers that contain weirs or counting towers for more accurate values and have long enough time series to compare with our juvenile Pink salmon abundance index. These include the Eldorado, Snake, Kwiniuk, Nome, and North rivers. The annual indices of total Norton Sound adult Pink salmon returns are the sum of total annual harvest from the Norton Sound area, as most salmon harvest occur in marine waters downstream of spawner assessment projects, plus the sum of annual adult Pink salmon spawners to the index rivers.

Annual mean Nome air temperatures (1995 to 2018; August $_{(t)}$ to June $_{(t+1)}$) where *t* represents the year of adult Pink salmon spawning, were obtained from the National Weather Service web site: https://w2.weather.gov/climate/xmacis.php?wfo=pafg. The mean August $_{(t)}$ to June $_{(t+1)}$ air temperature represents the period of incubation (adult Pink salmon that entered freshwater streams and rivers to spawn during late July through August of year *t*) and rearing (over winter to when they leave freshwater as fry to enter the marine environment during late May through June of year *t*+1) of Pink salmon in northern regions of their distribution. We used the annual mean air temperature as a proxy for stream and river temperatures in the northern Bering Sea region for the Pink salmon production models. Air temperatures have been used to estimate seasonal freshwater stream temperatures (McNyset et al., 2015), however we

understand there are caveats given the span of seasons (includes winter) in our use of air temperatures as proxy for stream temperatures in this region.

Annual mean sea surface temperatures (1995 to 2018; SST_{t+1}) within the northeastern Bering Sea, where *t* represents the year of adult Pink salmon spawning, were estimated using data from satellite sources (NOAA Coral Reef Watch, 2018). Daily SST data were averaged within the northeastern Bering Sea (latitudes 60°N to 65°N; longitudes 166°W to 171°W) for each month. We then averaged the monthly mean sea surface temperatures for June to September for each year to represent sea temperature juvenile Pink salmon would experience during their first summer at sea.

The number of adult Pink salmon that return (*R*) to the river each year is a function of the number of adult spawners (*S*) two years prior as well as life-cycle events that occur during freshwater and marine residence. One measure of productivity is to examine the number of adults produced per spawner. Adult Pink salmon return and spawner data for the Yukon River and Norton Sound region are shown in Fig. 1a,b. There is increased variation in return indices at higher spawner index levels for both the Yukon River stocks and Norton Sound region stocks suggesting a multiplicative error structure. To understand between-stock variability in the northern Bering Sea region, we calculated the correlation of ln(*R/S*) between the Norton Sound region stock group and the Yukon River stock group to determine whether their productivity is synchronous. To take into account density dependent effects, we included models that relate the number of spawners to the number of adult returns (see Quinn and Deriso, 1999),

(1) $\ln R_{t+2} = a + \gamma \ln S_t + \epsilon$ Cushing Model (Cushing, 1971)
(2) $\ln (R_{t+2}/S_t) = a - \beta S_t$ Ricker Model (Ricker, 1975)

where *a* is the natural log of the productivity parameter and γ and β are the density-dependence parameters. While the Cushing model includes a density-dependent parameter, this model lacks a peak level of recruitment (Quinn and Deriso, 1999); recruitment continues to increase as spawning level increases. To provide density dependence in the Cushing model, γ must be less than 1. The Cushing model is typically not used for salmon stocks to examine the relationship between the number of returns and spawners due to lack of density dependence at high spawning levels; however, it may be informative for northern river systems experiencing rapid warming with potential for shifts in the underlying capacity of these ecosystems to support higher production. In addition, we included the annual estimates of Nome air temperature, as a proxy for freshwater temperatures, and annual average of sea temperature in the life-cycle models to test whether their inclusion helps explain production dynamics in this region.

A step-wise selection of a linear regression model (S-plus; Insightful Corporation, 2001) was used to determine the most parsimonious life-cycle models that explain production dynamics of Pink salmon in the northern Bering Sea region. In S-plus, the effects of additional terms to the model are determined by comparing the Mallow's C_p statistic estimated by

$$\boldsymbol{C_p = \left(\frac{RSS}{\hat{\sigma}^2}\right) + 2 * p -}$$

where *n* is the sample size, $\boldsymbol{\hat{\sigma}^2}$ is the mean square error of the true regression model, RSS is the residual sum of squares and *p* is the number of parameters in the model, which equals the number of predictors plus 1 if the intercept is included in the model. The stepwise selection process requires an initial model often constructed explicitly as an "intercept-only" model. The step function in S-plus calculates the C_p statistic for the intercept only model as well as those for all reduced and augmented models. If any term has a C_p statistic lower than that of the intercept only model, the term with the lowest C_p statistic is dropped. We also tested the residuals of the most parsimonious models for autocorrelation between consecutive years to see if the other potential factors beyond those in the model could influence adult Pink salmon returns.

Life-history models

The information on juvenile Pink salmon marine ecology in the northern Bering Sea comes from integrated ecosystem surveys conducted during late summer and early fall months of 2003 to 2018 (except 2008) (Fig. 2). For this study, the northern Bering Sea consisted of stations sampled between 60°N to 65°N and juvenile Pink salmon captured in the survey region are assumed to be of wild origin originating from spawning populations within the Norton Sound region and Yukon River. Details on survey design can be found in Murphy et al. (2017). Briefly, juvenile Pink salmon were captured using a model 400/601 rope trawl, made by Cantrawl Pacific Limited of Richmond, British Columbia. The rope trawl was rigged with buoys on the headrope to sample from near surface to approximately 20 to 25 m depth. Sampling stations were generally completed during daylight hours (0730 – 2100, Alaska Daylight Savings Time). All trawl deployments lasted 30 minutes and covered between 2.8 – 4.6 km. A vertical (surface to near bottom depths) conductivity and temperature at depth (CTD) cast was done at each station to measure oceanographic characteristics during the survey. The surveys generally occurred during September; however, there was some variability in start and end dates among years (Table 1). The median year-day for the surface trawl survey during all years (2003 to 2018) was 256 (September 12).

A multi-year distribution map of juvenile Pink salmon in the northern Bering Sea using the standardized catch estimated as:

$$\boldsymbol{C\_std_{i,y}} = \frac{\boldsymbol{C_{i,y}}}{\boldsymbol{E_{i,y}}}\overline{\boldsymbol{E}}$$

where $C_{i,y}$ is the number of juvenile Pink salmon captured at station i during year y, $E_{i,y}$ is the area (km^2) swept by the trawl and E is the average effort (km^2) (Murphy et al., 2017). Zero catch boundary conditions were added to land masses, and the prediction surface was estimated with a neighborhood kriging model (Murphy et al., 2017).

Fish captured in the trawl were sorted to species. Subsamples of up to n=50 juvenile Pink salmon were randomly selected, and these fish were measured to fork length (nearest mm) and weighed (nearest gram). Juvenile pink salmon fork length and weight were adjusted to take into account the annual differences in the surface trawl survey median year-day that could influence our interpretation of juvenile Pink salmon size due to differences in size of juveniles that could occur over the course of the survey period. We estimated adjusted length and weight by:

$$\boldsymbol{L_{J,i,y}} = \left(\boldsymbol{YD_{Capture\,j,i,y}} - \mathbf{256}\right) * \mathbf{1.18}\boldsymbol{mm}$$
$$\boldsymbol{W_{j,i,y}} = \left(\boldsymbol{YD_{Capture\,j,i,y}} - \mathbf{256}\right) * \mathbf{0.2}\boldsymbol{g}$$

where $L_{j,i,y}$ and $W_{j,i,y}$ are the length and weight of a juvenile Pink salmon j caught at station i during year y, $YD_{Capture\ j,\ i,\ y}$ is the year-day of capture of the juvenile Pink salmon j at station i during year y, 256 is the median year-day (September 12) for all years (2003 to 2018) of the surface trawl survey, and 1.18 mm and 0.2 g are the estimated daily growth rate in length (Moss et al., 2009) and weight (Grant et al., 2009) for juvenile Pink salmon.

An abundance index of juvenile Pink salmon for the northern Bering Sea was based on catch per unit effort (CPUE, catch per km^2) where the number of juvenile Pink salmon caught at each station was divided by the area swept by the trawl. We used an index of relative abundance and not actual abundance because juvenile Pink salmon captured at the outer regions of our survey may be from stocks other than Yukon River and North Sound (Farley et al., 2005). Area swept by the trawl at each station was determined by multiplying the distance (km) traveled by the horizontal distance (km) of the trawl opening that was measured by net sonar. The distance traveled was estimated using:

$$\boldsymbol{x} = \mathbf{cos^{-1}}(\mathbf{sin}(\boldsymbol{lat_s}) * \mathbf{sin}(\boldsymbol{lat_e}) + \mathbf{cos}(\boldsymbol{lat_s}) * \mathbf{cos}(\boldsymbol{lat_e}) * \mathbf{cos}(\Delta\mathbf{lon})) * \mathbf{6371},$$

where lat_s is the trawl start latitude position in radians, lat_e is the trawl end latitude position in radians, Δlon is the longitude distance between the start and end trawl positions in radians, and 6371 is the earth radius in km (Murphy et al., 2017).

Mixed-layer depth expansions were applied to the area-swept indices of juvenile Pink salmon to generate an abundance index for juvenile Pink salmon as described in Murphy et al. (2017). Mixed layer depth expansions account for changes in the vertical extent of trawl sampling depths and juvenile habitat over time. Summer sea temperatures below the mixed layer depth in the northern Bering Sea are generally cold (< 2° C), which are not suitable habitat for juvenile salmon (Brett, 1952); therefore, this correction is used to provide a reasonable approximation for the vertical distribution of juvenile salmon in the northern Bering Sea (Murphy et al., 2017). Oceanographic characteristics from the CTD casts were used to determine the mixed layer depth defined as the depth where seawater density (sigma-theta) increased by 0.10 kg m^{-3} relative to the density at five meters (Danielson et al., 2011). Mixed layer depth was set to 5 m off bottom when the entire water column was vertically mixed. The mixed layer depth adjustments applied to annual relative abundance estimates, θ_y, were estimated by

$$\boldsymbol{\theta_y} = \frac{\sum_i \boldsymbol{M_{i,y} C_{i,y}}}{\sum_i \boldsymbol{C_{i,y}}}$$

where $C_{i,y}$ is the number of juvenile Pink salmon captured at station i during year y, and $M_{i,y}$ is equal to the ratio of mixed-layer depth to trawl depth when trawl depth is shallower than mixed layer depth, and 1.0 when trawl depth is below the mixed-layer depth. The juvenile abundance index for Pink salmon was estimated by multiplying the average ln(CPUE) by θ_y

$$\boldsymbol{N_y} = \frac{\sum_i \boldsymbol{ln(CPUE_{i,y})}}{\boldsymbol{n_y}} * \boldsymbol{\theta_y}$$

where n is the number of stations i sampled during year y.

Life-history models were constructed for northern Bering Sea Pink salmon using multiple sources of data. The models included the juvenile Pink salmon abundance index and adjusted average juvenile weight during the northern Bering Sea surface trawl survey. A subset (2003 to 2018) of Nome air temperatures and summer SSTs described above were used in the life-history models to represent freshwater and early marine conditions for relationships with juvenile Pink salmon relative abundance and adult returns. Annual estimates of adult Pink salmon returns and spawners to the Northern Bering Sea region were developed from a subset of the available annual estimates (2003 to 2018) of adult Pink salmon returns and spawners to the Yukon River and Norton Sound region.

Because the juvenile Pink salmon relative abundance is estimated during September, the life-history model for juvenile abundance incorporates potential freshwater and early marine effects

ln (juvenile relative abundance $_t$) = ln (adult spawners$_{(t-1)}$) + Nome air temp + ln (adjusted weight $_t$) + SST_t

and includes the number of adult Pink salmon that spawned during the prior year, stream temperature during their freshwater life history stage, adjusted weight of juvenile salmon during year t, and summer sea surface temperatures during year t.
The life-history model relating early marine effects with adult Pink salmon returns

ln (adult returns $_{(t+1)}$) = ln (juvenile relative abundance $_t$) + SST_t + ln (adjusted weight $_t$)

examined the relationship between the number of adult Pink salmon returning the following year to the region with juvenile abundance, juvenile weight (condition), and sea temperature in the early marine period. We applied the step-wise variable selection procedure described above to select the most

parsimonious life-history models that explain production dynamics of Pink salmon in the northern Bering Sea region.

Results

Life-cycle productivity

The adult Pink salmon return and spawner indices to the Norton Sound region and Yukon River during 1995 to 2018 ranged between a few thousand to several million (Table 2). More adult Pink salmon return during even years than odd years, especially within the Norton Sound region. However, adult returns to the Norton Sound region during the recent odd year of 2017 was much higher (> 2 million) than most of the previous odd years (generally < 1 million except for 2005) within the time series. Overall, productivity (ln *R/S*) appears higher during the late 1990s and from 2013 to 2015 (Fig. 3). The correlation between Yukon River and Norton Sound region productivity was positive and significant ($r = 0.47$, $p = 0.02$).

The average Nome air temperature (proxy for freshwater temperatures) for the period covering adult Pink salmon spawning, fry emergence and smolt migration to the marine environment was below 0°C during each year (Table 2). Coldest temperatures occurred during 1999, 2009 and 2012 with warmer temperatures occurring during 2003 to 2005 and 2014 to 2016. The summer SSTs covering the period of juvenile Pink salmon residence in the northeastern Bering Sea had similar trends with coolest temperatures during the late 1990s and during 2008 to 2012 and warmer temperatures during the early 2000s and from 2015 to 2017 (Table 2). The correlation between Nome air temperatures and summer SSTs was positive and significant ($r = 0.61$, $p = 0.002$).

The life-cycle model fits and results for the Norton Sound region and Yukon River are shown in Fig. 1a,b and Table 3. For the Yukon River, the most parsimonious Cushing model included the natural log of spawners and summer SST which explained 71% of the variation in the natural log of returning adult Pink salmon. However, the parameter estimate for summer SST is not significant ($p = 0.11$) in the model. The most parsimonious Ricker model included SST, explaining 11% of the variation in adult Pink salmon production to the Yukon River; neither parameter estimates for number of spawners and SST were significant ($p = 0.232$ and 0.124, respectively). For Norton Sound stocks, the most parsimonious Cushing model was one that included the natural log of spawners and summer SST, explaining 77% of the variation in the natural log of adult Pink salmon returns to the region. The most parsimonious Ricker model was one that contained spawners and summer SST, explaining 53% of the variation in the natural log of adult Pink salmon production to the region. No significant autocorrelation between consecutive years is evident in the residuals of the most parsimonious models (Fig. 4 a-c). In addition, the gamma parameter for the Cushing model was 0.66 for Norton Sound stocks and 0.82 for the Yukon River stock suggesting that density-dependence on the spawning grounds may be more evident in the Norton Sound stocks than the Yukon River stocks.

Early life-history

Juvenile Pink salmon are distributed throughout the northern Bering Sea during late summer months (Fig. 2). The region of highest catch densities occurred within the shallow (< 50 m) coastal habitats from the northern to southern margins of the northern Bering Sea survey area. Observed average size of juvenile Pink salmon varied from 136 to 193 mm (25.7 to 70.8 g) with an average of 164.6 mm (44.8 g) (Table 1). Adjustments for survey timing increased the overall average size of juvenile Pink salmon to 165.6 mm (44.9 g) with the largest differences occurring during 2005 and 2007. Juvenile Pink salmon were generally smaller during 2006, 2009, 2011 and from 2015 to 2018 (Fig. 5a,b). Moreover, the number of larger fish that occurred as outliers to the sample of juvenile Pink salmon was highest during 2007 and

2016 to 2018 (Fig. 5b), years that coincided with warm sea temperatures. Mixed layer depth corrections ranged from a low of 1.00 (<1%) during 2016 to a high of 1.79 (79%) during 2005 with an overall average of 1.22 (22%) to juvenile Pink salmon relative abundance estimates (Table 4). Juvenile Pink salmon relative abundance was high during 2003 to 2007 and again from 2013 to 2018 with lower abundance during 2009 to 2012.

The step-wise model selection statistics to explore life-history events that may impact Pink salmon production in fresh water and the early marine period are shown in Table 5. For the juvenile abundance model, freshwater effects including the number of spawners and Nome air temperatures were significant and explained 55% of the variation in juvenile Pink salmon relative abundance during September (Fig. 6). The step-wise selection process removed summer SST and the natural log of weight, (both represent early marine effects) as these variables did not contribute to the most parsimious model. For the adult return model, the *Cp* values for the natural log of weight and sea temperature during September were lower than the intercept only model, suggesting these variables could be removed. The most parsimonious model (Fig. 7) that included juvenile Pink salmon relative abundance explained 62% of the variation in adult Pink salmon returns to the northern Bering Sea region.

Discussion

Our analysis provides new insights into production dynamics of Yukon River and Norton Sound Pink salmon stocks. The best fit life-cycle models suggest that density-dependence on the spawning grounds may be low within the Yukon River but may be present within river systems draining into Norton Sound. We interpret this result to indicate that there may be potential for increased freshwater production especially within the Yukon River. The best fit life-history models suggest that the number of juvenile Pink salmon during September is a function of the number of adult Pink salmon spawners and Nome air temperature, reflecting the importance of freshwater production to overall numbers of juvenile Pink salmon. In addition, juvenile Pink salmon relative abundance during September is a good predictor of the number of adult Pink salmon that return the following year indicating that conditions in fresh water and early marine environments are key to our understanding of Pink salmon production dynamics in this region.

Our analysis of the productivity patterns highlights the synchrony (positive, significant correlation) in temporal variation among Pink salmon stocks in the northeastern Bering Sea. These patterns have been found for Pink salmon stocks across western North America (Malick and Cox, 2016) as well as other salmon stocks that show positive correlation at regional scales (Pyper et al., 2001, 2002, 2005; Peterman et al., 1998; Peterman and Dorner, 2012; Dorner et al., 2017). The synchrony in production suggests shared factors that are affecting Pink salmon stocks throughout the study region. The best fit life-cycle models included summer SSTs indicating the potential importance of sea temperature on Pink salmon production in this region. This result is similar to other analyses of salmon productivity in the Northeast Pacific Ocean (Mueter et al., 2002), illustrating the importance of summer sea temperatures to production of Pink salmon in the northeastern Bering Sea.

The best fit life-history models were those that included the number of spawners, Nome air temperatures and the relative abundance of juvenile Pink salmon. For the juvenile abundance model, we found positive, significant relationships between annual juvenile Pink salmon relative abundance and the number of adult Pink salmon spawners the prior year along with annual average Nome air temperatures. This result supports the hypothesis that warming air temperatures in this region (as a proxy for river and stream temperatures) may be improving freshwater production leading to higher numbers of juvenile Pink salmon in the northern Bering Sea region during summer months. For the adult Pink salmon return model, the number of juvenile Pink salmon in the northern Bering Sea region during late summer predict the number of adults returning the following year. While summer SSTs were not included in these

models, we note that there is a significant positive correlation between SSTs and Nome Air temperatures that may indicate that temperature, either fresh water or early marine are important for Pink salmon production in this region.

These relationships suggest a possible connection between changes in fresh water and early marine environments and subsequent adult production. However, the amount of variation in juvenile Pink salmon relative abundance explained by adding adult Pink salmon spawners and Nome air temperatures was less than the amount of variation explained in the adult Pink salmon returns by the juvenile index. This suggests other factors affecting early marine survival of juvenile Pink salmon in the northern Bering Sea during summer months could influence total production or that Nome air temperatures may not fully reflect the freshwater temperature dynamics thereby reducing the influence of juvenile Pink salmon relative abundance.

Although freshwater conditions in the Arctic are known to limit salmon production, it can be difficult to predict how salmon will respond to warming freshwater habitats (Nielson et al., 2013). A case study on projecting effects of climate warming on Atlantic salmon suggested that northern rivers could become more productive with increased colonization success northward and diminished production to river systems in the southern range (Reist et al., 2006). Density-dependent mortality due to too many spawners on the river, temperature, and stream flows are all factors contributing to fluctuations in freshwater survival (Heard, 1991). In addition, stream habitats with a minimum temperature of 4°C during spawning and temperatures above 2°C during egg incubation were found to benefit establishment of Chum and Pink salmon in high latitude and high elevation watersheds (Dunmall et al., 2016). Nome air temperatures from August (spawning year) to June the following year were used as a proxy for freshwater stream temperatures in the region. The average air temperature was below 0°C which is most likely colder than stream temperatures, especially during summer months. Limited information on stream temperatures at various locations along the Pilgrim River (north of Nome, Alaska) during the summer months of 2013 to 2016 show that temperatures varied between 8.4°C to 18.7°C (Carey et al., 2019). These temperatures are well above the minimum temperature of 4°C for successful Pink salmon spawning suggested in Dunmall et al. (2016). In addition, some river systems in the Norton Sound region experienced extremely high temperatures during summer 2019 that were believed to contribute to observed adult Pink salmon die offs on the spawning grounds (pers. Comm. Gay Sheffield). Given the nature of rapid warming in the region with respect to the marine ecosystem (Baker et al., 2020; Danielson et al., 2020; Huntington et al., 2020), it is likely that freshwater temperatures during winter and summer months in the Norton Sound and Yukon River drainage are warming enough to both improve survival and to open new areas along rivers and streams for Pink salmon to establish thereby increasing production potential in this region.

Pink salmon returns to this region are typically higher during even years (odd year juvenile Pink salmon brood), but more recently the returns to the Norton Sound region during odd years have also been high. Studies have indicated that embryonic survival of the even-year broodline for British Columbia Pink salmon is higher than the odd-year broodline in a cold (4°C) incubation environment with higher alevin and fry growth observed (Beacham and Murray, 1988). Increasing dominance of odd-year brood lines has been documented with the inference of favorable survival during period of warming freshwater habitats (Irvin et al., 2014). The difference in temperature tolerance between the even and odd-year brood lines has been linked to dispersal after the Pleistocene Era glaciation some 10,000 years ago (Beacham et al., 2012), where even-year broodlines likely survived the glaciation in the northern refugia (Aspinwall, 1974) and the odd-year brood line may have occupied more southern refugia (McPhail and Linsey, 1970). Therefore, warming freshwater habitats in the northern regions may be improving odd-year broodline survival, leading to more adult Pink salmon returning during odd years.
Earlier studies on juvenile Pink salmon marine ecology in the northern Bering Sea found that warmer sea surface temperatures during spring and summer were positively related to their growth (Andrews et al.,

2009; Farley et al., 2009; Wechter et al., 2017). Presumably, higher growth rates during their early marine period would reduce size-selective mortality and lead to higher survival for juvenile salmon (Parker, 1968). We found that juvenile Pink salmon adjusted weight and length declined over the course of our time series even though sea temperatures were increasing during the survey period. This result was counter-intuitive as growth rates typically increase with temperature. Dispersal, changes in prey quality and quantity, and migratory patterns of juvenile Pink salmon could be contributing to this apparent negative relationship between size and temperature.

Although juvenile Pink salmon were distributed throughout the northern Bering Sea survey region, the vanguard of their distribution can be under sampled, particularly during warm years. Moss et al. (2009) examined juvenile Pink salmon distribution and size within the northern Bering Sea and Chukchi Sea during 2007. They found that the highest catches of juvenile Pink salmon were in the Chukchi Sea and that these juveniles were larger than those in the northern Bering Sea region. The year 2007 was characterized by exceptionally warm sea temperatures in the Chukchi Sea and significantly increased annual mean water transport through the Bering Strait (Woodgate et al., 2010). Moreover, the water flow from the northern Bering Sea through the Bering Strait and into the Chukchi Sea has increased by 50% over the past two decades (Woodgate et al., 2015). Given that the sea temperatures have been much higher during recent years of our survey period, it is possible that juvenile Pink salmon from the northern Bering Sea region were advected north with the largest fish at the vanguard of the migration through the Bering Strait and into the Chukchi Sea and out of the northern Bering Sea survey area.

The large numbers of juvenile Pink salmon found near the Bering Strait could also be related to higher Pink salmon production in the northern regions of the PAR. Adult Pink salmon have become more prevalent in subsistence catches in the high Arctic particularly during even-numbered years (Dumnall et al., 2013; Dunmall et al., 2018). Further, the large catch of juvenile Pink salmon in the Chukchi Sea during 2007 (Moss et al., 2009) coincided with higher adult returns to the Beaufort Sea coast during 2008 (Dunmall et al., 2013; Dunmall et al., 2018). While Pink salmon appear to be poised to take advantage of warm-water thermal refugia within several watersheds of the Arctic (North American North Slope; Dunmall et al., 2016), it is unknown whether spawning has been successful in this region. Adult Pink salmon returns to the northern regions of the Kamchatka peninsula have recently increased (Klovach et al., 2018) and record returns have occurred during most recent years to Norton Sound rivers (Menard et al., 2018). Farley et al. (2005) speculated that juvenile Pink salmon caught offshore in the northern Bering Sea could be of Russian origin. In addition, Kondzela et al. (2009) found that most of the juvenile Chum salmon caught in the Bering Strait area during 2007 were from Anady-Kanchalan rivers in the northern Kamchatka region. In any case, stock-specific juvenile data for Pink salmon are needed to better understand movement and production dynamics during this time of rapid warming.

The significant correlation between juvenile Pink salmon relative abundance and adult returns the following year suggests that the second critical period has not contributed as much to the annual variation in Pink salmon production to the northern Bering Sea region. The addition of sea surface temperature and weight did not improve our model for adult Pink salmon returns to the northern Bering Sea region. Our result is similar to studies that utilized juvenile salmon abundance indices from surface trawl data to predict adult returns. For example, a stock-specific juvenile Yukon River Chinook salmon index collected in the northern Bering Sea is used to provide management advice for expected run sizes (Murphy et al., 2017). Within southeast Alaska, adult Pink salmon returns are predicted using a juvenile Pink salmon index collected during summer months within Icy Strait (Orsi et al., 2016). Both applications are used to inform management decisions and provide more accurate outlooks than previous models.

Lastly, it is important to note results from the life-cycle models that utilize harvest and spawner data for Pink salmon to the Yukon River and Norton Sound regions are limited by incomplete data. Our estimates

of Pink salmon total number of returns and spawners to the Yukon River and Norton Sound region are considered indices of abundance as total accounting of Pink salmon abundance in this region is not currently possible. Total harvest includes stocks not indexed in the spawning escapement and escapement assessment programs are designed to estimate other salmon species and do not fully account for Pink salmon abundance. Productivity values and inferences are presented here to illustrate relative change over time or relationships to environmental parameters, and should not be considered absolute values. Consequently, our interpretation of the results from these models should be considered cautiously. In addition, separate analyses of odd and even year broodlines may be warranted given that they are ecologically and reproductively isolated, suggesting that stock-recruitment relationships may differ between broodlines. The adult return and spawner time series for the region are short, therefore combining the two broodlines allowed a more complete examination of relationships between environmental conditions and indices of productivity in the context of changing climate conditions. Additional analyses into these relationships should be explored in the future, as the extension of time series and collection of new environmental data enable such models.

Continued monitoring of salmon through life-cycle and life-history models will provide insight into how warming Arctic climate conditions are impacting critical periods in salmon production. Our analyses suggest that Pink salmon production in the northeastern Bering Sea is driven by freshwater and early marine habitat dynamics. While we used air temperature as a proxy for stream temperature, broad-scale predictive models of climate change in the Arctic provide little information about feedback processes contributing to local conditions (Nielsen et al., 2013). To explore emerging connections within freshwater habitats, local knowledge regarding stream conditions, salmon abundance and spawning locations will be needed for perspective to current observations. Further monitoring of stream temperatures, flow and ice dynamics will improve our understanding of how climate warming is impacting this important habitat and context to shifts in abundance northward into the high Arctic.

Acknowledgements

The authors sincerely thank two anonymous reviewers for comments that greatly improved the manuscript. We also thank Jordan Watson for providing the summer sea surface temperatures for the northeastern Bering Sea. In addition, the authors thank all captains, crew, and science teams who collected these data. These samples were collected over 18 surveys with support and funding from many different entities including: Bering Sea Fisherman's Association, The Alaska Coastal Impact Assistance Program (Arctic Ecosystem Integrated Survey 2012 and 2013), Bureau of Ocean and Energy Management, The Alaska Sustainable Salmon Fund, NCEAS – State of Alaska's Salmon and People and the Yukon River Drainage Fisherman's Association. This project is a collaborative effort with the Alaska Department of Fish and Game and the North Pacific Anadromous Fish Commission. The northern Bering Sea surface trawl survey is part of the NOAA Alaska Fisheries Science Center's, Bering Arctic Subarctic Integrated Survey (BASIS). This manuscript is a product of the North Pacific Research Board Arctic Integrated Ecosystem Research Program, NPRB publication number ArcticIERP-12.

ABSTRACT

The northern Bering Sea (NBS) surface trawl survey is a multi-disciplinary research survey that has supported annual sampling of the inner domain (bottom depths generally less than 55 m) of the NBS (60°N–66.5°N). Average sea surface temperature (SST, 11.5°C, upper 10 m) during the 2019 survey was the warmest on record and contributed to significant changes in the NBS ecosystem. Similar to prior years, the jellyfish species, northern sea nettle (*Chrysaora melanaster*), had the largest surface trawl catch biomass with a total catch of 6,989 kg in 2019. Pacific herring (*Clupea pallasii*) were the most abundant species of fish with a total catch of 142,512 fish. Juvenile pink salmon (*Oncorhynchus gorbuscha*) were the most abundant species of salmon with a total catch of 13,507 fish. Annual catch rates of several pelagic fish species increased with temperature, reflecting the influence of temperature on the distribution (e.g. Bristol Bay juvenile sockeye salmon (*O. nerka*), $\rho = 0.9$) and survival (e.g. juvenile coho salmon (*O. kisutch*), $\rho = 0.7$). The abundance and proportion of juvenile Yukon River Chinook salmon (*O. tshawytscha*) in 2019 were the lowest observed in the northern Bering Sea. The abundance of the Canadian-origin stock group (stock proportion of 30%) was estimated at 575,100 juveniles. The abundance of the Total Yukon River stock group (stock proportion of 65%) was estimated at 1,246,000 juveniles. Projected run-sizes for Yukon River Chinook salmon in 2021 and 2022 are 52,300 and 46,300 for the Canadian-origin stock group and 143,800 and 129,000 for the Yukon River stock group, respectively. The abundance of juvenile pink salmon reached a record high abundance in 2019, resulting in an outlook of 6.5 million pink salmon for Yukon River and Norton Sound in 2020. Average lengths of juvenile salmon were typical of past years except for coho salmon, which had the lowest recorded average length in 2019. The proportion of non-target prey consumed by juvenile coho and chum (*O. keta*) salmon

has increased in recent years suggesting a decrease in preferred prey. A total of 2,870 km of transects were surveyed. We recorded 3,310 birds on transect, comprised of 38 species plus a few unidentified passerines, with the northern fulmar (*Fulmarus glacialis*) the most abundant seabird species encountered.

INTRODUCTION

The northern Bering Sea (NBS) surface trawl survey (NBS survey) is a multi-disciplinary survey that supports research on pelagic fish species and oceanographic conditions in the eastern Bering Sea. Surface trawl surveys in the NBS were initiated by NOAA's Alaska Fisheries Science Center (AFSC) in 2002 as part of the Bering-Aleutian Salmon International Survey (BASIS). BASIS was a basin-wide research program developed by member nations of the North Pacific Anadromous Fish Commission and designed to improve our understanding of the marine ecology of salmon in the Bering Sea. Surface trawl surveys in the NBS were continued through 2007 as part of the BASIS survey for the eastern Bering Sea shelf. The NBS was not sampled in 2008, but it has been sampled on an annual basis since 2009 to support research objectives on the ecology of salmon in the NBS and to improve our understanding of how the NBS ecosystem is changing in response to warming climate and loss of arctic sea ice.

The NBS survey has supported a range of different survey operations and research objectives in the NBS. Survey operations have included the following: surface and midwater trawl sampling for pelagic nekton, midwater acoustics, seabird and marine mammal observations, bongo net sampling for zooplankton and ichthyoplankton, electronic conductivity, temperature, depth (CTD) data, and water collections for chlorophyll-a, phytoplankton, and nutrients. Survey objectives have supported research objectives on salmon and other pelagic fish resources in the NBS, including: juvenile salmon abundance and run-size forecasts (Murphy et al. 2017, Howard et al. 2019, Howard et al. 2020, Farley et al. 2020), size selective mortality (Murphy et al. 2013, Howard et al. 2016), energy allocation (Andrews et al. 2009, Murphy et al. 2013, Moss et al. 2017), diet (Farley et al. 2009, Andrews et al. 2016, Auburn and Sturdevant 2013, Honeyfield et al. 2016, Garcia and Sewall 2021), and species distribution (Murphy et al. 2009, Murphy et al. 2016, Andrews et al. 2016). An emphasis has been given to Chinook salmon over the last 5 to 10 years due to the decline in their survival (ADF&G 2013) and their importance to subsistence fisheries in the Yukon River. The declining sizes of Chinook salmon in the Yukon River has a widespread impact on subsistence fisheries throughout Alaska and the Yukon Territory, and it has had a significant impact on pollock fisheries in the eastern Bering Sea through efforts to reduce Chinook salmon bycatch (Ianelli and Stram 2014, Stram and Ianelli 2014).

The 2019 NBS survey was a cooperative research survey by AFSC, the Alaska Department of Fish and Game (ADF&G), the Alaska Pacific University (APU), and the U.S. Fish and Wildlife Service (USFWS) to improve our understanding of the marine ecosystem in the NBS. Key funding was provided by the Alaska Sustainable Salmon Fund to help maintain research on juvenile salmon in the NBS. The primary objectives of the 2019 NBS surface trawl survey were to 1) conduct surface trawl operations in support of ecosystem science, with a focus on the marine ecology of juvenile fish species; 2) estimate stock-specific abundance of juvenile Chinook salmon and update run-size forecast models for the Yukon River; 3) collect electronic oceanographic data and water samples for temperature, salinity, chlorophyll-a, nutrients, particulate organic carbon, and harmful algal blooms with a SBE-9-11 CTD and Niskin bottles; 4) collect zooplankton and icthyoplankton samples with a 20 cm (150 µm mesh) and 60 cm (505 µm mesh) bongo array; and 5) assess the distribution and abundance of seabirds and marine mammals on the NBS shelf.

METHODS

The 2019 NBS survey began and ended in Dutch Harbor, AK, with a port call in Nome, AK. The survey occurred over 25 days inclusive of mobilization, demobilization, travel, sampling, and weather days aboard the chartered fishing vessel FV *Northwest Explorer*, August 27 to September 20, 2019. The survey crew consisted of scientists from Alaska Fisheries Science Center, Alaska Department of Fish and Game (ADF&G), U.S. Fish and Wildlife Service (USFWS), and Alaska Pacific University (APU) (Table 1).

The survey consisted of 44 stations in the NBS between 60°N–66.5°N and east of 171°W, and three additional stations just north of the Bering Strait (Fig. 1, Table 2). Rough weather conditions at the end of the survey prevented sampling at the distributed biological observatory (DBO) stations in 2019. Each day typically consisted of sampling three stations during daylight hours. The order of operations at each station was 1) a Conductivity Temperature Depth (CTD) instrument system, 2) a Van Veen grab sample to collect benthic organisms and sediment samples for the presence of harmful algal blooms (HABs), 3) an oblique zooplankton net tow with bongo array and a FastCat CTD, and 4) one surface trawl tow. Seabird and marine mammal observations were recorded while travelling between stations.

Oceanographic Conditions

The primary CTD (SeaBird Instruments SBE-9-11+) was outfitted with dual temperature and conductivity (TC) sensors, a Photosynthetically Active Radiation (PAR) spherical sensor (QSP 2300, Biospherical Instruments), chlorophyll-a fluorometer, beam transmissometer (Wet Labs C-star), and two dissolved oxygen sensors (SeaBird Instruments SBE-43). The CTD measured temperature (°C), salinity (psu), and pressure (db) from the surface down to 5 m from the bottom. A SeaBird Instruments SBE-32 carousel water sampler frame with 1.5 liter Niskin bottles was used to collect water samples from the surface down to 5 m from the bottom in 10 m increments. The water samples from the Niskin bottle were filtered following water collection protocols (Appendix A).

The temperature and salinity for each meter of the CTD cast was calculated by averaging the readings from the primary and secondary temperature and salinity sensors. Sea surface temperature (SST) and salinity were estimated by averaging the temperature and salinity measurements from the top 10 m of the water column. Bottom temperature and salinity were equal to the measurements from the deepest cast of the CTD at each station. The average annual SST was estimated for all stations within the NBS (latitudes: 60°N - 65.5°N) and for a restricted spatial range to account for changes in sampling locations over time (longitudes east of 171°W, and latitudes south of 64°N). Norton Sound stations were restricted to three stations along 64°N.

Mixed-layer depth (MLD) was defined as the depth where seawater density (kg/m^3) increased by 0.10 kg/m^3 relative to the density at 5 m (Danielson et al. 2011; Murphy et al. 2017). Seawater density was calculated from temperature and salinity using the oce package (Kelley and Richards 2020) in R (R Core Team 2020). The MLD was set to the maximum depth of the CTD cast when the water column was mixed. The MLD was calculated from the FastCat CTD (SeaBird Instruments SBE-49) when the primary CTD data were not available. Average MLD from adjacent stations was used when both the CTD and FastCat data were not available.

A bongo net array was deployed to sample zooplankton and ichthyoplankton throughout the water column. The bongo array consisted of two 60-cm diameter bongo nets with 505 micron mesh and two 20-cm diameter bongo nets with 153 micron mesh. A FastCat CTD was affixed above the bongo net array to measure depth in real time using a conducting wire. The bongo nets were towed obliquely from the surface down to 5 m off the bottom at a 45° angle. One net from each bongo frame was preserved in 5% buffered formalin, the second bongo net was sorted for on-board Rapid Zooplankton Assessment (RZA) (Appendix A).

RZA was used to provide information on zooplankton abundance and community structure from coarse taxonomic categories of zooplankton during the 2019 NBS survey. Taxonomic categories included small copepods (< 2 mm; example species: *Acartia* spp., *Pseudocalanus* spp., and *Oithona* spp.), large copepods (> 2 mm; example species: *Calanus* spp. and *Neocalanus* spp.), and euphausiids (< 15 mm; example species: *Thysanoessa* spp.). Small copepods were counted from the 153 µm mesh, 20 cm bongo net. Large copepods and euphausiids were counted from the 505 µm mesh, 60 cm bongo net. Bongo net samples were split with Stemple pipettes to reach a total count of at least 100 individuals per sample. This method was first used in the NBS survey in 2018.

Surface Trawl Data

A Cantrawl 400/601 rope trawl from Cantrawl Pacific Ltd. (Murphy et al. 2003) was used to conduct surface trawl operations. All surface trawl tows were 30 min in duration and trawl dimensions were monitored during each tow with a Simrad FS70 net sounder. A SeaBird Instruments SBE-39 temperature and depth sensor mounted to the center of the footrope measured footrope depth and temperature during each tow. The number of fish (or weight of jellyfish) caught in a single tow was divided by the area swept by the trawl (km^2) to estimate catch-per-unit-effort (CPUE) and was used to describe species distribution and abundance. The area swept by the trawl was calculated using the horizontal opening from the net sonar and the distance sampled from GPS positions at the start and end of the trawl set.

Surface trawl catches were sorted by species and life history stage and up to 50 individuals from each species and life history stage combination were measured for length and weight at each station. Individual specimen weights were not recorded for species with weights less than 10 g due to the limited accuracy of ship-board weights. Mixed-species subsamples were used to estimate the catch of a few small and numerous species (typically ninespine stickleback (*Pungitius pungitius*), age-0 Pacific herring (*Clupea pallasii*), and moon jellyfish (*Aurelia* spp.). Total catch weight and average weight of measured individuals were used to estimate the total number of species when a subsample of the catch was measured. Annual sample requests were used to define specimen collection protocols for juvenile salmon (*Oncorhynchus* spp.), immature/mature salmon, and non-salmon species (Appendix A). Subsample sizes for juvenile salmon species were reduced in 2019 to accommodate specimen requests from the unexpectedly large numbers of juvenile pink (*O. gorbuscha*), chum (*O. keta*), and sockeye (*O. keta*) salmon. Subsample sizes for individual jellyfish widths and weights were also reduced to 10 individuals per species per station in 2019. All biological data were recorded in an electronic catch logging system, known as the Catch Logger for Acoustic and Midwater Surveys (CLAMS). Individual specimens collected in surface trawls were assigned a specimen number (barcode number) and electronically scanned into CLAMS to ensure a consistent record of all specimens collected during the survey. Juvenile chum and pink salmon caudal fins were collected for genetic analysis, frozen, and assigned a station number. All Chinook salmon were scanned for missing adipose fins, coded-wire-tags (CWTs), and Passive Integrated Transponder (PIT) tags.

Correlations between CPUE of the most abundant pelagic fish species and SST were plotted using the ggcorrplot package (Kassambara 2019) in R (R Core Team 2020) to provide insight into how the NBS fish community is responding to warming climate conditions in the eastern Bering Sea. Species-specific CPUE indices were based on log-transformed average CPUE adjusted for MLD as

$$\ln(CPUE_y) = ln\left(\frac{\sum_i C_{iy} M_{iy}}{\sum_i a_{iy}}\right),$$

where C_{iy}, and a_{iy} are the catch and effort, at station i, and year y, respectively, and M_{iy} is equal to the ratio of mixed-layer depth to trawl depth when trawl depth is shallower than mixed layer depth at station i, and 1.0 when trawl depth is below the mixed-layer depth. The Optimal Interpolation Sea Surface Temperature (OISSTv2.1) dataset (Huang et al. 2021) provided by NOAA's CoastWatch West Coast Regional Node ERDDAP cite for the eastern Bering Sea shelf (54° to 66°N, and 146° to 176°W) from June through August was used in lieu of *in situ* SST measured by the CTD to enable a broader spatial and temporal scale of temperature. Temperature data at this scale were thought to be more relevant to the overall distribution and abundance of fish species in the NBS; however, *in situ* temperatures were highly correlated with the broader-scale SST data, therefore, the overall conclusions are similar with both temperature datasets.

A multi-year distribution of juvenile Chinook salmon (*O. tshawytscha*) CPUE was created using a simple kriging model with a gaussian semivariogram as part of the geostatistical analyst extension in ArcGIS (ESRI 2019). Juvenile Chinook salmon CPUE was multiplied by average effort (across all years) to scale the distribution to the catch at each station and a first order trend was removed before kriging. The prediction surface was generated with a neighborhood kriging model with a minimum of five and maximum of 20 points within each of four search quadrants. CPUE data from the southern Bering Sea and Chukchi Sea were included to help define the spatial distribution of juvenile Chinook; however, CPUE within Bristol Bay (near the Kuskokwim and Nushagak rivers) were excluded to maintain a focus on the distribution of Chinook salmon within the NBS. The locations of CWT and adipose fin-clipped juveniles from the Whitehorse Rapids Fish Hatchery (WRFH) within the Yukon River were added to the distribution map of juvenile Chinook salmon to highlight the known locations of Yukon River Chinook salmon.

Length-frequency distributions, length-weight relationships, and box plots of lengths were used to describe the size of juvenile salmon and primary non-salmon species captured in the surface trawl. Length-weight relationships were used as a quality control measure to ensure large errors in length or weight were not present. Juvenile salmon lengths (fork length, mm) were standardized to a common capture date using juvenile growth rates calculated from previous NBS surveys (Howard et al. 2019). The common capture date was equal to the average capture date calculated for each species. Growth rates of 1.06 mm/day for Chinook salmon, 1.69 mm/day for chum salmon, and 1.76 mm/day for pink salmon were then used to standardize length (Howard et al. 2019). Growth rates of coho and sockeye salmon in the NBS are not available; therefore, coho salmon were assumed to grow at the same rate as Chinook salmon (1.06 mm/day) and the average growth rate of all juvenile salmon species was used to standardize sockeye salmon lengths (1.50 mm/day). Length frequency distributions of species captured in surface trawls were corrected by the proportion of the catch that was measured at each station to ensure length distributions reflected the total number of fish caught during the survey.

Juvenile Salmon Origin

All juvenile Chinook salmon were scanned for coded-wire-tags (CWTs) and caudal fin clips were collected from all juvenile Chinook and coho salmon and from a subsample of sockeye, pink, and chum salmon captured during the survey. Pectoral fin clips were collected from all immature Chinook and chum salmon. Individual fin clips were placed on Whatman paper cards specific to Chinook, coho, and sockeye salmon and barcode IDs were recorded on the Whatman cards. Caudal fin clips were collected from juvenile chum and pink salmon and were placed on plastic wrap, frozen, and pooled by species for each station. Pelvic fin clips from immature chum salmon were individually labeled and stored in plastic bags. All genetic tissue samples were shipped to the ADF&G Gene Conservation Lab as part of the cooperative NOAA/ADF&G research on salmon stock origin. Genetic mixed stock analysis has not been initiated for sockeye, coho, and pink salmon but samples are being archived to support analyses when funding and specific interest becomes available.

Genetic mixed-stock analysis was completed for juvenile Chinook and chum salmon and immature Chinook salmon, but only stock mixtures of juvenile Chinook salmon are reported here. DNA was extracted from the tissue samples using the NucleoSpin 96 Tissue Kit (Macherey-Nagel, Düren, Germany). Single nucleotide polymorphism (SNP) genotyping of the 80 SNPs common to the AYK baseline of 60 populations (Howard et al. 2019) was performed with standard TaqMan chemistry (Applied Biosystems, Waltham, USA). Quality control analyses included comparison of discrepancy rates between original genotypic data and genotypic data of 8% of individuals that were re-extracted and re-genotyped, removal of individuals missing 20% or more genotypic data, and removal of duplicate individuals. Stock composition was estimated by comparing genotypes of catch samples to reference baseline allele frequencies using the Bayesian statistical approach implemented in the software package BAYES with a flat prior (Pella and Masuda 2001). Contributions of juvenile Chinook salmon from four

reporting groups were estimated: Lower Yukon, Middle Yukon, Upper Yukon, and Other Western Alaska. Estimates from the three intra-Yukon River groups (Lower Yukon, Middle Yukon, and Upper Yukon) were summed to estimate the total Yukon River stock contribution.

Juvenile Chinook Salmon Abundance and Run Forecasts

The methods for estimating juvenile Chinook abundance were initially described in Murphy et al. (2017) and revised in Howard et al. (2019) and Howard et al. (2020). Juvenile Chinook salmon catches are scaled to the MLD by dividing the catch of juvenile Chinook salmon by the proportion of the mixed layer sampled at that station. The NBS was divided into four latitude strata: 1) Lower NBS (60 to 62°N), 2) Upper NBS (62° to 64°N), 3) Norton Sound, and 4) the Bering Strait region. The average CPUE within each stratum *n*, was estimated by dividing the total catch by the total effort as

$$CPUE_n = \frac{\sum_{i=1}^{I} C_{ni}}{\sum_{i=1}^{I} a_{ni}},$$

where C_{ni} and a_{ni} are the MLD adjusted catch and area swept, respectively, for station *i* and stratum *n*, and *I* is the total number of stations in stratum *i* (Quinn and Deriso 1999). The variance of *CPUE* by strata was defined as

$$CPUE_A = \sum_n \frac{A_n}{A} CPUE_n,$$
$$V(CPUE_A) = \sum_n \frac{A_n}{A} V(CPUE_n).$$

The area sampled within each strata (A_n) was calculated from the number of stations in the strata and the average grid area (the average area of the 0.5° latitude by 1° longitude grid, calculated with average latitude). A fixed sample grid area (A_{NS}) was assumed for the Norton Sound stratum as the effective habitat for juvenile Chinook salmon was assumed to be limited by the high turbidity and shallow bottom depths (Murphy et al. 2017). The mean proportion of juvenile Chinook salmon in the Bering Strait (6.7%) and Norton Sound (8.2%) during 2003, 2007, 2009 to 2015, and 2017 were used to adjust abundance estimates in years when these strata were not sampled (2004 to 2006 for Bering Strait and 2016 for Norton Sound). The sum of the individual strata areas was used to estimate the total survey area, *A*. The average *CPUE* for the survey, $CPUE_A$, and variance, V($CPUE_A$), were simply the weighted average based on the strata area as

$$\hat{N} = CPUE_A \cdot A,$$
$$V(\hat{N}) = A^2 \cdot V(CPUE_A).$$

Juvenile abundance ($\hat{N}$) and variance V($\hat{N}$) estimates for the survey were calculated as

$$\hat{N} = CPUE_A \cdot A,$$
$$V(\hat{N}) = A^2 \cdot V(CPUE_A).$$

Juvenile Chinook salmon abundance estimates were apportioned by stock composition to Upper Yukon (hereafter Canadian-origin) and total Yukon River groups (combined Canadian-origin, Middle Yukon, and Lower Yukon stock groups). The variance of stock-specific abundance was derived from a Taylor series approximation to the multiplicative variance of 2 random variables (*X* and *Y*) using the Delta method as

$$V(X,Y) = \mu_Y^2 \sigma_X^2 + \mu_X^2 \sigma_Y^2 + 2\mu_X \mu_Y \sigma_X \sigma_Y \rho,$$

where μ_X and σ_X are the mean and standard deviation of juvenile abundance, μ_Y and σ_Y are the mean and standard deviation of the stock group proportion, and ρ is the correlation between juvenile abundance and stock proportion.

Canadian-origin and Total Yukon Chinook salmon forecasts were generated using juvenile abundance estimates, brood tables, and age at maturity estimates for both Canadian-origin and Total Yukon Chinook

salmon. The number of juvenile Chinook salmon predicted to return to the Yukon River was based on the midpoint and 80% prediction interval of the linear regression model between juvenile abundance and adult returns. The majority of Yukon River Chinook salmon spend a full year growing in fresh water after hatching and therefore juvenile abundance is assumed to be offset from spawner abundance by two years (one year is added to account for overwinter egg incubation). The marine ages of returning adults (typically 2 to 4 years) are used to scale juvenile abundance to run year. Projected run sizes were based on recent 3-year average maturity schedules derived from Canadian-origin brood tables (JTC 2020) and the total Yukon River drainage (Howard et al. 2020).

Juvenile Pink Salmon Abundance

Catch and effort, abundance indices, and forecast models for Yukon River and Norton Sound pink salmon were developed and reported in Farley et al (2020). Mixed layer depth corrections were applied to the annual abundance index as

$$\theta_y = \frac{\sum_i M_{iy} C_{iy}}{\sum_i C_{iy}},$$

where C_{iy} is the catch at station i and year y, and M_{iy} is equal to the ratio of mixed-layer depth to trawl depth when trawl depth is shallower than mixed layer depth, and 1.0

when trawl depth is below the mixed-layer depth. The juvenile abundance index for pink salmon was estimated as

$$N_y = \frac{\sum_i ln\left(CPUE_{iy}\right)}{n_y} \cdot \theta_y,$$

where n_y is the number of trawl stations in year y.

Juvenile Salmon Diet

Stomach contents were examined either at sea or in a laboratory setting between 2004 and 2019. Stomach processing followed standard methods developed by Tikhookeanskiy Nauchno-Issledovatelskiy Institut Rybnogo Khozyaystva I Okeanografiy (Chuchukalo and Volkov 1986, Volkov and Kuznetsova 2007, Moss et al. 2009, Coyle et al. 2011). Typically, the contents of up to 10 stomachs from randomly sampled fish were combined together from each station, and prey composition was recorded as a stomach content index (SCI) and stomach fullness index (SFI). The SCI was calculated as individual prey taxon weight (g) multiplied by 10,000 and divided by predator body weight (g). Multiplying by a factor of 10,000 made these numbers easier to handle, as predator body weight was always much larger than prey taxon weight. The SFI was equal to the sum of all prey SCIs at a given station and gives an indication of fullness as a proportion of prey weight to predator weight. The average SFI was calculated for each year and compared with SST. In some cases, accurate prey weights could not be measured due to movement of the vessel. In these instances, prey taxon weight was estimated based upon percent volume and the assumption of equal body density of all prey items. Laboratory based weights were typically measured at 0.001 g. Prey composition was summarized as %SCI contribution (individual prey category SCI divided by the sum of SCI in a given year). Prey categories occurring in less than 10% of all stomachs within a predator species were combined into broader taxonomic groups. Prey groups were determined by the overall contribution to the diet within a predator species across all years, the proportion of the SFI within years, and in terms

of percent frequency of occurrence over all years. Rare prey items that did not fall into a larger category were placed into an "Other" category. *Thysanoessa* was used as a prey category for sockeye salmon diets because they composed 95% or higher of all the euphausiids while euphausiids was used as a broader prey category for pink and chum diets. All stations where stomachs were analyzed, but no prey was present in stomachs or contents were not identified were removed from this analysis. Years with diet data from less than five stations were not included in the diet summaries/figures.

Juvenile Salmon Energetic Condition

Energetic condition (energy density, ED) of juvenile Chinook salmon from the NBS was obtained using bomb calorimetry on dried samples of homogenized whole fish tissues for 2006-2019 (Fergusson et al. 2010). From 2006 to 2015, samples were heated at 75°C in a drying oven and manually re-weighed until mass was constant. Starting in 2016, the method of sample drying and moisture determination prior to bombing was changed. Since 2016, samples were heated at 135°C to dryness using a LECO Thermogravimetric Analyzer 601. Moisture values obtained by the two methods were known to differ by less than 1% (Vollenweider et al 2011).

Comparing annual average ED among years required use of weighted least squares in Welch's ANOVA (Welch 1951, Day and Quinn 1989) due to unequal variances among years. Testing for differences in ED among years while controlling for fish size was accomplished using one-way ANCOVA and post-hoc Tukey's pairwise comparisons of adjusted means. Due to unequal variances among years, ANCOVA results were compared to results from a rank-based Kruskal-Wallis test performed on the residuals from a simple linear regression of ED against length, followed by Tukey's pairwise comparisons on the ranked residuals.

Spearman's rank correlation test was used to evaluate the effects of SST on ED and nonlinearity in the relationship was described using generalized additive models (GAMs; Wood 2006) limited to 4 knots to avoid overfitting. Multiple linear regression models of fish length and SST on annual average ED were selected based on Akaike Information Criteria (AICc) (Burnham and Anderson 2004).

Seabird and Marine Mammal Observations

The USFWS conducted seabird surveys during the NBS survey. The USFWS was supported by an Interagency Agreement with the Bureau of Ocean Energy Management (project AK-17-03: Marine Bird Distribution and Abundance in Offshore Waters). This study will combine data collected during the NBS survey with data from other USFWS seabird surveys to examine the distribution of marine birds relative to prey and oceanographic properties. It will also be used to describe seasonal and interannual changes in marine birds and their communities in the Beaufort and Chukchi Planning Areas. Marine birds and mammals were surveyed from 28 August to 19 September, 2019. Survey data will be archived in the North Pacific Pelagic Seabird Database (http://alaska.usgs.gov/science/biology/nppsd).

Marine birds and mammals were surveyed from the port side of the bridge using standard USFWS protocols. Observations were conducted during daylight hours while the vessel was underway. The observer scanned the water ahead of the ship using hand-held 10 x 42 binoculars for identification and recorded all birds and mammals. Bird surveys used a modified strip transect methodology with four distance bins from the center line: 0-50 m, 51-100 m, 101-200 m, 201-300 m. Rare birds, large flocks, and mammals beyond 300 m or on the starboard side ('off transect') were also recorded but will not be included in density calculations. We recorded the species, number of animals, and behavior (on water, in air, foraging). Birds on the water or actively foraging were counted continuously, whereas flying birds were recorded during quick 'Scans' of the transect window.

Geometric and laser hand-held rangefinders were used to determine the distance to bird sightings. Observations were directly entered into a GPS-interfaced laptop computer using the DLOG3 program (Ford Ecological Consultants, Inc., Portland, OR). Location data were also automatically written to the

program in 20-second intervals, which allowed us to track survey effort and simultaneously record changing weather conditions, Beaufort Sea State, glare, and ice coverage (no ice was encountered during this cruise). Other environmental variables recorded at the beginning of each transect included wind speed and direction, cloud cover, sea surface temperature, and air temperature.

RESULTS AND DISCUSSION

Oceanographic Conditions

The CTD data were collected at each of the 47 stations sampled in 2019 (Table 2). Surface temperatures (upper 10 m) in the NBS in 2019 ranged from 7.9°C to 13.8°C with an average of 11.5°C, which was 2.9°C above average (restricted SST range, 2003 to 2018) (Fig. 2). Surface and bottom temperatures were highest in the shallow nearshore stations and in Norton Sound. Surface temperatures were coldest at stations northeast of St. Lawrence Island; bottom temperatures were much colder due to the presence of the eastern Bering Sea cold pool and were coldest just south of St Lawrence Island (Fig. 3). Surface salinities ranged from 21.7 PSU to 31.9 PSU. The lowest salinities were in Norton Sound and just outside the Yukon River Delta with salinity increasing with distance from shore (Fig. 4). Mixed layer depths ranged from 7 m to 29 m with an average of 19 m (Table 3, Fig. 5). The MLD estimates from the SBE9-11 CTD for stations 2 and 5 were missing data from the top 11 m of the water column; therefore, the MLD estimates for those stations were derived from the FastCat (SBE49) data collected during the bongo tow.

Small copepods (< 2 mm) were abundant across the sampling area, with abundances approaching 10,000 ind/m^3 (Fig. 6). In contrast, large copepod (> 2mm) abundances were low overall, and copepods were largely absent in many stations between 62°N and 64°N. Large copepods abundances would be expected to be higher in an average year, based on the accumulation of *Calanus* spp. C5 stages later in the year (Stabeno and Bell, 2019). Small copepods have faster turnover times, multiple generations per year, and metabolic rates that scale less dramatically with temperature. Warm temperatures in 2018 and 2019 are likely a contributing factor to the elevated abundance of small versus large zooplankton (Kimell et al. 2018, Kimell et al. 2019). The abundance of small and large copepods declined from 2018 and may indicate an overall decline in productivity during 2019. Euphausiid numbers were also low across the NBS, with no euphausiids recorded north of 62°N. Above average temperatures in 2019 may have caused earlier entry into diapause or increased advection of local populations of *Calanus* spp. into the Chukchi Sea. The low euphausiid abundance was expected; bongo tows typically undersample adult euphausiids due to depth distribution.

Surface Trawl Data

Bottom depths at stations sampled during the survey ranged from 14 m to 63 m (Table 2). Footrope setback chains were shortened to collapse the vertical opening of the trawl when sampling locations with bottom depths less than approximately 22 m. The average horizontal and vertical opening of the trawl was 49.8 m and 17.5 m, respectively. The average footrope depth from the SeaBird SBE39 depth sensor was 18.9 m (Table 4), indicating that the average depth of the center of the headrope (where the net sonar is located) was 1.4 m. The average distance towed during each 30 minute trawl set (based on GPS coordinates of the start and end of each tow) was 3.9 km, which results in a calculated average speed of 4.2 knots. MLD expansions were required at 27 of the 47 stations and ranged from 2% to 33% (Table 4).

Similar to previous years, the species with the largest biomass in the surface trawl catches was the northern sea nettle (*Chrysaora melanaster*) at 6,898 kg, and the species with the largest catch in numbers was Pacific herring at 142,512 individuals (Tables 5-7). Juvenile pink salmon was the most abundant species of salmon at 13,507 fish. Ninespine stickleback were the third most abundant species at 9,464 individuals. The catch of age-0 walleye pollock (*Gadus chalcogrammus*, n = 8,798) was above average, but the catch of other forage fish species, including Arctic or Pacific sand lance (*Ammodytes* spp., n = 2) (Orr et al. 2015) and capelin (*Mallotus villosus*, n = 11) were quite low. Sand lance are able to avoid

capture with trawl gear, therefore, a low catch does not necessarily reflect low abundance. Capelin are known to be less abundant in the NBS during warm years (Andrews et al. 2016).

The spatial distribution of fish and jellyfish captured in surface trawls varied significantly by species (Appendix B). Surface trawl catch rates of the Juvenile chum and pink salmon were the most widely distributed salmon species with relatively high CPUEs across most of the survey area. Unlike previous years, juvenile Chinook salmon were absent in a number of stations between 60°N and 62°N and their highest catch rates were just west of Norton Sound where surface temperatures tended to be a bit colder. Juvenile coho salmon exhibited high CPUEs south of 62°N, in Norton Sound, and just northwest of the Yukon Delta. Juvenile sockeye salmon catches were concentrated at offshore stations south of St. Lawrence Island. sockeye salmon runs in the Yukon River and Norton Sound are relatively small so we suspect the high catches of sockeye salmon encountered during the 2019 survey were of Southern Bering Sea origin. Except for sockeye salmon, all other salmon species were caught at stations north of 66°N. The northern sea nettle, the most abundant of jellyfish, were caught in all but four stations during the 2019 survey. The moon jellyfish were found throughout the survey except just west of Norton Sound. Water jellyfish (*Aequorea* spp.) and the whitecross jellyfish (*Staurophora mertensi*) were encountered infrequently. The highest catch rates of Lion's mane jellyfish (*Cyanea capillata*) were in the shallow nearshore stations. Age-0 walleye pollock had high CPUEs west of 167.5°W and south of 63°N, whereas age-1+ walleye pollock catches were sparsely distributed throughout the survey grid. Both age-0 and age-1+ walleye pollock were caught at stations north of the Bering Strait. Pacific herring were captured throughout the NBS, but catches tended to be higher in Norton Sound and nearshore habitats where age-0 herring occur (Appendix B). Rainbow smelt (*Osmerus mordax*) were caught at nearshore stations and in Norton Sound and were absent west of 168°W. Similar to rainbow smelt, ninespine sticklebacks were constrained to nearshore stations east of 168°W and Norton Sound. Documenting species catch and distribution during NBS surface trawl surveys will help identify northward shifts in species's migration and distribution as the Bering Sea continues to increase in temperature over time.

Approximately half of the primary species captured in the NBS were significantly ($\alpha = 0.5$) correlated with SST (Figs. 7 and 8). Average catch rates of juvenile sockeye salmon had the highest positive correlation with SST ($\rho = 0.9$). Increased catch rates of sockeye salmon with temperature stems from the northward dispersal and increased abundance of juveniles from the southeastern Bering Sea (primarily Bristol Bay) as there are only minor spawning populations of sockeye salmon within the Yukon River and Norton Sound (Estensen et al. 2018, Menard et al. 2020). Spawning locations of walleye pollock also are predominantly in the southeast Bering Sea and therefore the positive correlation between age-0 pollock and SST ($\rho = 0.6$) reflects increased northward dispersal of age-0 pollock with temperature. The relationship between age-0 pollock and temperature in non-linear therefore the correlation coefficient underestimates the significance of temperature to the catch rates of age-0 pollock. There are significant spawning stocks of coho salmon in the Yukon River and Norton Sound (Estensen et al. 2018, Menard et al. 2020); therefore the correlation betwenn CPUE and SST ($\rho = 0.7$) most likely reflects an increase in the abundance of juvenile coho salmon stocks within the NBS. Capelin was the only species with a negative correlation ($\rho = - 0.6$) with SST. Capelin are known to have a preference for cooler water in the eastern Bering Sea (Andrews et al. 2016); therefore, this may also reflect a northward shift in their distribution (into the Chukchi Sea) as temperatures increases in the eastern Bering Sea.

Significant positive correlations were present between catch rates of ninespine stickleback and Pacific herring ($\rho = 0.8$), Arctic lamprey (*Lethenteron camtschaticum*) ($\rho = 0.7$), and Chinook salmon ($\rho = 0.6$) (Fig. 8). Ninespine stickleback are an abundant species within the nearshore habitats of the NBS and nearly all ninespine stickleback are captured in the shallowest stations sampled in the NBS (Appendix B). Although age-0 Pacific herring are likely the dominant species within the nearshore fish community, catches of age-0 Pacific herring are not separated from the older age classes, and could reflect a mixture of herring from the NBS and SEBS (Andrews et al 2016). The highly piscivorous diet of juvenile Chinook salmon (Farley et al. 2009, Auburn and Sturdevant 2013, Honeyfield et al. 2016, Miller et al.

2016, Garcia and Sewall 2021) and Arctic lamprey (Shink et al. 2019) would logically support a dependency of these two species on the nearshore fish community. It is possible that the correlations between CPUE of ninespine stickleback and juvenile Chinook salmon and Arctic lamprey could stem from a dependency of Chinook salmon and Arctic lamprey on the nearshore estuarine fish community in the NBS in general, not necessarily a direct association with ninespine stickleback.

Size Distributions

Length-frequency distributions for the primary species captured in surface trawl catches are summarized in Figs. 9 to 11. Juvenile salmon lengths in 2019 were typical of those encountered in past NBS surveys (Fig. 9). Individual lengths and weights of juvenile salmon (Appendix C) confirm that there is limited error in the size data and that juvenile salmon have a relatively stable relationship between length and weight. Juvenile Chinook salmon lengths ranged from 10 to 24 cm, and averaged 20 cm. Most juvenile Chinook salmon caught in the NBS survey spend one year in fresh water (total age 2); however, smaller juvenile Chinook may be indicative of sub-yearlings (Chinook salmon that migrate to sea without spending a year in fresh water). Due to their multi-year residence in fresh water, coho salmon were the largest juvenile salmon species caught in the survey with lengths between 20 and 30 cm and averaging 25 cm. Chum and pink salmon were the smallest species caught with lengths ranging between 12 and 25 cm. The overlap in juvenile Chum and pink salmon lengths suggests that their growth rates during the early marine stage may be similar. Except for a few larger individuals, juvenile sockeye salmon lengths ranged between 15 and 22 cm.

There was not a consistent trend in the size of juvenile salmon within or between species across the time series (Fig. 12), which emphasizes the importance of species-specific factors in the growth and size of juvenile salmon. The average lengths of juvenile Chinook salmon from recent warm years (2016-2019) are smaller than those from prior warm years (2004, 2014-2015). The average lengths of juvenile coho salmon has declined in the recent warm years. The recent warm temperatures may be limiting the growth of piscivorous species like juvenile Chinook and coho salmon through changes in prey quality and quantity. The average length of juvenile coho salmon in 2019 was the lowest observed since the survey began in 2003. Due to the multiple fresh water ages of coho salmon (predominantly fresh water ages of 1 and 2), the reduced size of coho salmon could also reflect an earlier age of marine entry. Variation in the average length of juvenile chum and pink salmon did not vary consistently with temperature and above and below average lengths were present in warm and cold years. This highlights the importance of dynamic ecosystem impacts on their size and growth, including prey availability. Growth potential models are in development and will clarify the role of warming temperature on pink and chum salmon in the NBS.

The size and growth of juvenile salmon during the early marine life stage have important implications for future marine survival. Larger juvenile salmon are more likely to survive than smaller individuals because they are able to avoid predators and maintain high energy reserves necessary to survive their first winter at sea (Beamish and Mahnken 2001). Prior research on juvenile Chinook salmon correlated growth and size in the early marine stage with increased adult returns (Tomaro et al. 2012). Additionally, scale pattern analyses have shown that small juvenile Chinook, coho, pink, and sockeye salmon are subject to size-selective mortality during their first summer at sea (Beamish et al. and Mahnken 2001, Moss et al. 2005, Howard et al. 2016), providing further evidence that larger juvenile salmon have higher likelihoods of surviving than their smaller conspecifics. Juvenile salmon caught in the NBS are caught in September, after they have spent their first summer in the ocean, and their size at this critical period may inform whether they are likely to survive their first marine winter.

Length measurements were also taken from immature salmon and non-salmon species. Fork lengths were measured for immature chum, sockeye, and Chinook salmon (Fig. 10). Immature sockeye (n = 19) and Chinook salmon (n = 24) are less frequently encountered during the NBS survey compared to immature chum salmon (n = 194). Immature sockeye salmon lengths ranged from 26 cm to 53 cm and averaged 36

cm. Immature Chinook salmon (n = 24) ranged from 31 cm to 79 cm and averaged 43 cm. Immature chum salmon lengths ranged from 29 cm to 79 cm. The bimodal distribution of fork length measurements for immature chum salmon suggest two age classes are encountered during survey operations. Although immature sockeye salmon greater than 45 cm suggest the presence of a separate, older age class, there are not enough samples to categorize age distributions. Bell diameters for moon jellyfish, northern sea nettle, and lion's mane jellyfish were between 10 and 50 cm. Bell diameters were skewed towards smaller sizes between 10 cm and 15 cm for moon jellyfish (mean of 15.3 cm), centered around 23 cm for the Northern Sea Nettle and bimodal at 18 cm and 33 cm for lion's mane jellyfish (Fig. 11, Table 7). Ninespine stickleback were larger than those encountered in the NBS survey in past years, ranging between 4.0 cm and 6.5 cm (Fig. 11, Howard et al. 2020). Pacific herring, rainbow smelt, and walleye pollock length frequencies reflect the multiple age classes of each species encountered during the survey (Fig. 11).

Juvenile Salmon Origin

Juvenile Chinook salmon are distributed within the inner domain (bottom depths less than 55 m) of the NBS and can occur throughout the latitude range of the NBS (Fig. 13). CWT recoveries are particularly useful in characterizing marine distributions of Chinook salmon (Appendix D). All CWTs recovered from juvenile Chinook salmon (including two CWTs in 2019) have been from the Whitehorse Rapids Fish Hatchery (WRFH). All juvenile Chinook salmon released from the WRFH have adipose fin clips and all tagged juveniles exhibit a subyearling migration pattern. Juveniles with an adipose fin clip and not CWT were assumed to be the result of tag shedding and were assumed to be subyearling Chinook salmon from the WRFH. WRFH Chinook salmon had an average length of 151 mm (range: 109 to 207 mm), and an average weight of 43 g. The size of hatchery Chinook salmon were slightly below the average size of pink salmon (164 mm) and chum salmon (177 mm), which migrate to sea during the same year that they hatch. Although hatchery Chinook salmon have been caught throughout the latitude range of the NBS survey, they are most commonly captured in the nearshore stations adjacent to the Yukon River Delta and within Norton Sound (Appendix D).

Although CWTs are useful in identifying the origin of individual Chinook salmon, genetic stock identification is the primary method used to identify the origin of Chinook salmon in the NBS. A total of 125 juvenile Chinook salmon were successfully genotyped for mixed-stock-analysis (MSA) during the 2019 NBS survey. Mean stock composition estimates were: 30% Upper Yukon (hereafter Canadian-origin), 22% Middle Yukon, 14% Lower Yukon, and 35% Other Wester Alaska (non-Yukon River) stocks (Table 8, Fig. 14). The Canadian-origin proportion was lower than the historical average (48%), and the non-Yukon River proportion was higher than the historical average (12%); however, the composition of Lower Yukon and Middle Yukon stocks were similar to historical averages (12% and 27%, respectively). The Canadian-origin stock group had the largest reduction from the historic average (an 18% decrease from average) followed by the Middle Yukon River stock group (6% decrease from average). The proportion of the Lower Yukon River stock group was slightly higher (2%) than the historic average. The increase in non-Yukon stocks (23% increase) may reflect a combination of northward dispersal of Chinook salmon stocks from the southern Bering Sea (e.g., Kuskokwim River Chinook salmon) and possibly an increase in the relative contribution of Norton Sound Chinook salmon.

Juvenile Chinook Salmon Abundance and Run Forecasts

The overall abundance of juvenile Chinook salmon in the NBS during 2019 (2.0 million fish) was significantly below their average abundance during 2003-2018, (3.2 million fish). Abundance estimates of juvenile Chinook salmon were expanded by 10% (MLD adjustment) to account for incomplete sampling of the mixed layer, which was higher than the recent 5-year average of 2%. The abundance of Canadian-origin juvenile Chinook salmon during 2019 was the lowest observed in the NBS at 575,094 fish (sd = 164,126; CV = 29%) (Table 9, Fig. 15), and was less than half of the average abundance (1.57 million) during previous years (2003-2018). Similar to the Canadian-origin stock group, the abundance of Yukon River juvenile salmon was also the lowest observed at 1,246,038 fish (sd = 326,257; CV = 26%), and was

less than half of the 2003-2018 average of 2.75 million fish (Table 10, Fig. 15). The juvenile Chinook salmon caught during the 2019 NBS survey will primarily contribute to adult runs in 2021 (as age-4), 2022 (age-5), and 2023 (age-6).

Juvenile abundance is significantly ($\rho < 0.001$) related to adult Chinook salmon returns up to three years into the future (Fig. 16). Both the Canadian-origin and total Yukon runs are expected to decline over the next two years due to the reduction in juvenile abundance during 2017-2019. The projected run sizes for Canadian-origin Chinook salmon are 52,300 (31,200 to 73,400) fish in 2021, and 46,300 (24,800 to 67,900) fish in 2022. The projected run sizes for the total Yukon River run are 143,800 (95,200 to 192,400) fish in 2021, and 129,000 (79,500 to 178,500) fish in 2022. Although the ranges of possible run sizes are very wide, they indicate an expected decline in abundance of Chinook salmon. New forecast models for the Canadian-origin stock group are being developed by the Joint Technical Committee of the Yukon River Panel which will integrate juvenile and other sibling data into a Bayesian model framework. Similar models are also expected to be developed for the total run of Chinook salmon to the Yukon River. Estimates of future run size to the Yukon River have been of particular interest by managers, biologists, and stakeholders within the Yukon River as it helps support fisheries management decisions needed to protect the spawning stock and subsistence fisheries in the Yukon River (JTC 2020).

The number of Chinook salmon juveniles-per-spawner in 2019 was the lowest observed since 2003 for the Canadian-origin stock group (8.4) and the Yukon River stock group (5.3) (Fig. 17, Tables 9 and 10). The number of juveniles-per-spawner has been quite low for the last three years (2017-2019) and indicates a distinct downward shift in the survival of Yukon River Chinook salmon. Although the cause of the reduced survival is unclear, it may be tied to recent losses of arctic Sea ice and warming of the NBS and Yukon River. The number of juveniles-per-spawner does not vary predictably with spawner abundance for either the Canadian-origin or total Yukon River stocks. Similarly, there is no relationship between the number of spawners and the resulting number of juveniles for either the Canadian-origin or Yukon River stock groups. Juveniles-per-spawner and returns-per-spawner are highly correlated ($\rho = 0.76$) for both the Canadian-origin and Yukon River stock groups (Tables 9 and 10) and therefore the survival of Yukon River Chinook salmon during the initial fresh water and/or marine stages of salmon is the key factor in both the decline and variation in abundance over time.

Measurement error in juvenile abundance is a key limitation in the analysis and interpretation of juvenile survival. There are a number of unique features of the NBS survey that help limit the measurement error of surface trawl estimates of the distribution and abundance of juvenile salmon. We are able to restrict abundance of juvenile Chinook salmon to large stock groups such as the Total Yukon (average proportion of 86%) and the Canadian-origin (average proportion of 47%) stock groups, which minimizes the stock identification error in abundance estimates. The shallow depths and presence of the eastern Bering Sea cold pool play a key role in limiting the vertical distribution of juvenile salmon in the NBS. MLD corrections are used to account for changes in the sampling depth of surface trawls relative to juvenile habitat. The relatively limited dispersal rate of juvenile Chinook salmon in the NBS (compared to coastal habitats in the Gulf of Alaska) allows a single survey to sample through the distribution of juveniles and limits the influence of year to year variation in the migration of juveniles on abundance estimates. There has been limited mixing of juvenile Chinook salmon stocks from regions outside of the Yukon River prior to 2019. This has helped clarify the spatial distribution and dispersal patterns of juvenile Chinook salmon stocks from the NBS and has helped establish survey designs for juvenile Chinook salmon in the NBS. However, caution is still needed when interpreting abundance estimates as measurement has not been stationary over time due to changes in sea states, vessel platforms, juvenile distributions, and survey designs over time.

Juvenile Pink Salmon Abundance

The juvenile pink salmon abundance index ranged from 1.0 to 5.4 with an overall average of 2.9 from 2003 to 2019 (Fig. 19). The index is significantly correlated with pink salmon returns to Yukon and

Norton Sound rivers and provides an informative tool to forecast adult returns to these regions (Fig. 20). The preliminary index for 2019 was 5.3, which forecasted an adult return of 6.5 million pink salmon to the region in 2020.

Juvenile pink salmon abundance has increased along with the recent warming conditions in the eastern Bering Sea. The NBS is experiencing significant warming and extremes in seasonal ice extent and thickness that may benefit the growth and survival of pink salmon stocks in this region. Increased pink salmon abundance in the NBS and overall warming climate conditions are both thought to play an important role in the expansion of pink salmon into the Arctic (Farley et al. 2020). The critical period (Beamish and Mahnken 2001) in the production dynamics of pink salmon in the NBS appears to be more strongly tied to the initial life-history stages (fresh water and initial marine) than later marine life-history stages and may reflect temperature limitations present in high latitude stocks of salmon. Stock-specific information on juvenile pink salmon abundance would significantly improve our understanding of their movement and production dynamics in the NBS. Farley et al. (2005) identified discontinuous distribution in the size of juvenile pink salmon that may stem from the presence of both North American and Russian stocks in the NBS. Support for this interpretation was provided by the observation that 76% of the juvenile chum salmon in the Bering Strait region were from Russia during the 2007 NBS survey (Kondzela et al. 2009).

Juvenile Salmon Diet

Stomach fullness and species composition of juvenile salmon diets are summarized in Figs. 21 to 27 and in Appendix E. Station numbers and the number of stomachs sampled are also summarized in Appendix E.

Chum salmon fed upon gelatinous plankton, fish, hyperiid amphipods, and euphausiids in most years (Fig. 21). The proportion of hyperiid amphipods, which are rich in fatty acids (Persson and Vrede 2006), increased during cool years (2006-2012) (Appendix E). Feeding on prey high in fatty acids and lipids facilitates the accumulation of energy stores which are needed for overwinter survival (Heintz et al. 2013, Rogers et al. 2020).

Pink and sockeye salmon fed on a combination of fish and zooplankton confirming findings from previous investigations (Cook and Sturdevant 2013). Pink and sockeye salmon demonstrated no preference for a single species of zooplankton prey. Fish prey were most common in pink salmon diets during anomalously warm conditions (2003-2006), a transitional period from warm to cool (2007), and during the anomalously warm year of 2015 (Fig. 22). The composition of prey in sockeye salmon diets varied inter-annually and no pattern or prey preference during cool or warm years was apparent (Fig. 23).

Coho salmon preyed primarily upon sand lance, age-0 walleye pollock, capelin, and other fish (Fig. 24). Capelin increased in coho salmon when ocean conditions were cool (2007-2011) and capelin abundance was elevated in the NBS (Andrews et al. 2016). The proportion of decapods and other prey items not commonly consumed by coho salmon increased during warm years (2006-2012, 2014-2019), with the exception of 2007 and 2014, which were years when thermal conditions switched from anomalously warm to cool and cool to warm, respectively. Age-0 walleye pollock accounted for a larger proportion of prey in coho salmon diets during warm years, consistent with increased catches and of age-0 walleye pollock in the NBS and northward with warm temperatures (Fig. 7 and 8).

Chinook salmon fed primarily upon fish in the NBS (Fig. 25) which has also been reported by previous investigations (Cook and Sturdevant 2013, Garcia and Sewall 2021). However, piscivory by juvenile Chinook salmon has decreased as SSTs have increased in the NBS (Fig. 26). There has been a clear decline in piscivory in Chinook salmon relative to other species of juvenile salmon in the NBS. Fish composed 88.9% of the diet of Chinook salmon on average during 2004-2017, but decreased to 72.8% on average during 2018-2019. Age-0 walleye pollock were common in Chinook salmon diets when ocean

conditions were anomalously warm but were rare when conditions were cool. Capelin was a common prey item composing 16.7-68.4% of the diet during 2004-2013, with the exception of one year (2012), when capelin were not detected. The absence of capelin from the 2012 diet is more likely an artifact of the diet processor than an ecological reflection. No fish were identified to species from the 2012 survey, though a large percent of the diet was still fish. The presence of capelin declined to only 4.7-11.0% during 2014-2018 and were absent from the diet in 2019 (Fig. 25). Concurrent with the decrease and disappearance of capelin from the diet was an increase in the consumption of decapod larvae during 2018-2019, which may reflect a decrease in the availability of fish prey or a reduced ability to capture fish resulting from a concurrent decrease in body size. Our findings highlight key features in the feeding ecology of juvenile Chinook salmon in the NBS and identify areas of potential concern.

The level of piscivory in Chinook salmon and the survey design in 2005 were atypical and the therefore the data from 2005 is treated as an outlier in the time series (Fig. 26). The 2005 survey started later than usual in 2005 and stations were sampled from North to South. Stations at the southern end of the NBS were sampled a month later than most years and juveniles had already begun to disperse into the southern Bering at that point. The unusual distribution of juvenile Chinook salmon in 2005 is believed to be contributing to an atypical pattern in their diet.

The average stomach fullness index (SFI) of all juvenile salmon except for coho salmon has declined as SSTs have increased in the NBS (Fig. 27). The overall average SFI was similar for Chinook (157), pink (156), and coho salmon (153), but lower for chum salmon (126). The average SFI in 2019 for Chinook salmon (67) and chum salmon (49) were the lowest on record and less than half of their overall average. Warmer temperatures increase metabolic rates which would require a higher overall amount of prey consumed or an increase in the energetic quality of prey consumed for a fish to realize the same growth rate under cooler conditions. Therefore, the combination of an increase in thermal experience and a decrease in the amount of food consumed will have a larger effect on growth than an increase in thermal experience alone.

Larger body size requires higher energy prey (Schabetsberger et al. 2003). Years in which piscivory decreased for juvenile Coho and Chinook salmon may signal a lack of energy-rich forage. Sand lance and capelin are energetically rich prey (Litzow 2006). In the absence of high quality prey, lower quality prey may be substituted (Weitcamp and Sturdevant 2008), and an increase in prey diversity may indicate more generalized feeding and a greater reliance on non-preferred prey items (Weitcamp and Sturdevant 2008). If ocean conditions continue to warm and alter lower trophic levels in the Bering Sea (Hunt et al. 2011), these changes are likely to cascade up to higher trophic levels and affect salmon growth and survival. This analysis combined all juvenile salmon diets of a given species without regard to habitat (bottom depth) to provide a synoptic view across the entire NBS survey area. Previous studies have noted that certain prey may be more commonly consumed in certain habitats by juvenile salmon (Cook and Sturdevant 2013) and forage fishes (Andrews et al. 2016).

Juvenile Salmon Energetic Condition

The energetic condition of NBS juvenile Chinook salmon varied across the 12 years of available data, partially driven by differences in fish size (Fig. 28). Average ED (kJ/g dry tissue mass) differed significantly among years (Welch's ANOVA, $F = 10.36$, $R^2 = 17.9\%$, $\rho < 0.001$), with 2016 being the highest, 2011 the lowest, and 2019 of intermediate value slightly lower than 2018. Average lengths of analyzed fish also differed among years (Welch's ANOVA, $F = 22.12$, $R^2 = 21.9\%$, $\rho < 0.001$), with 2007 the largest, 2011 the smallest, and 2019 of intermediate size slightly larger than 2018. With all data pooled across years, linear regression analysis indicated that the energetic condition of juvenile Chinook salmon increased with fish length (slope = 0.0230; $R^2 = 39.7\%$; $\rho < 0.001$; Fig. 29). This positive relationship was expected, as energetic condition commonly increases with size in fishes that must store energy prior to winter (Post and Parkinson 2001), and has been previously observed in juvenile Chinook salmon (Murphy et al. 2014). However, this indicated that approximately 60% of the variation in

individual ED was due to factors other than fish size. Including year in addition to length increased the explained variation to 50.9%, with a significant effect of year after controlling for length (ANCOVA, $F_{11,562} = 11.56$, $\rho < 0.001$). Mean size-adjusted energetic condition overlapped significantly among years but was lowest in 2011 and highest in 2018 (Table 11). Similar results regarding yearly comparisons were obtained using a rank-based test and comparisons of ranked residuals from the regression fit of ED versus length (Kruskal-Wallis Test, H = 103.9, $\rho < 0.001$; Table 12). Monitoring yearly differences in autumn energetic condition may help understand and project juvenile survival, as cohorts that are able to store more energy prior to their first winter are more likely to survive (Sogard and Olla 2000).

Differences in ED among years also may be driven by annual differences in SST. Annual mean Chinook ED generally increased with mean autumn SST across years (Spearman's rho = 0.583, $\rho = 0.047$. However, temperature may have a non-linear, dome-shaped relationship to ED, as indicated by a GAM model fit (k = 4, edf = 2.26, adj $R^2 = 36.4\%$, $\rho = 0.108$) in which ED was highest at intermediate SST and appeared to decline at the highest SST observed in 2019 (< 11 °C; Fig. 30). Temperature effects on ED were evaluated in combination with fish size, given that average length alone accounted for 46.5% of the variation in annual average ED (slope = 0.0237; $F_{1,10} = 8.68$, $\rho = 0.015$; Fig. 31) in a simple linear regression model. Temperature combined with length in a multiple regression model explained 64.0% of the variation in average ED ($slope_{SST} = 0.146$, $slope_{LEN} = 0.0211$; $F_{2,9} = 7.99$, $\rho = 0.010$). The effect of SST on ED was marginally not significant ($\rho = 0.066$) in that model and was potentially weakened by collinearity with length due to the non-significant but positive influence of SST on length (slope = 1.72; $F_{1,10} = 0.313$; $R^2 = 3.04\%$, $\rho = 0.588$). The 17.5% improvement in fit versus length alone justified the inclusion of the SST term in the model (ΔAICc = - 0.034).

The positive influence of temperature on juvenile Chinook salmon energetic condition across most of the observed temperature range through 2018 may be expected for fish near the northern limit of their distribution, where temperatures are likely below optimal for growth and condition. Warmer temperatures are expected to have a positive effect up to a species-dependent optimal temperature, given the typical dome-shaped responses of fish growth and condition to temperature (Beauchamp et al 2007; Laurel et al 2016). Warmer temperatures in the past have supported higher survival of northern stocks of pink, chum, and sockeye salmon potentially through indirect effects on prey production (Mueter et al. 2002). However, anomalously warm temperatures seen in 2019 may have exceeded the optimum for juvenile Chinook salmon, and thus led to a decline in ED.

The 2019 decline in ED may have been caused by a combination of increased metabolic rates (Gillooly et al. 2001) and negative impacts on prey quality or quantity associated with unusually warm conditions. Higher ED observed in warmer years through 2018 suggests that juvenile Chinook salmon energetic condition during that period generally was not limited by food energy intake. Juvenile Chinook salmon may have adapted to decreased availability of capelin in warm years (Andrews et al. 2016) by eating more sand lance and early-stage decapods. Diet differences in warmer versus colder years make it difficult to strictly distinguish temperature effects from diet effects on energetic condition. However, despite eating fewer fish and less prey overall in warmer years, NBS juvenile Chinook salmon diets were adequate to support higher energetic condition than in cooler years through 2018. The 2019 decline in ED suggests juvenile Chinook salmon were unable to ingest sufficient energy to support optimal energetic condition, though it is difficult to infer mechanisms or trends based on a single anomalous year. If energetic condition consistently declines in response to anomalously warm conditions, continued ocean warming could lead to decreased survival of juveniles, which in 2019 had among the lowest abundances since monitoring began in 2003. These data indicate juvenile Chinook salmon energetic condition is sensitive to temperature-driven changes in ocean conditions that could impact future returns.

Seabird and Marine Mammal Observations

A total of 2,870 km were surveyed during the cruise with 324 km in the Chukchi Sea, 1,734 km in the NBS, and 809 km in the southern Bering Sea during transit to port in Dutch Harbor, AK. We observed a total of 3,310 birds on transect, comprising 38 species plus several unidentified passerines (Table 13).

The northern fulmar (*Fulmarus glacialis*) was the most abundant seabird species (28%) recorded during the survey. Highest concentrations of fulmars were observed in the southern Bering Sea south of 60°N near the shelf-break and the middle domain (Fig. 32). In the northern Bering and Chukchi seas, fulmar observations were generally lower and fulmars were largely absent on transects offshore of Norton Sound. Short-tailed shearwaters (*Ardenna tenuirostris*) and unidentified shearwaters (*Ardenna* spp.) were a predominant bird species (15%) recorded throughout the study area (Table 13). Shearwaters were widely distributed, with higher numbers in the southern Bering Sea, along with larger concentrations of birds near the Bering Strait (Fig. 33). Another *Procellariidae* species, the fork-tailed storm-petrel, was also common in the Bering Sea, with distribution centered in the southern Bering Sea (Fig. 33).

Aethia auklets (Crested, Least, and Parakeet) combined comprised 6% of the total seabird observations during the survey (Table 13). Crested auklets were primarily observed in two areas, southeast of St. Lawrence Island and near King Island in the NBS (Fig. 34). Least and parakeet auklets were more widely dispersed south of St. Lawrence Island, west of Nunivak Island, and in the southern Bering Sea (Fig. 34). Tufted puffins (3%) and common murres (3%) were other commonly detected *Alcid* species.

Phalaropus spp. consisting of red phalaropes (*P. fulicarius*), red-necked phalaropes (*P. lobatus*), and unidentified phalaropes, comprised 8% of total birds recorded during the survey. Phalaropes were mostly found in the NBS near St. Lawrence Island, the Bering Strait, and extending into the Chukchi Sea (Fig. 35). Black-legged kittiwakes (*Rissa tridactyla*) were the prevalent *Laridae* species recorded and comprised 19% of total seabird observations. Kittiwakes were widely distributed, with the highest numbers detected near the Pribilof Islands, east of St. Matthew Island, and Bering Strait (Fig. 36).

We recorded marine mammals during surveys, but because we used seabird survey protocols our observations cannot be used to calculate marine mammal densities. The USFWS observer recorded 65 marine mammals of seven species, including off-transect individuals (Table 14). northern fur seals (*Callorhinus ursinus*) were the most commonly encountered marine mammal, with individuals observed in the Bering Sea within 200 km of Dutch Harbor. The most common cetacean species observed was the humpback whale (*Megaptera novaeangliae*).

Sandhill cranes (*Grus canadensis*) were observed in five flocks near Bering Strait on 14 and 16 September, totaling 604 birds. We recorded three observations of Aleutian terns (*Onychoprion aleuticus)* totaling four birds in early to mid-September, east of St. Paul Island, north of Nunivak Island, and northeast of St. Lawrence Island. Near Nunivak Island we also observed two female Steller's eiders (*Polysticta stelleri*), and one marbled murrelet *(Brachyramphus marmoratus*) in early September.

Acknowledgements

We wish to thank the captain and crew of the FV *Northwest Explorer* for their exceptional support during the 2019 northern Bering Sea surface trawl survey. We also wish to thank Alex Andrews for his helpful review of this report. The 2019 survey was supported by the Alaska Sustainable Salmon Fund (AKSSF) through the project entitled northern Bering Sea Juvenile Chinook salmon Survey Phase 2 (project #51002), Alaska Fisheries Science Center, Alaska Department of Fish and Game, U.S. Fish and Wildlife Service (with funding from Bureau of Ocean Energy Management, project AK-17-03), and Alaska Pacific University. This report was prepared under award NA19NMF4380229 from the NOAA Cooperative Institute Program and administered by the Alaska Department of Fish and Game. The statements, findings, conclusions, and recommendations are those of the author(s) and do not necessarily reflect the views of NOAA or the Alaska Department of Fish and Game.

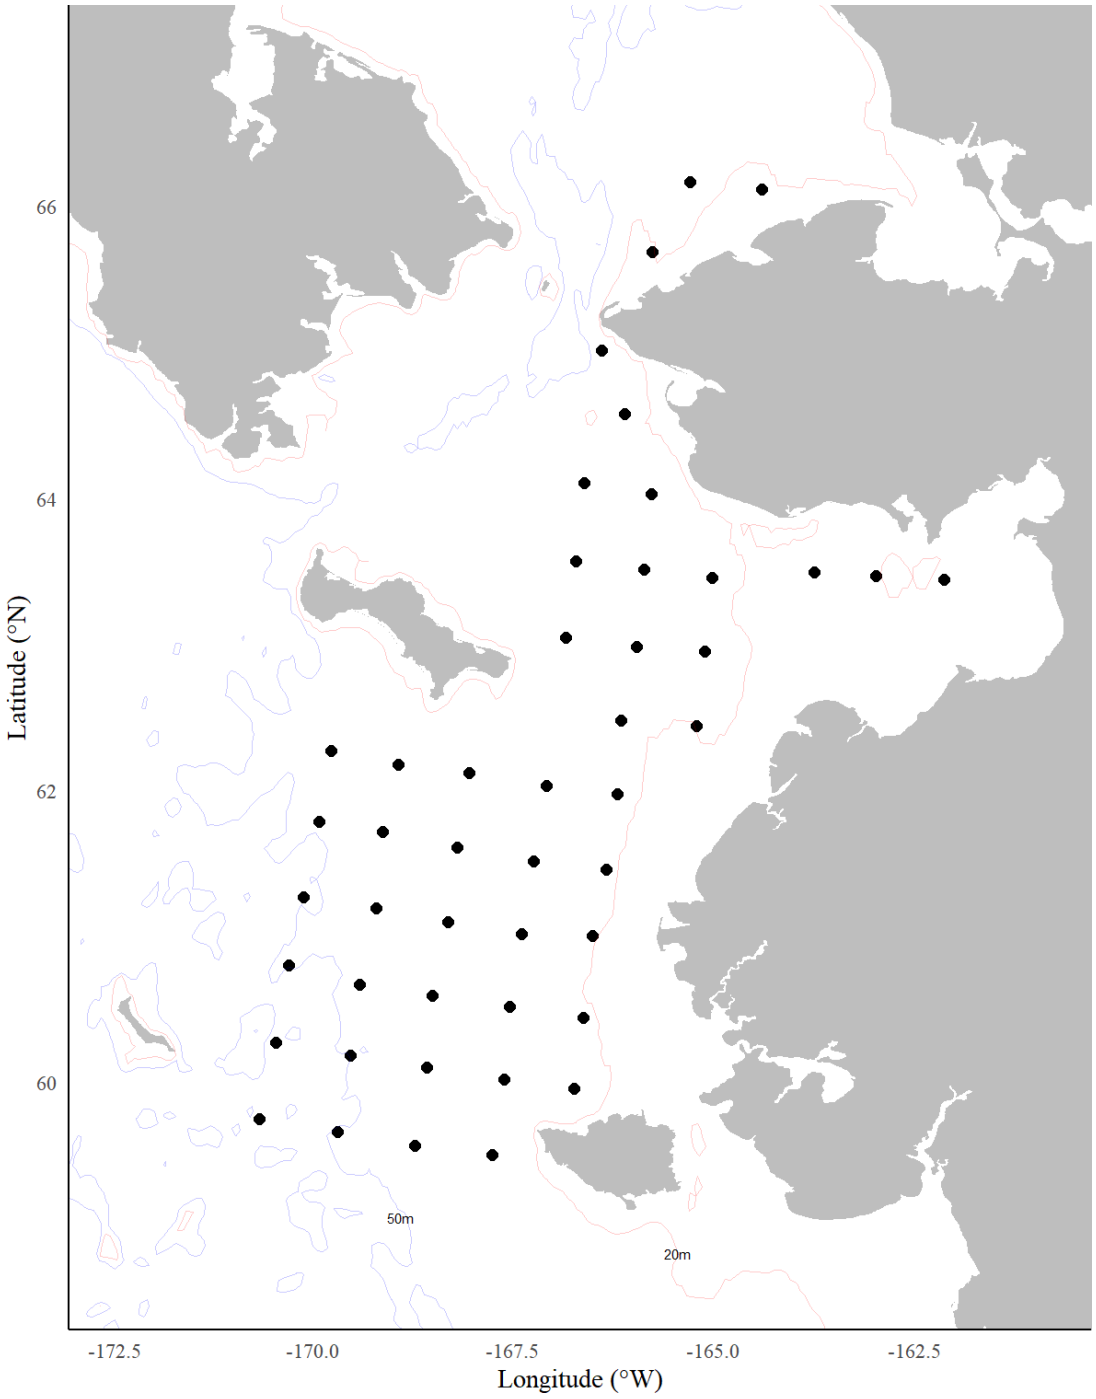

Figure 1. – Map of stations sampled during the northern Bering Sea surface trawl and ecosystem survey, 2019.

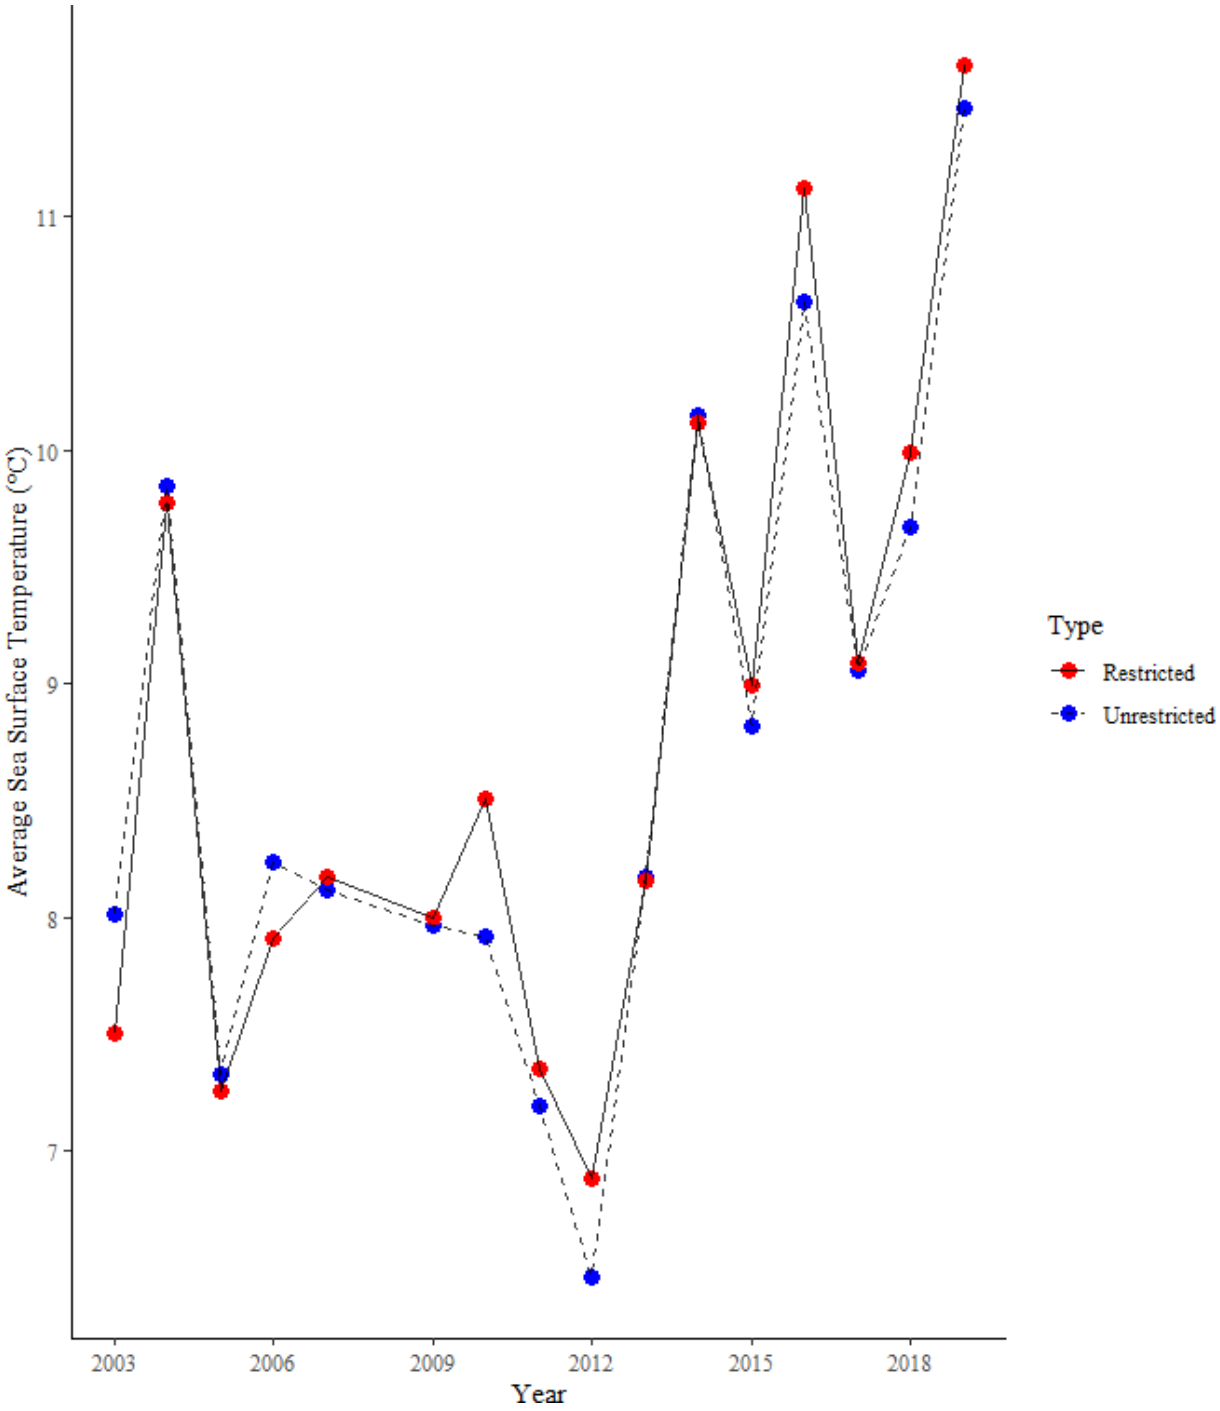

Figure 2. -- Average annual sea surface temperature (top 10 m of the water column) from CTD data collected during the northern Bering Sea surface trawl surveys, 2003-2019.

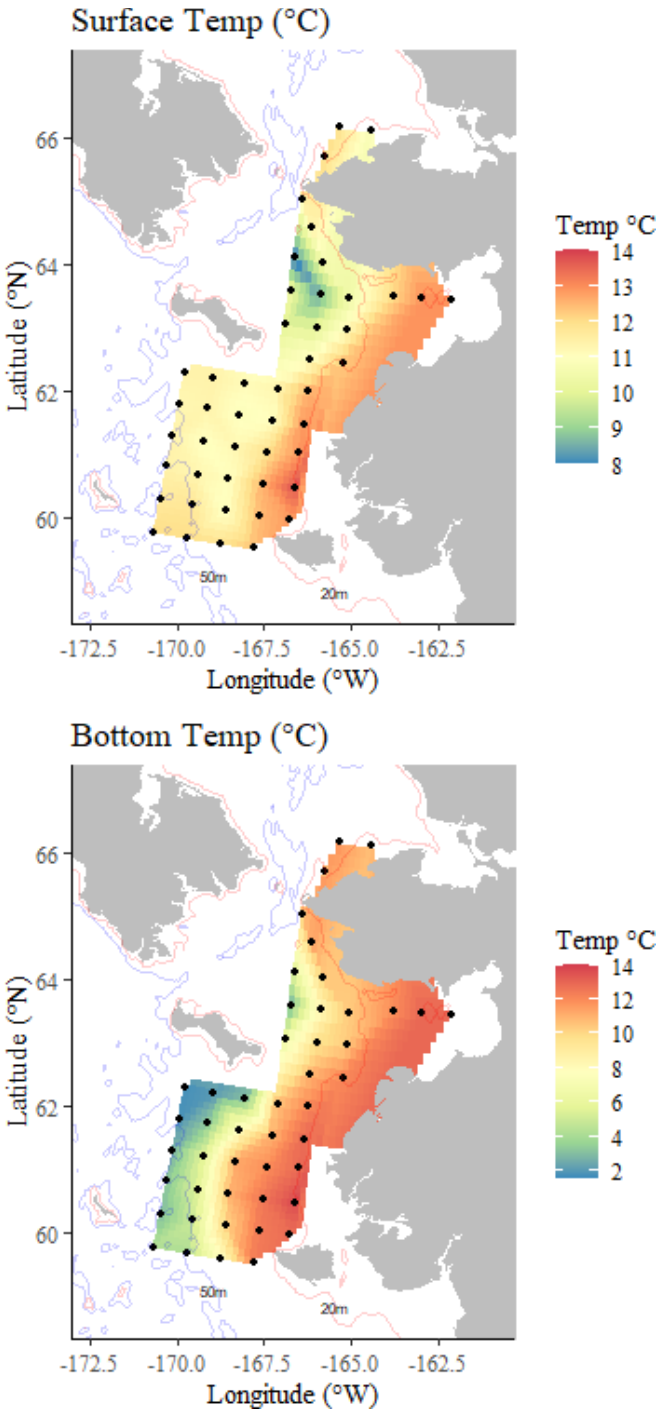

Figure 3. -- Interpolated map of surface (upper 10m) and bottom (deepest depth sampled) temperature (°C) from CTD data collected during the northern Bering Sea surface trawl survey, 2019.

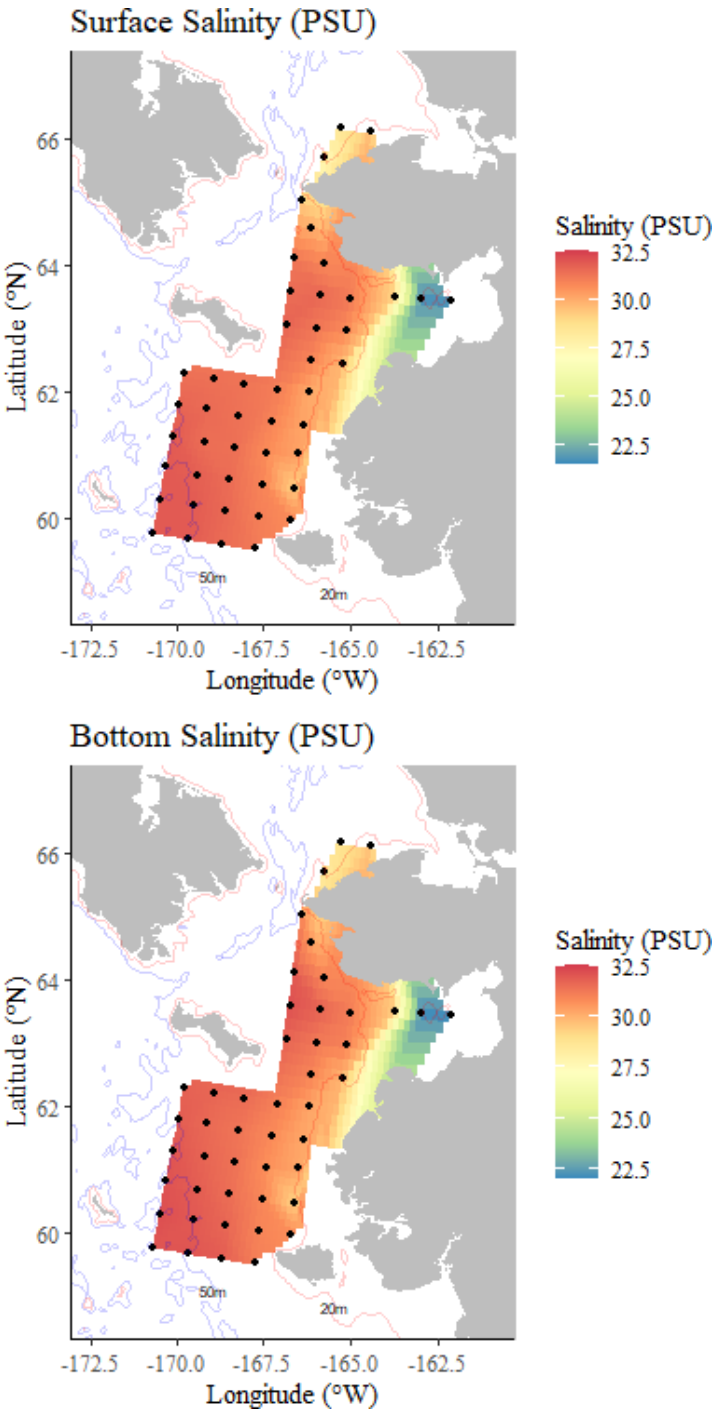

Figure 4. -- Interpolated map of surface (upper 10m) and bottom (deepest depth sampled) salinity (PSU) from CTD data collected during the northern Bering Sea surface trawl survey, 2019.

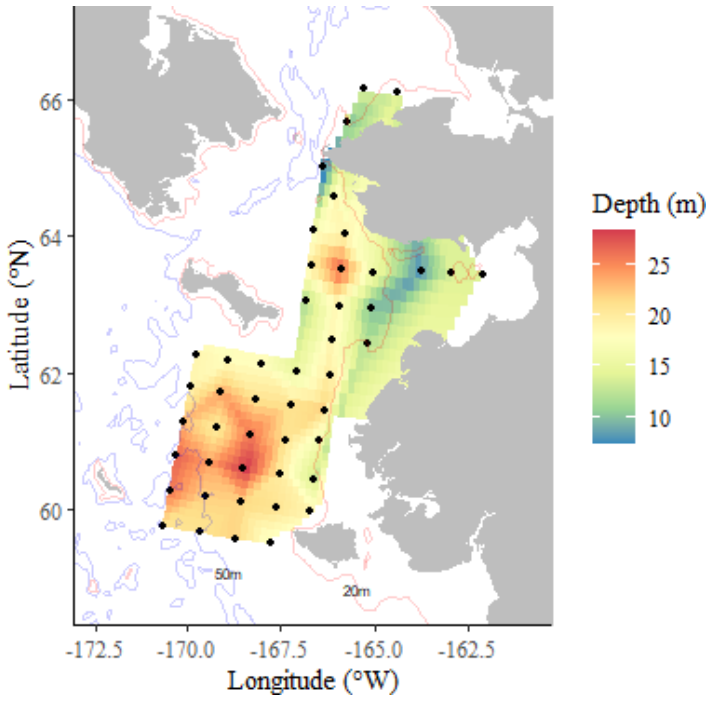

Figure 5. -- Interpolated map of mixed layer depth (m) from CTD data collected during the northern Bering Sea surface trawl survey, 2019.

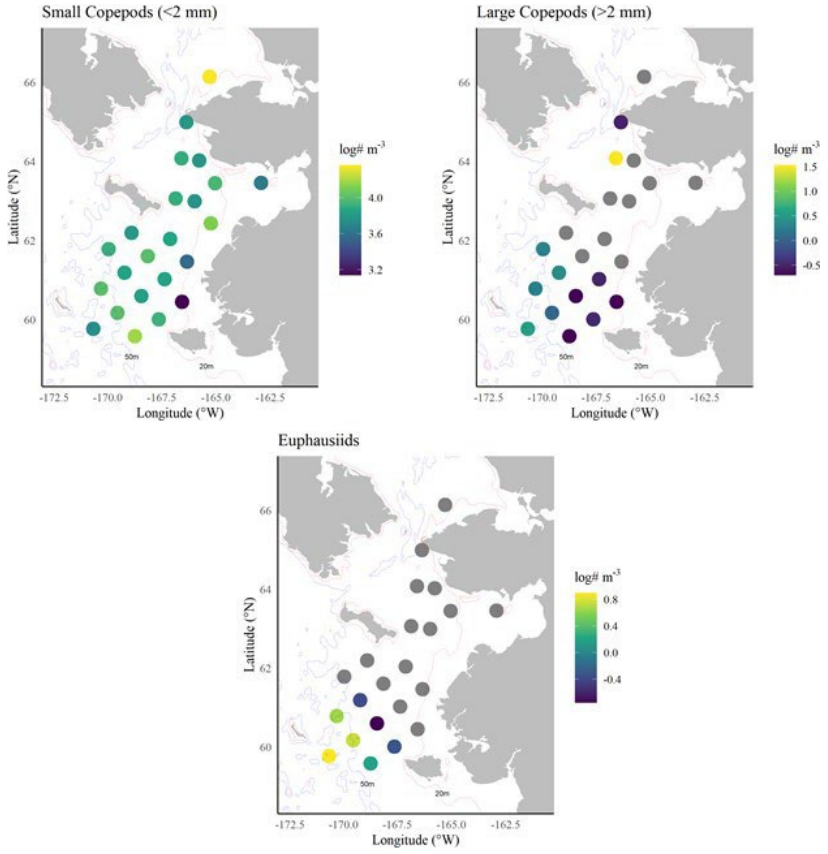

Figure 6. – Distribution of small copepods, large copepods, and euphausiids determined by rapid zooplankton assessment methods during the northern Bering Sea surface trawl survey, 2019.

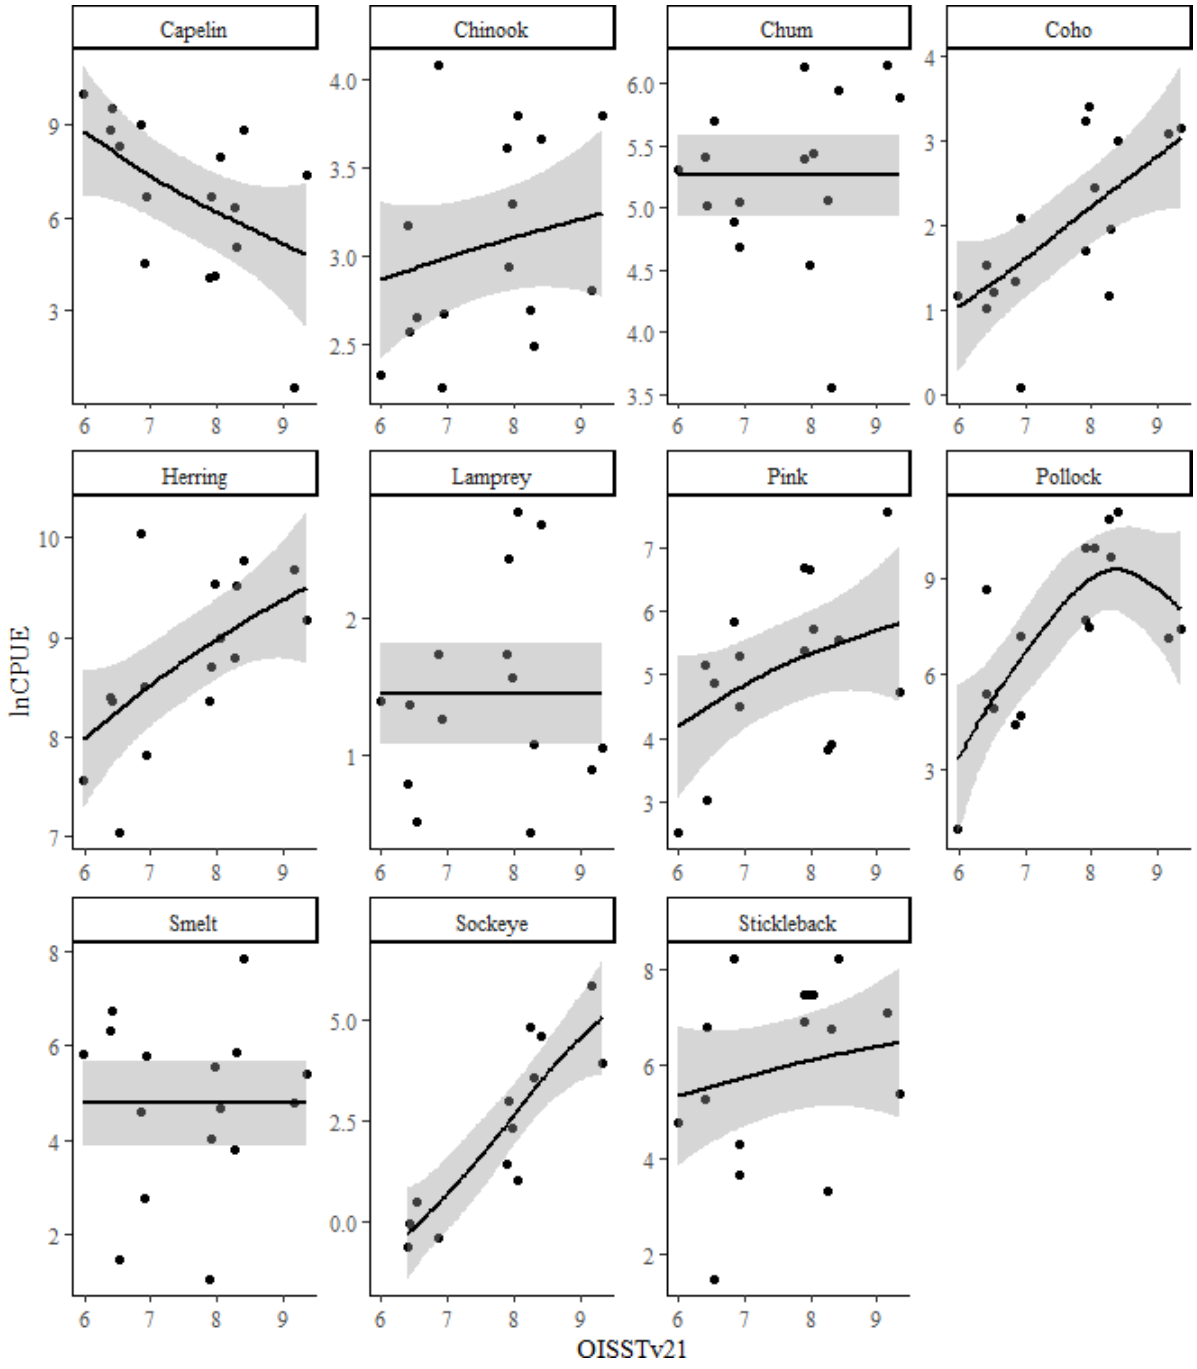

Figure 7. -- General additive model fits (black lines) with 95% confidence intervals (shaded regions) between average summer sea surface temperatures in the northern Bering Sea (OISSTv2.1) and catch rates (lnCPUE) of the primary fish species captured during the northern Bering Sea surface trawl surveys, 2003-2019.

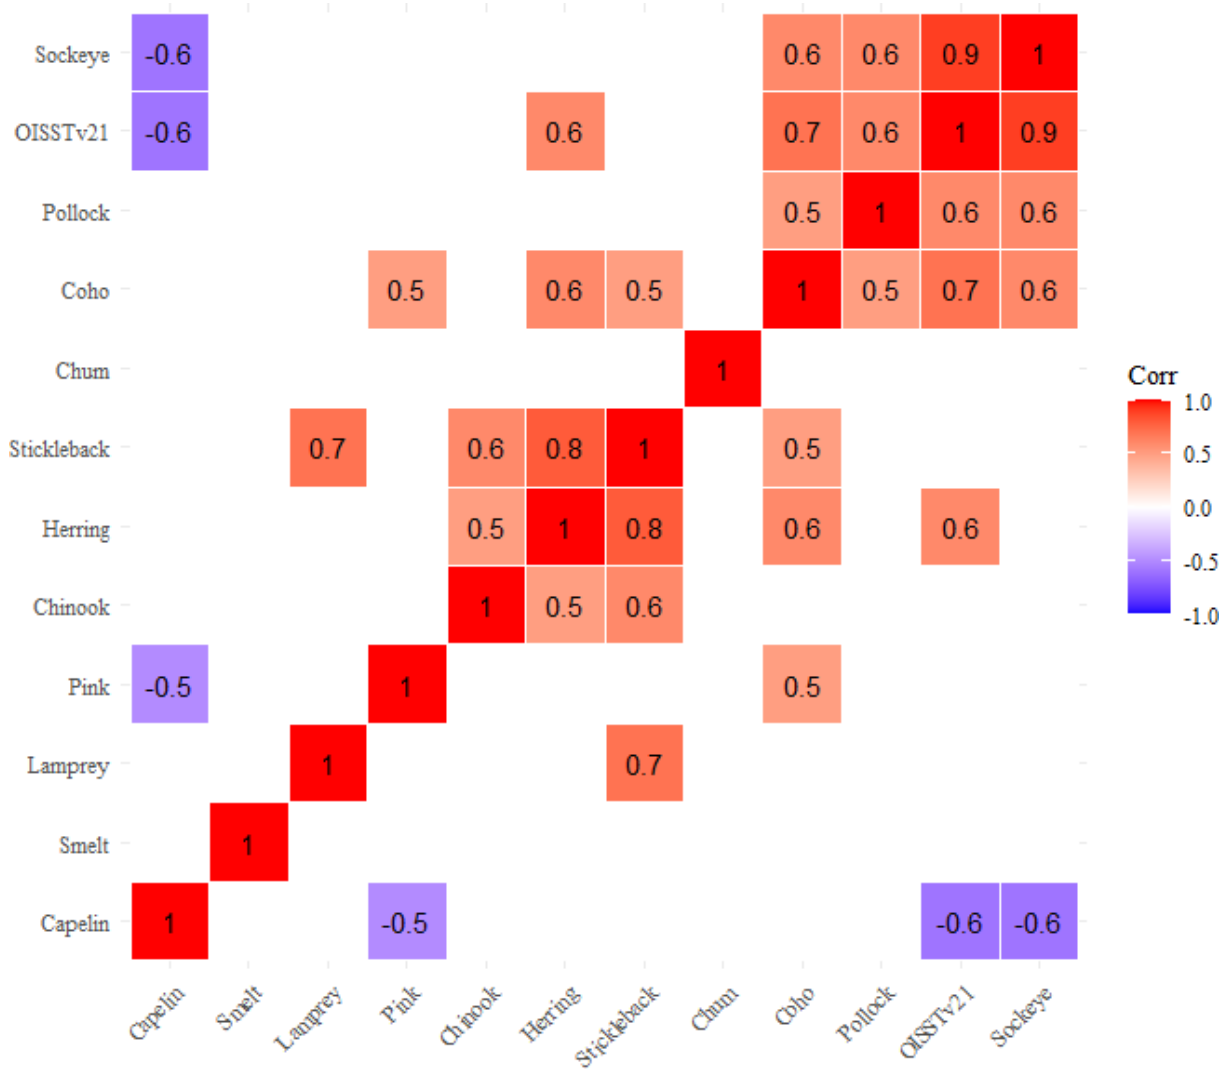

Figure 8. -- Significant correlations (Corr) between average catch rate (ln(CPUE)) of primary species captured during the northern Bering Sea surface trawl surveys and sea surface temperature data (OISSTv2.1), 2003-2019.

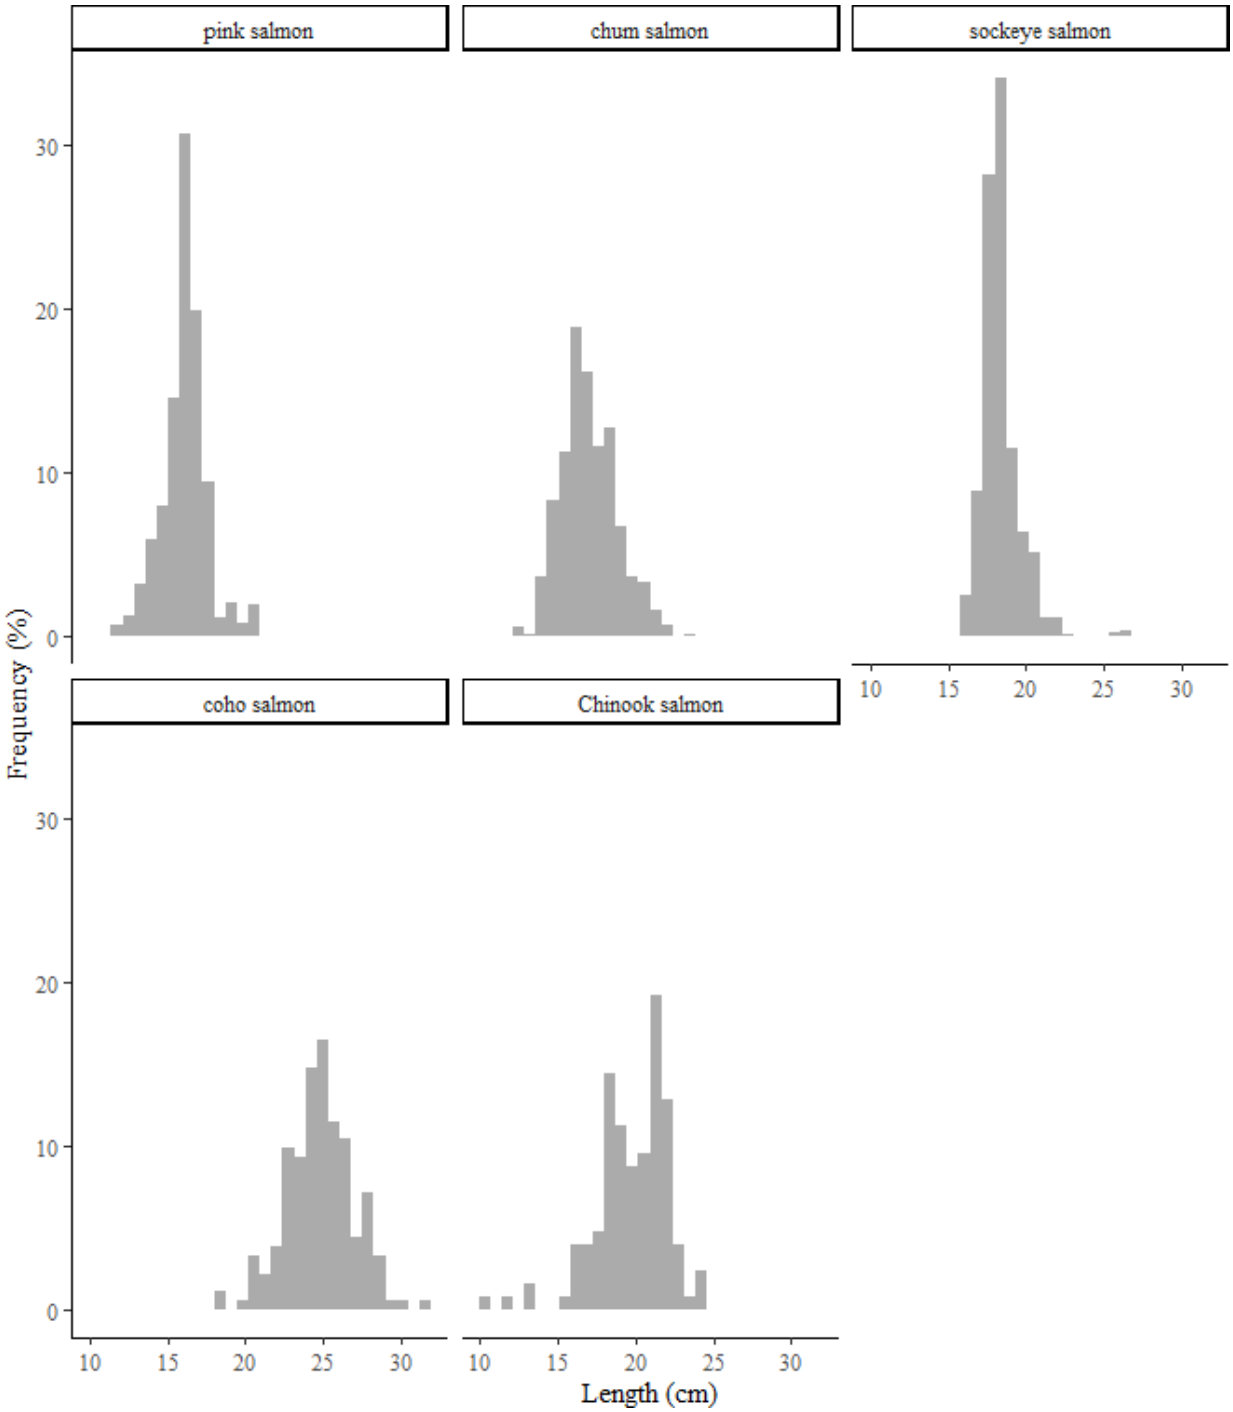

Figure 9. -- Length frequency distributions of juvenile salmon species captured during the northern Bering Sea surface trawl survey, 2019.

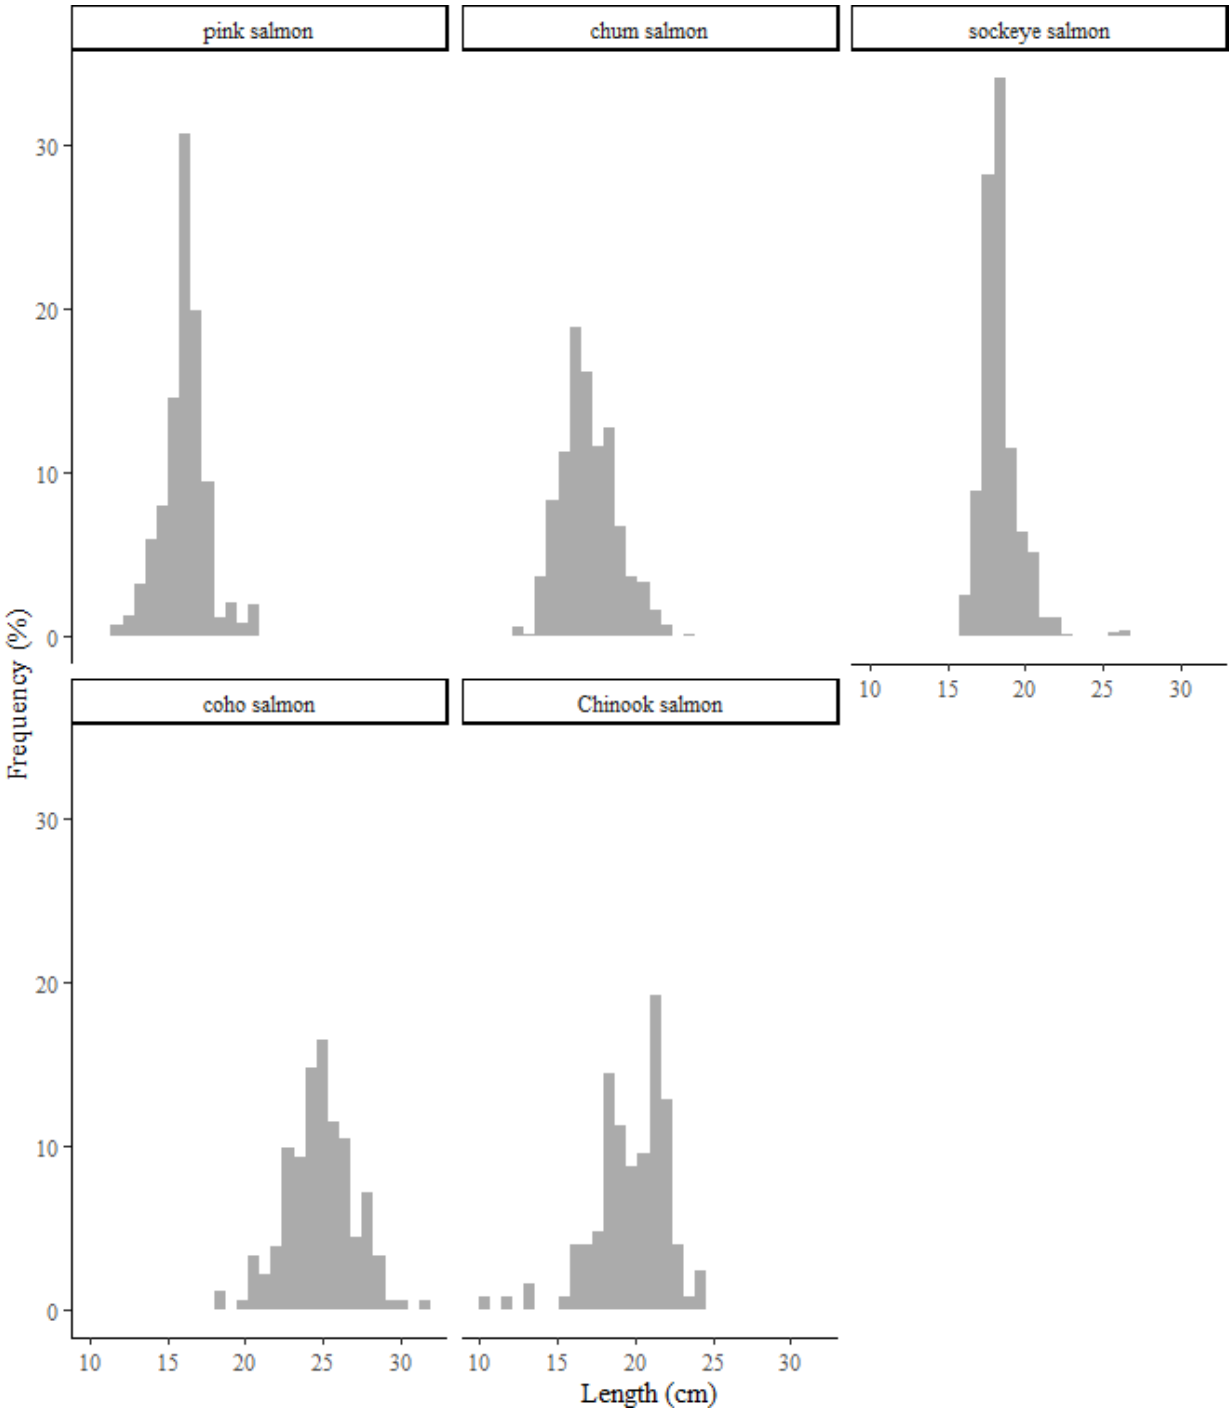

Figure 10. -- Length frequency distributions of immature salmon species captured during the northern Bering Sea surface trawl survey, 2019.

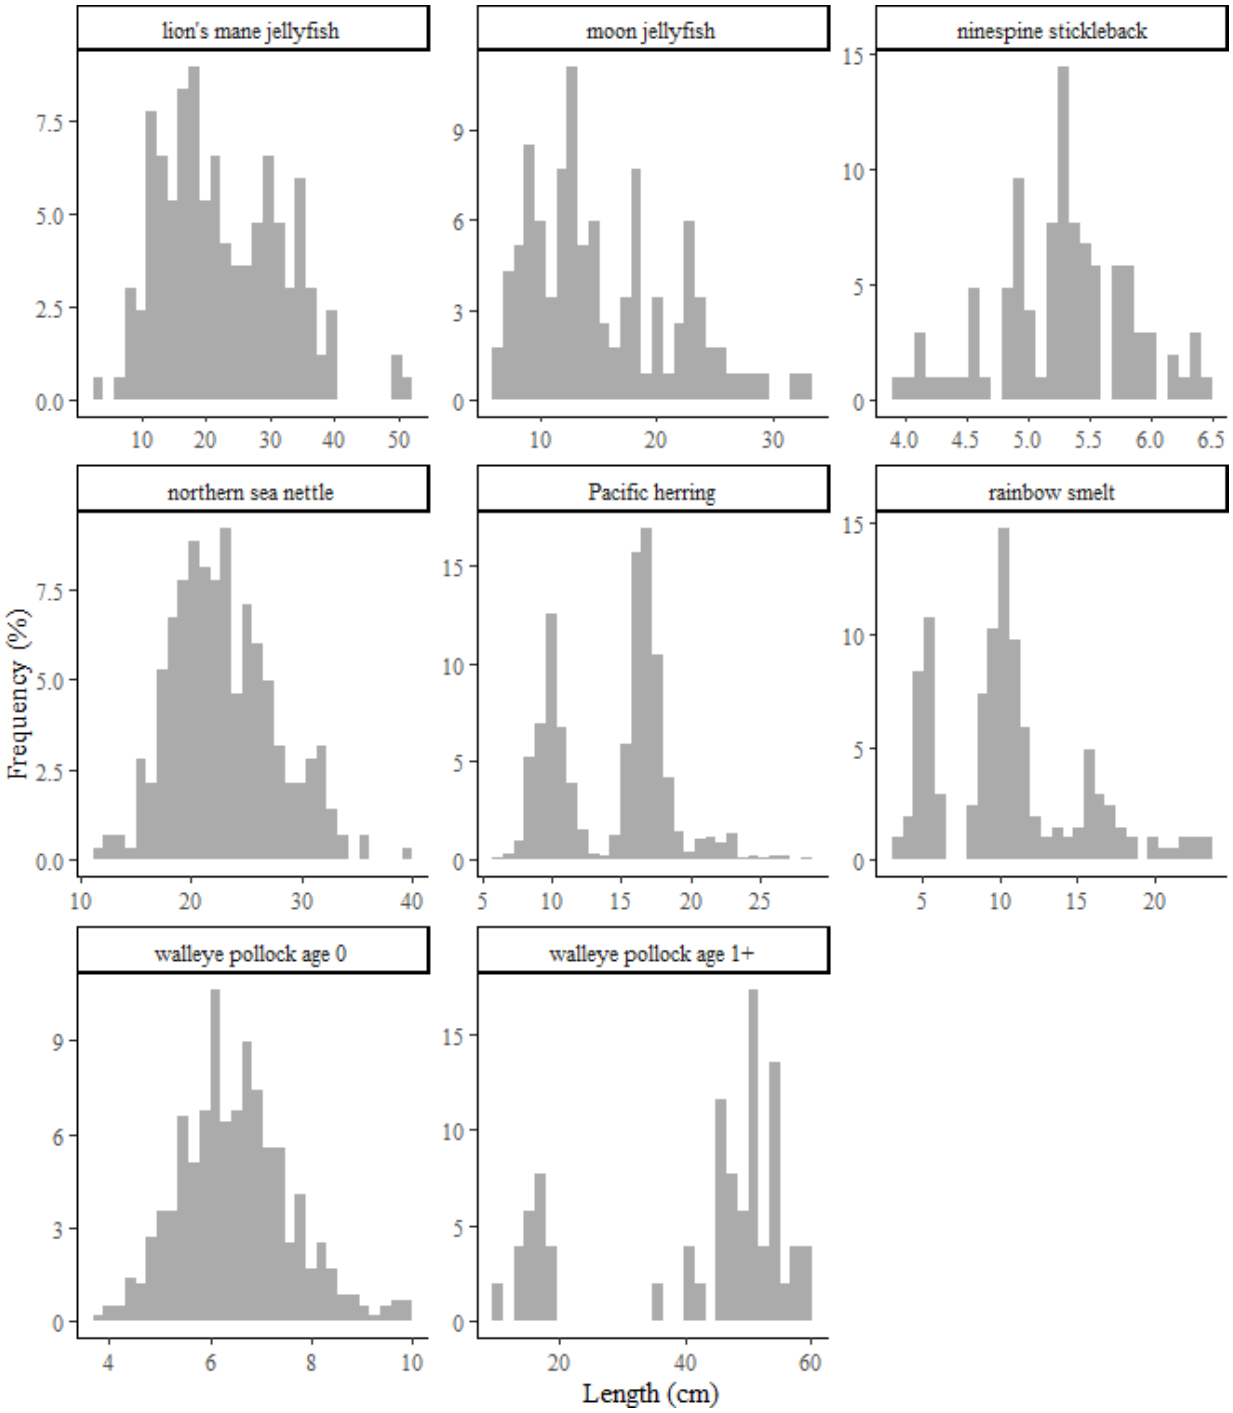

Figure 11. -- Length frequency distributions of the most abundant non-salmon species captured during the northern Bering Sea surface trawl survey, 2019.

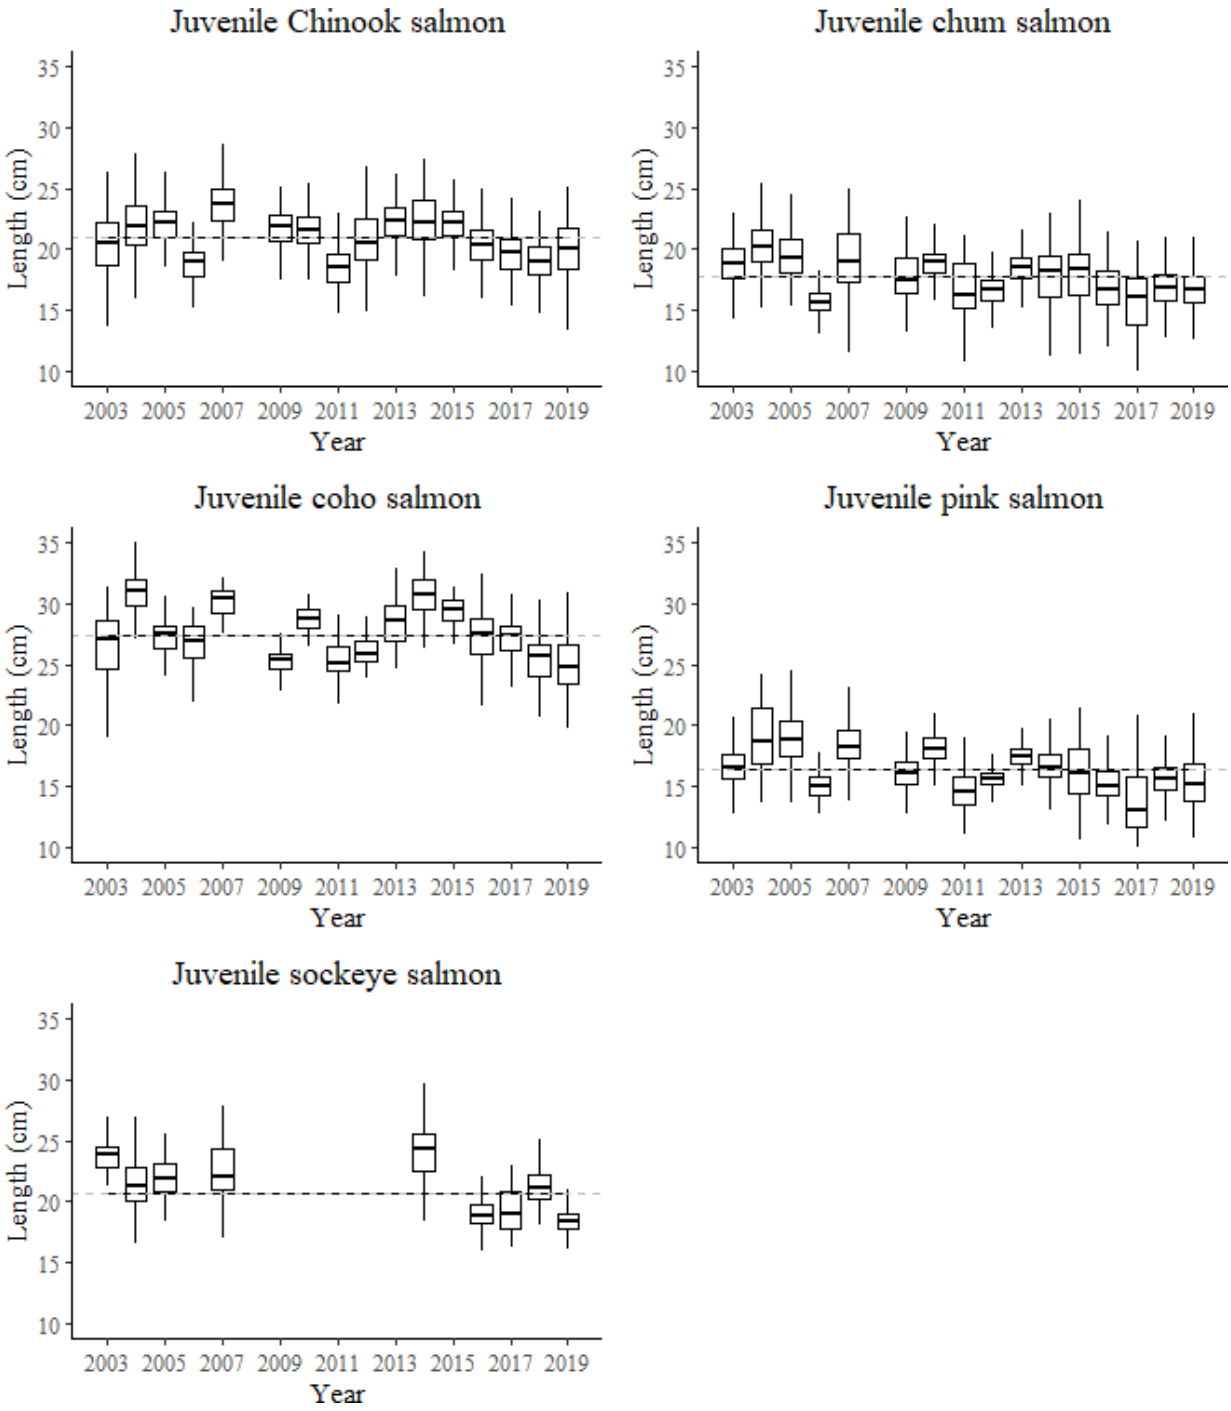

Figure 12. -- Box plots of juvenile salmon fork lengths (cm) sampled during the northern Bering Sea surveys, 2003-2019. The dashed line is the mean length across all years. Sockeye salmon lengths were limited to years where at least 20 lengths were measured.

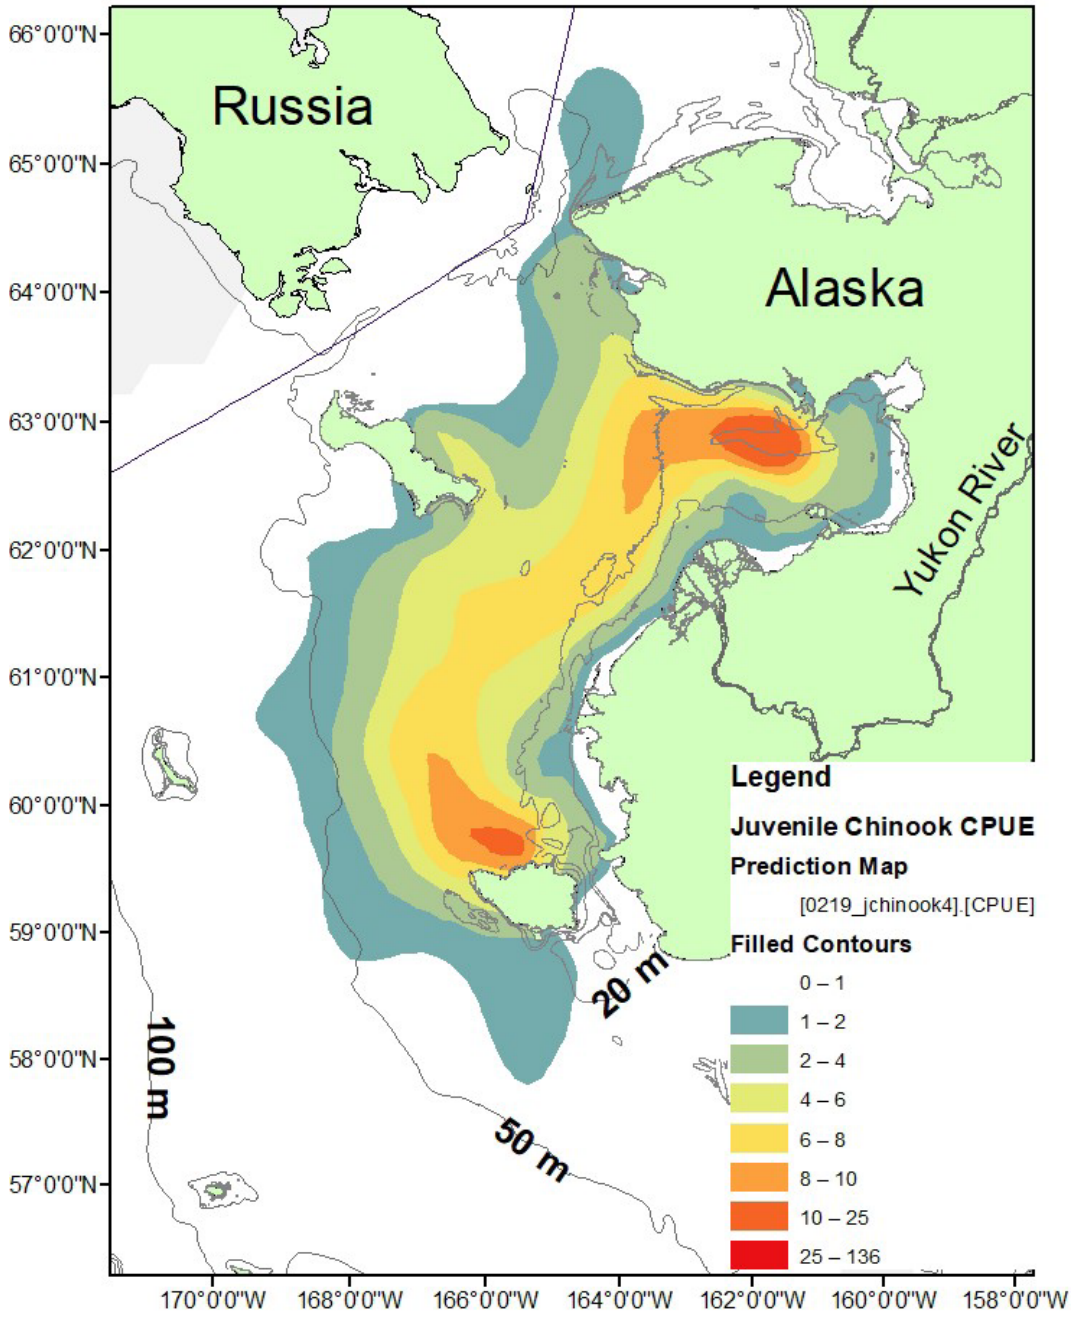

Figure 13. -- A kriging predicted surface of juvenile Chinook salmon catch rates during the northern Bering Sea surface trawl survey, 2003-2019.

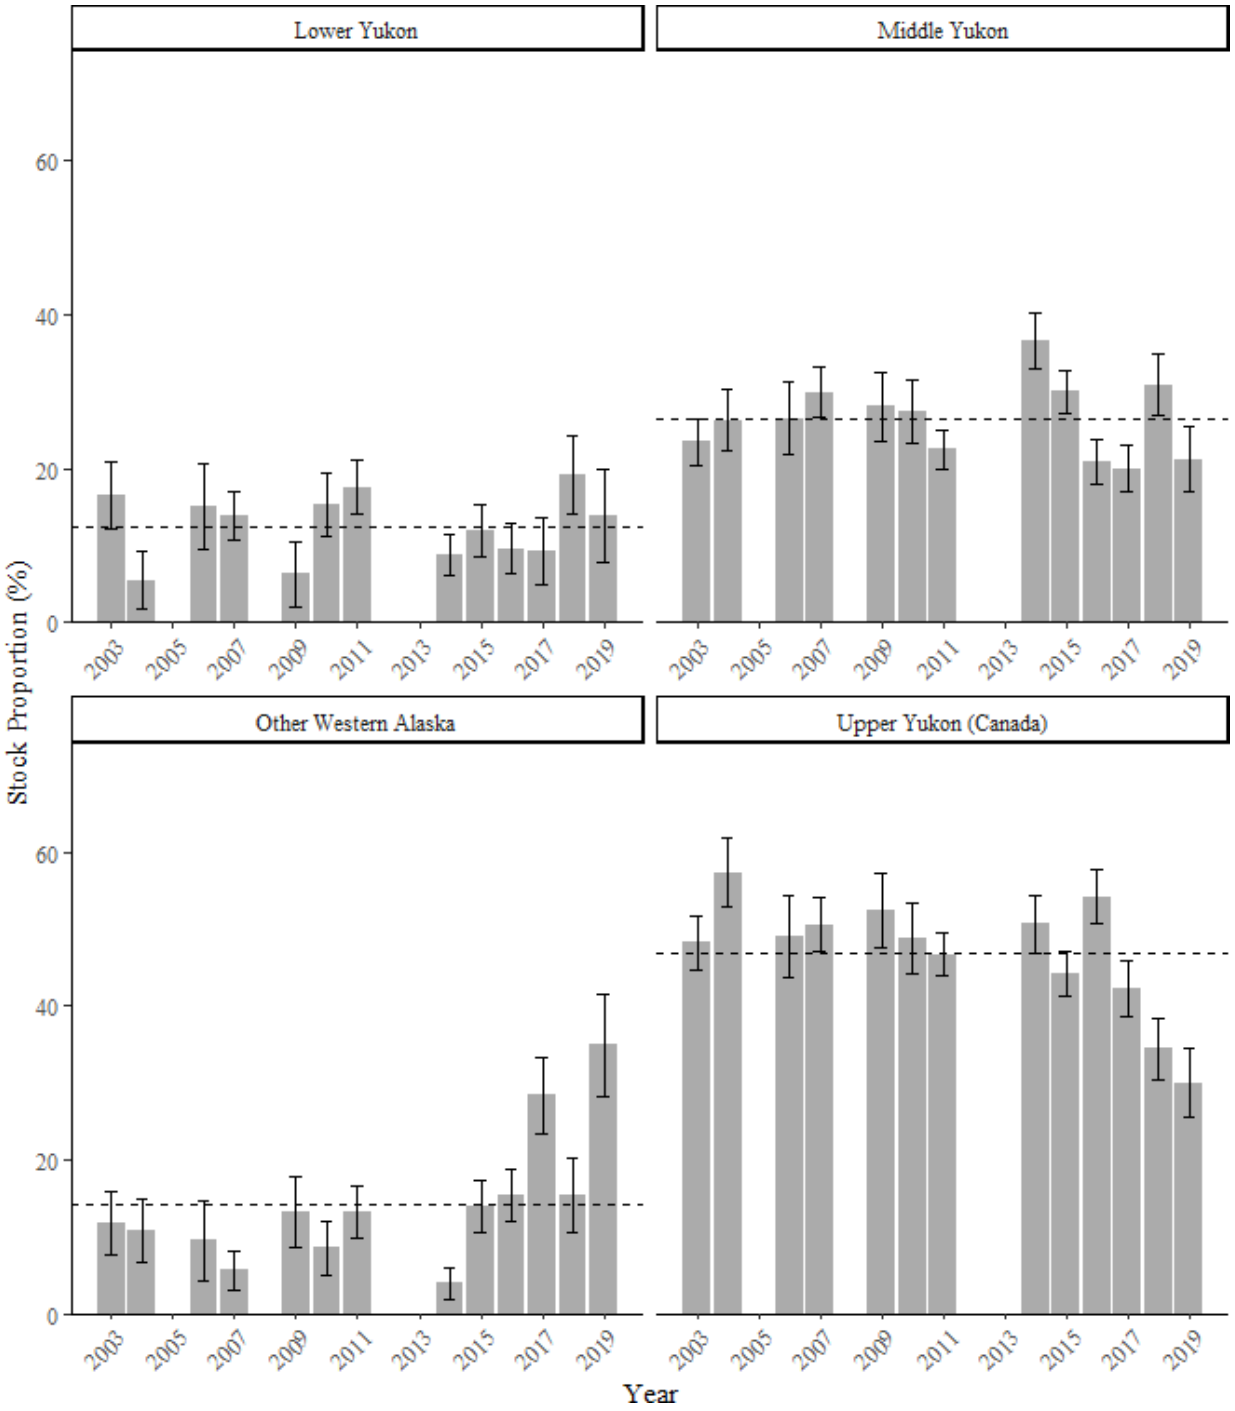

Figure 14. -- Genetic stock proportions of juvenile Chinook salmon captured during the northern Bering Sea surface trawl surveys, 2003-2019. Average stock proportions (dashed line) are included for each stock group.

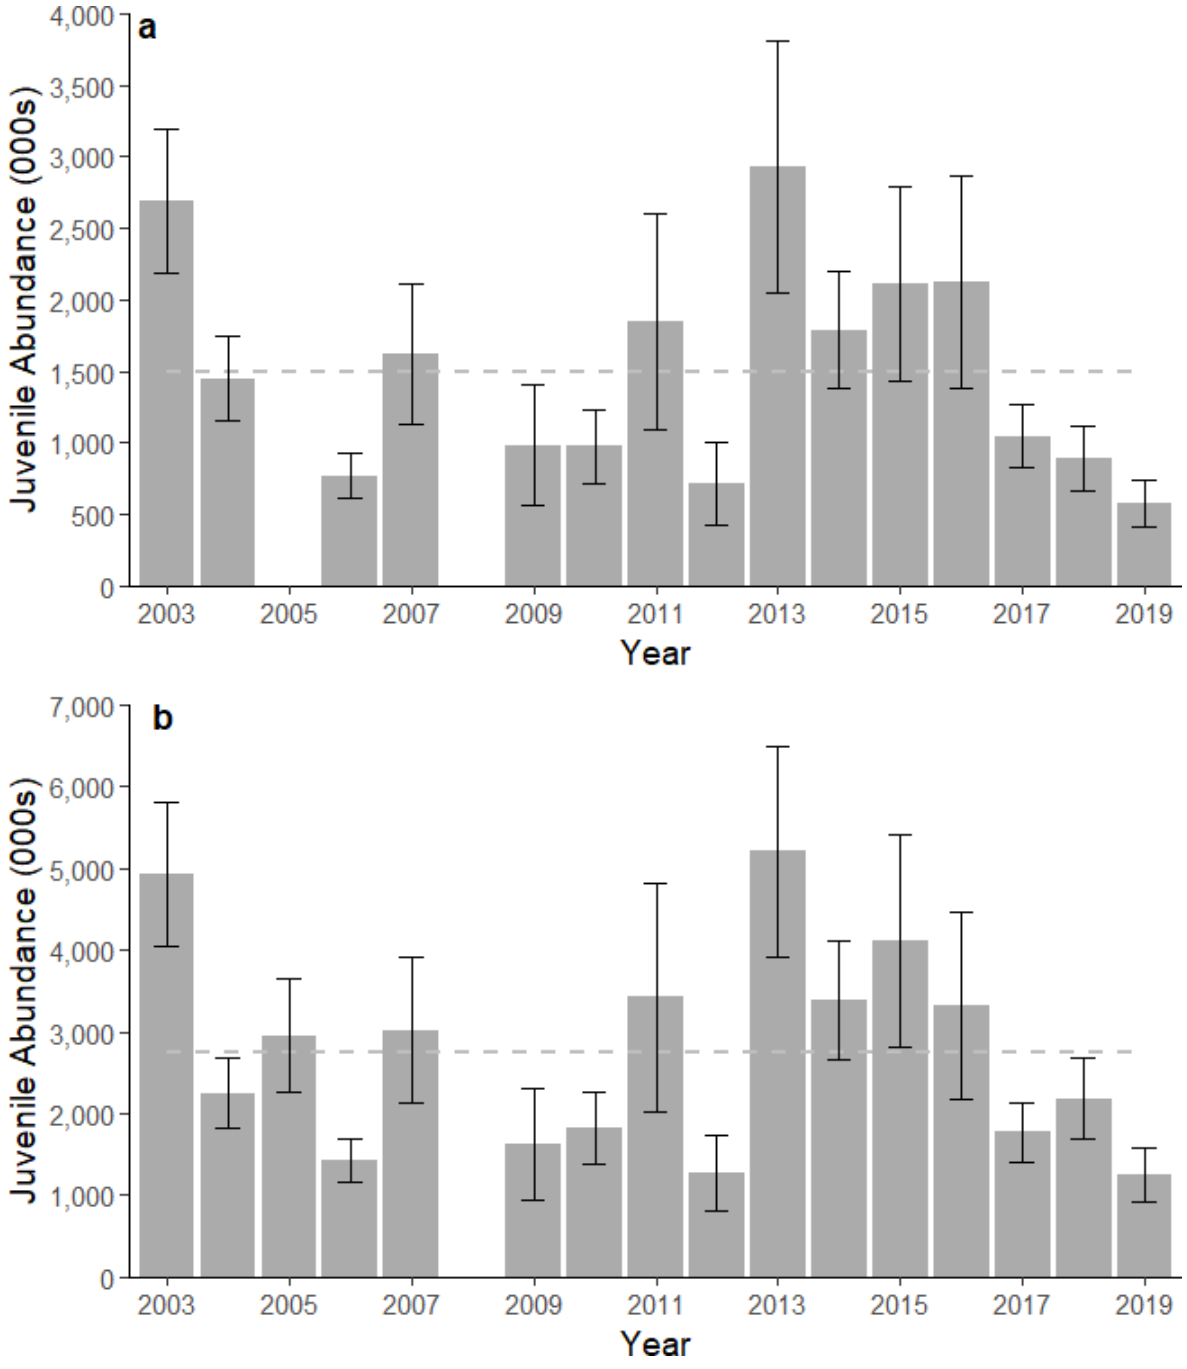

Figure 15. -- Stock-specific abundance estimates of Yukon River Canadian-origin (a) and Total Yukon (b) stock groups of Chinook salmon during the northern Bering Sea surface trawl surveys, 2003-2019. Average abundance for each stock group (solid line) is included.

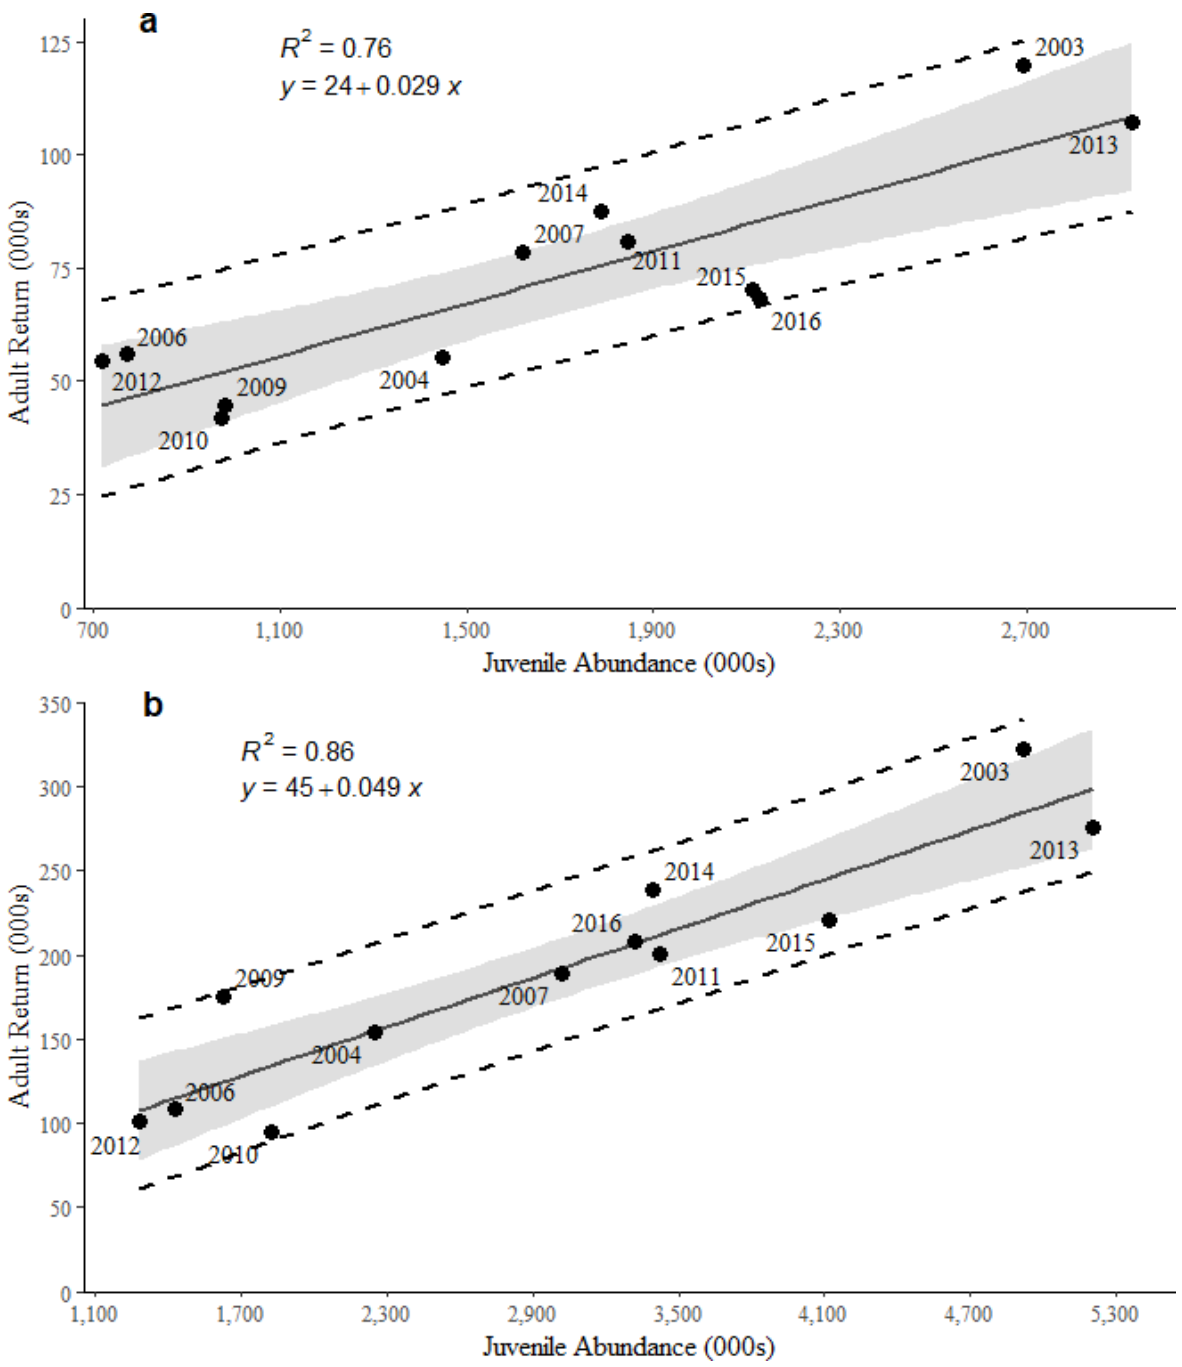

Figure 16. -- Relationships between juvenile abundance and resulting adult returns of Yukon River Canadian-origin (a) and Total Yukon (b) stock groups of Chinook salmon, 2003-2016. The fitted relationship (solid line), 80% prediction interval (dashed lines), 80% confidence interval (shaded region), and survey years (labels) are included.

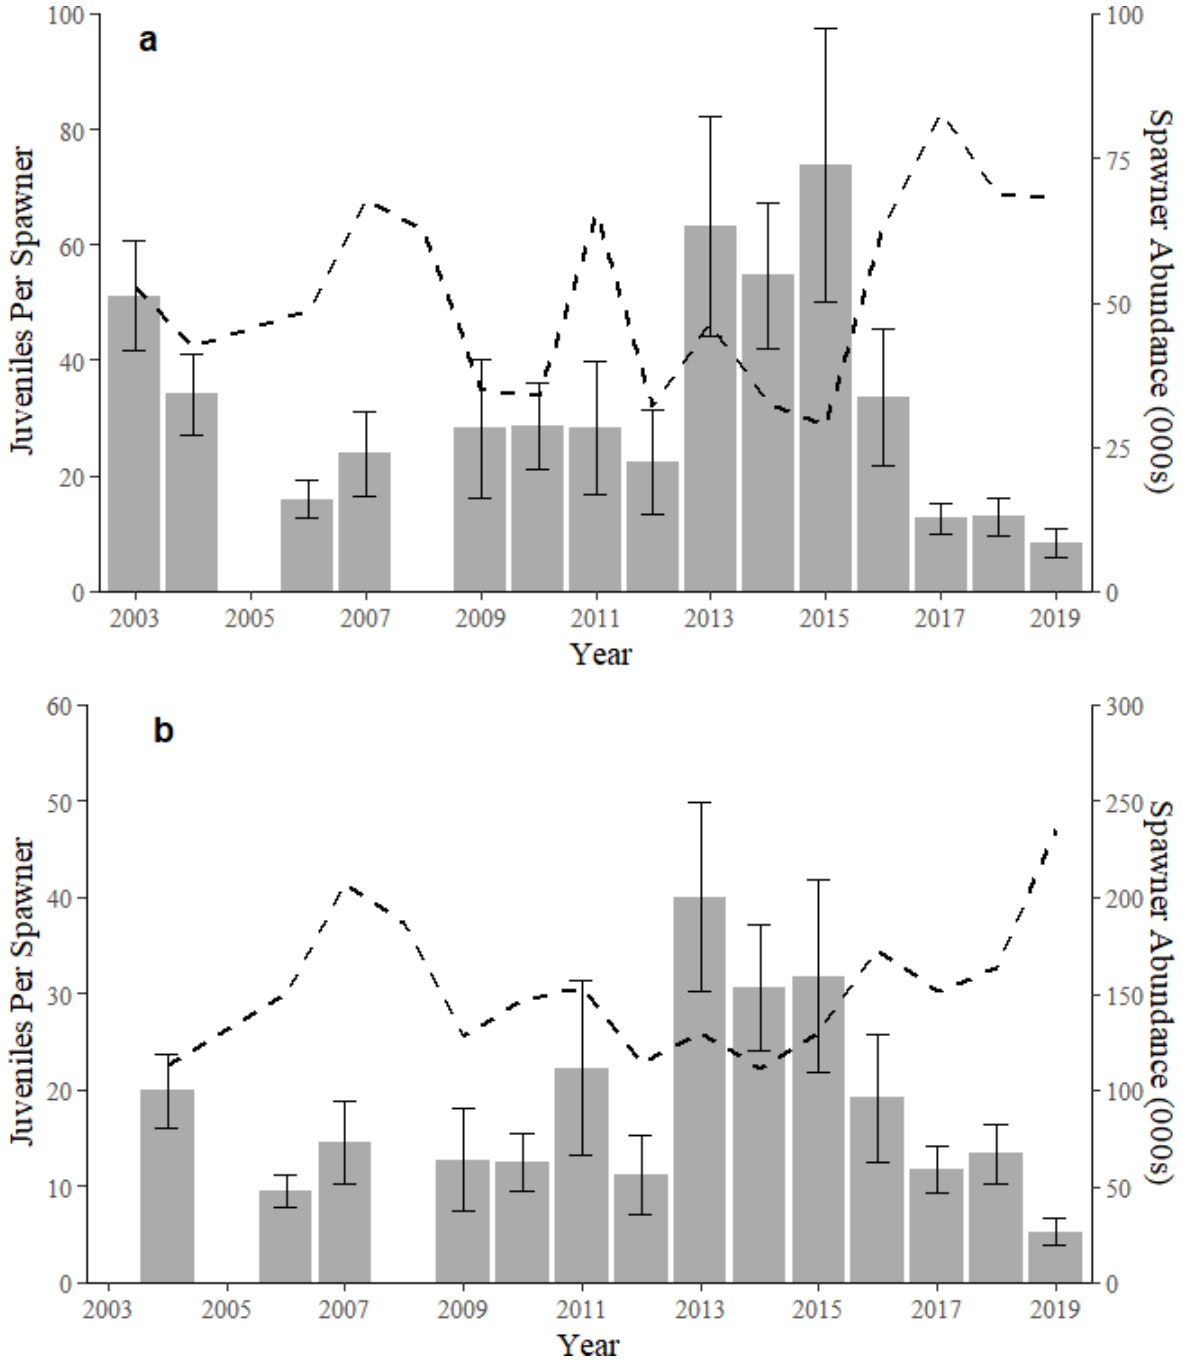

Figure 17. -- The number of juveniles-per-spawner (gray bars) and spawner abundance (dashed line) for the Yukon River Canadian-origin (a) and Total Yukon (b) stock groups of Chinook salmon, 2003-2019.

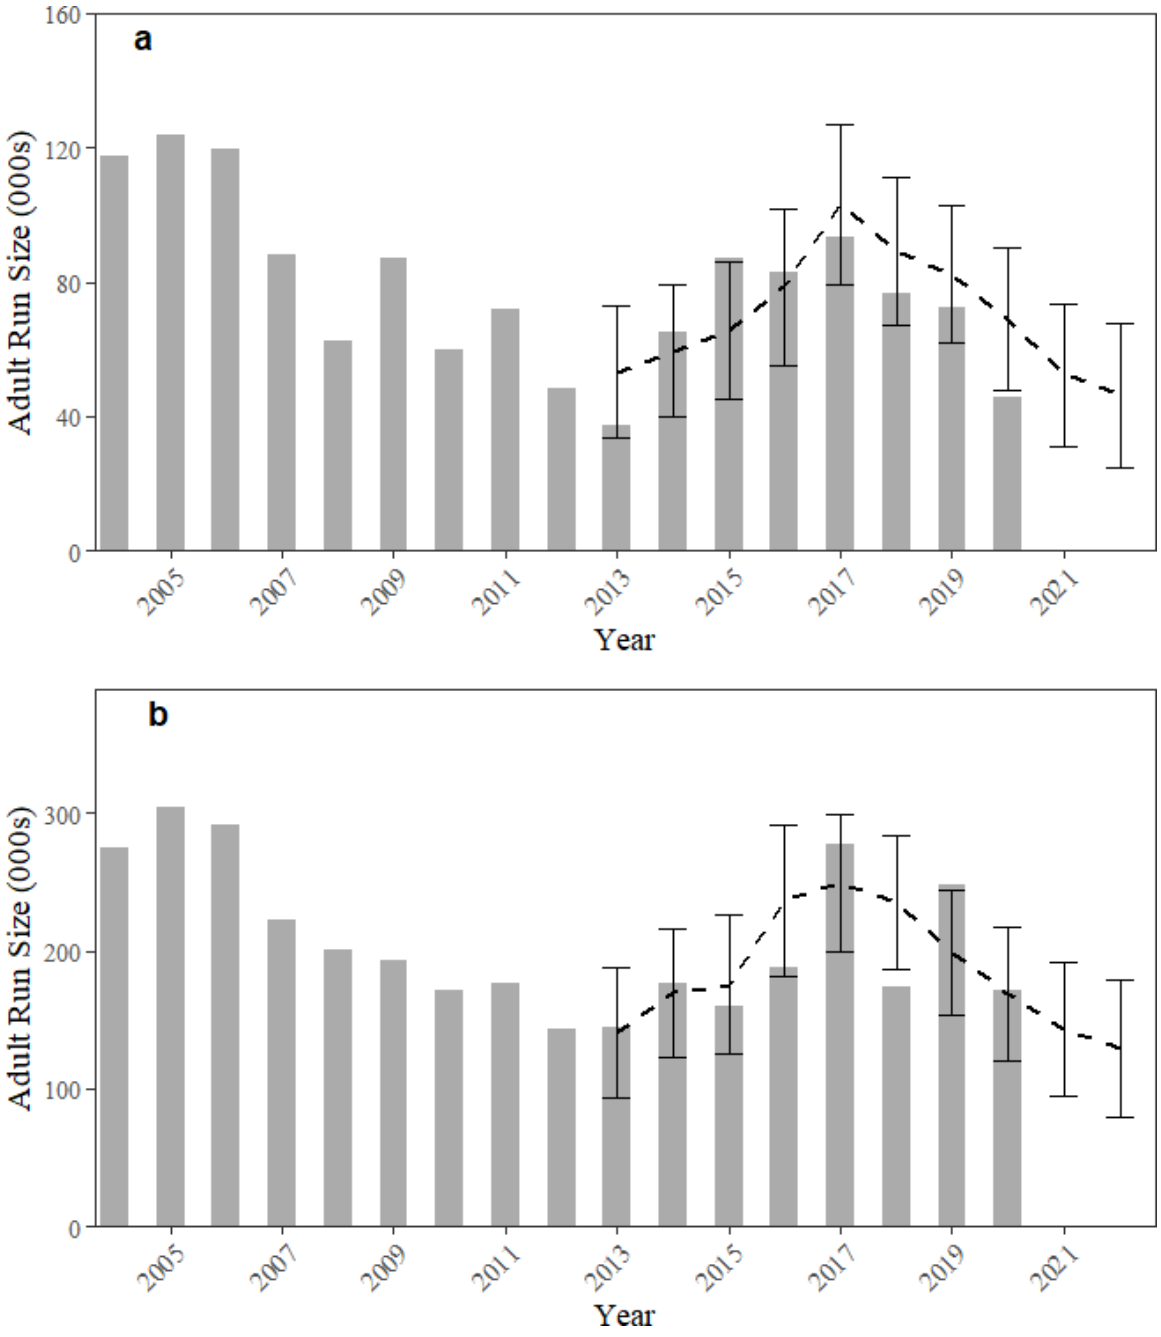

Figure 18. -- Observed (gray bars) and 80% predicted intervals of projected run sizes (black error bars) for the Yukon River Canadian-origin (a) and Total Yukon (b) stock groups of Chinook salmon, 2003-2022.

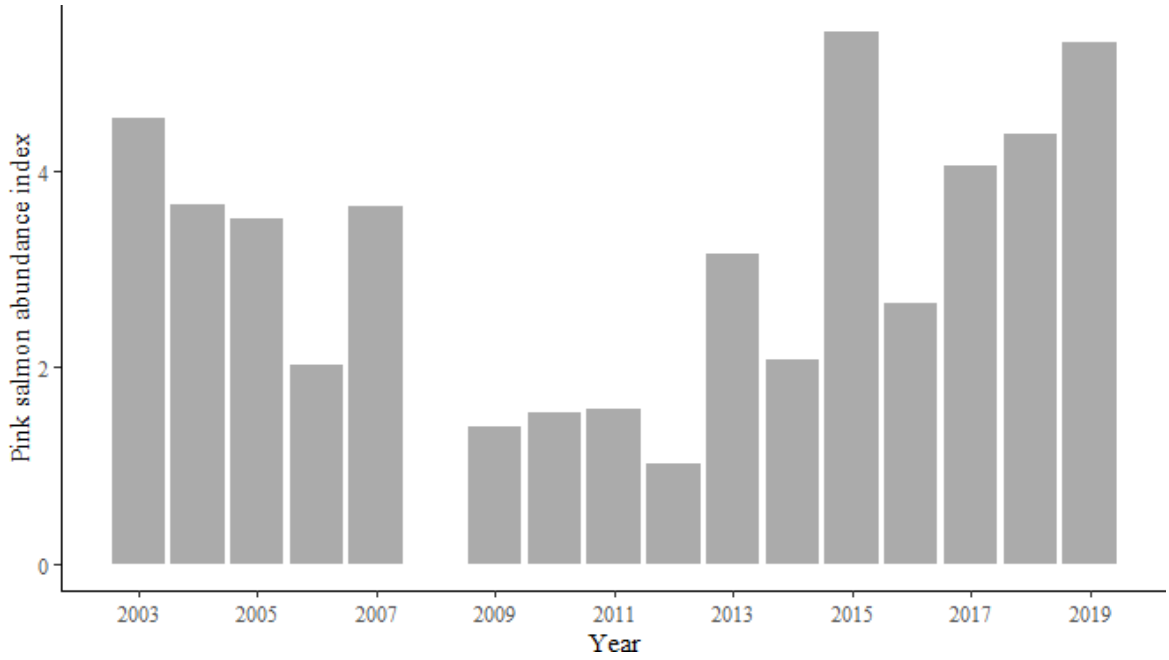

Figure 19. -- The juvenile pink salmon abundance index from the northern Bering Sea surface trawl surveys, 2003-2019.

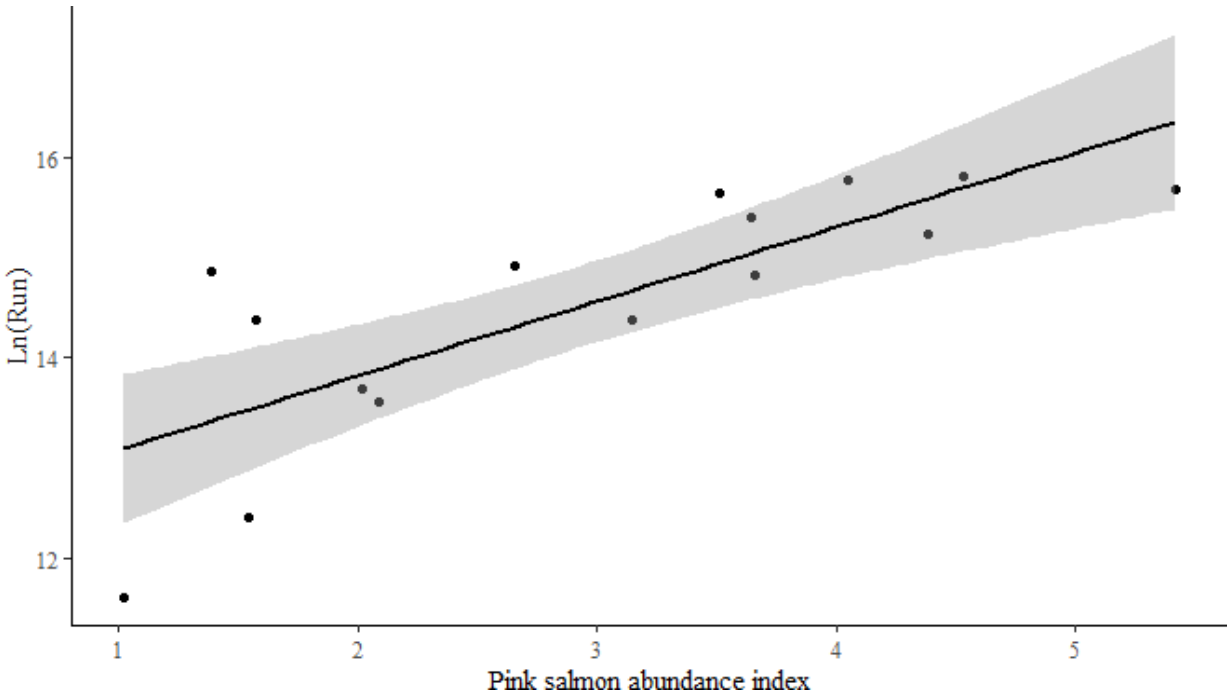

Figure 20. -- A linear regression model fit (black line) with 95% confidence interval (shaded region) between the juvenile pink salmon abundance index from the northern Bering Sea surface trawl surveys (black dots; 2003-2018) and the natural log of the adult pink salmon run index (Yukon River and Norton Sound; 2004-2019).

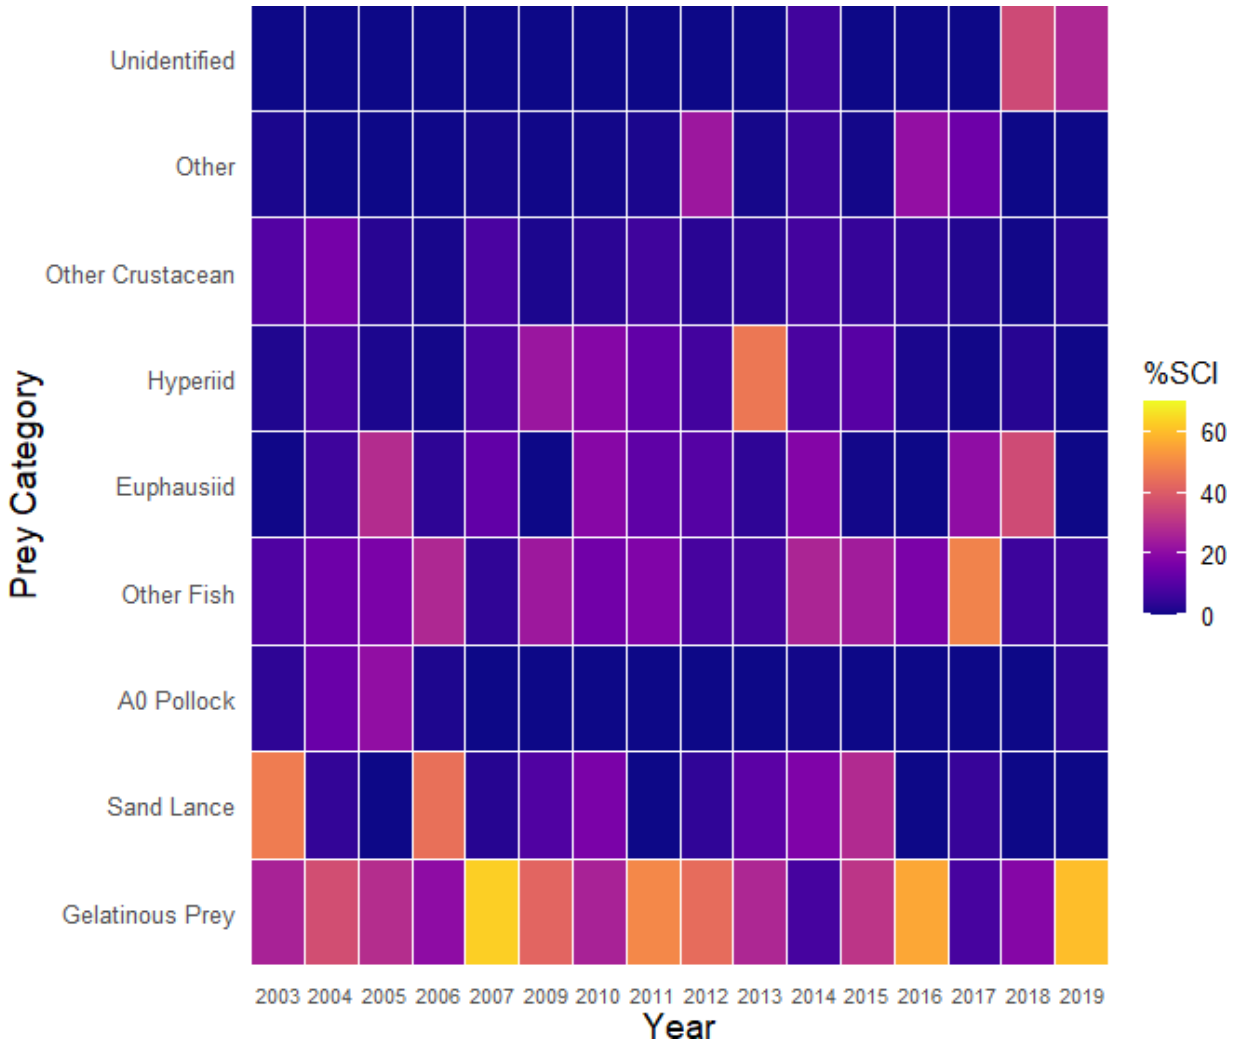

Figure 21. -- The percent of taxonomic prey groups by stomach content index in the stomachs of juvenile chum salmon sampled from the northern Bering Sea surface trawl surveys, 2003-2019.

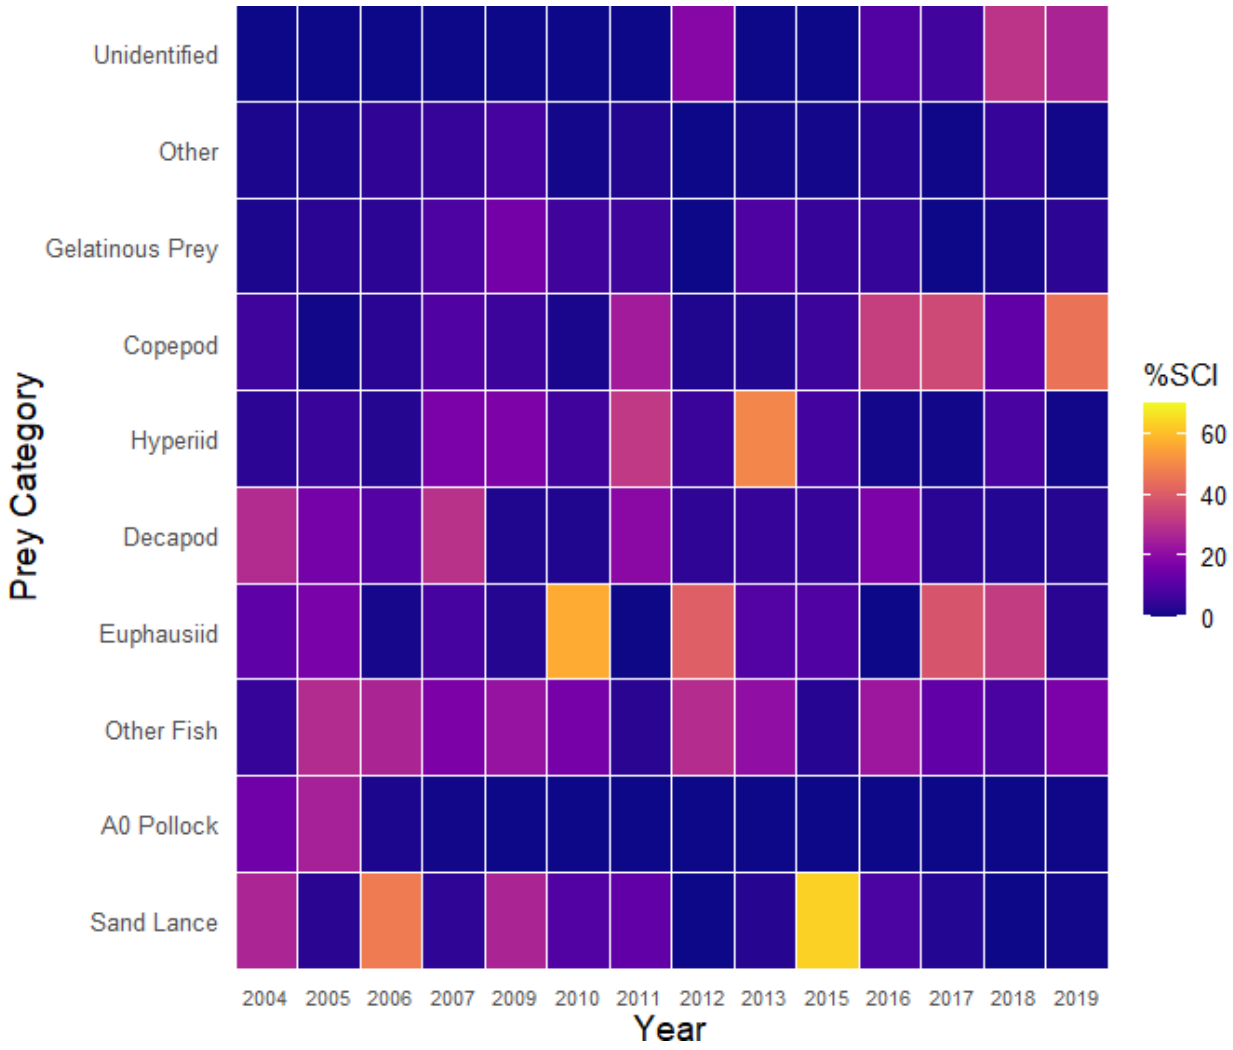

Figure 22. -- The percent of taxonomic prey groups by stomach content index in the stomachs of juvenile pink salmon sampled from the northern Bering Sea surface trawl surveys, 2003-2019.

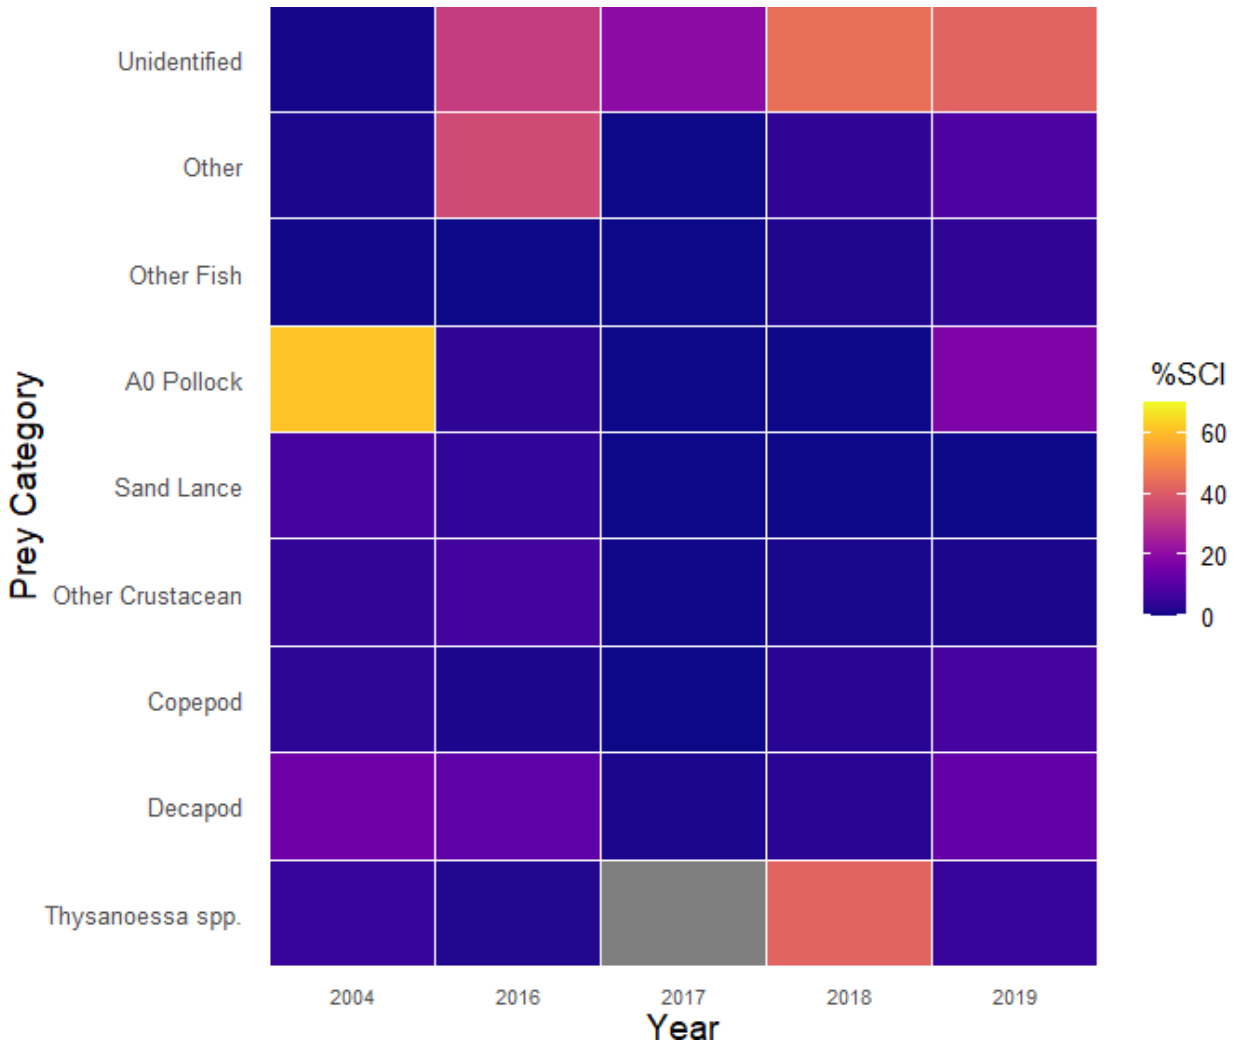

Figure 23. -- The percent of taxonomic prey groups by stomach content index in the stomachs of juvenile sockeye salmon sampled from the northern Bering Sea surface trawl surveys, 2003-2019.

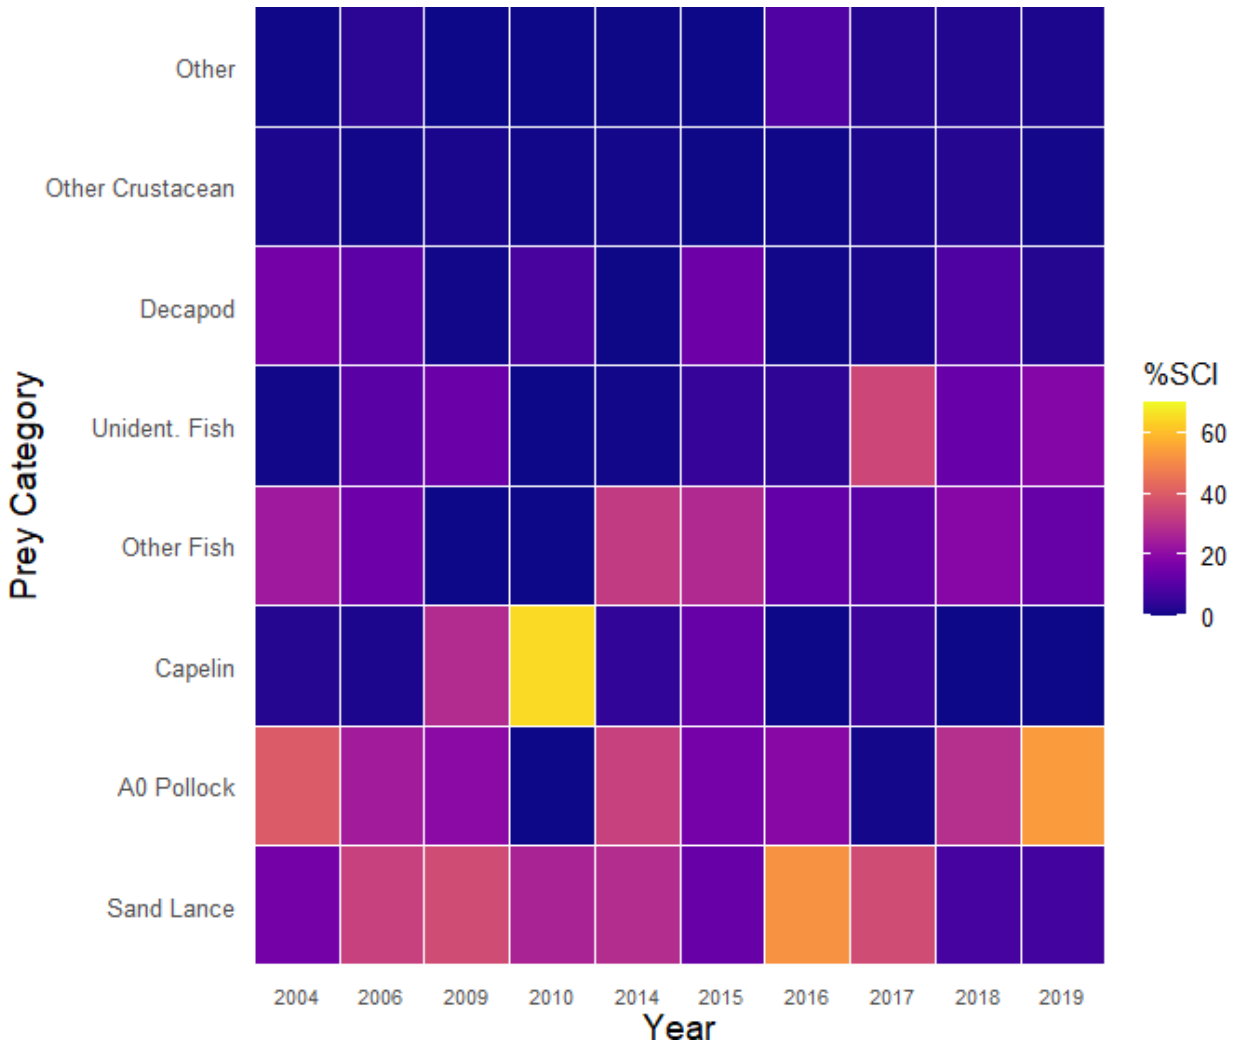

Figure 24. -- The percent of taxonomic prey groups by stomach content index in the stomachs of juvenile coho salmon sampled from the northern Bering Sea surface trawl surveys, 2003-2019.

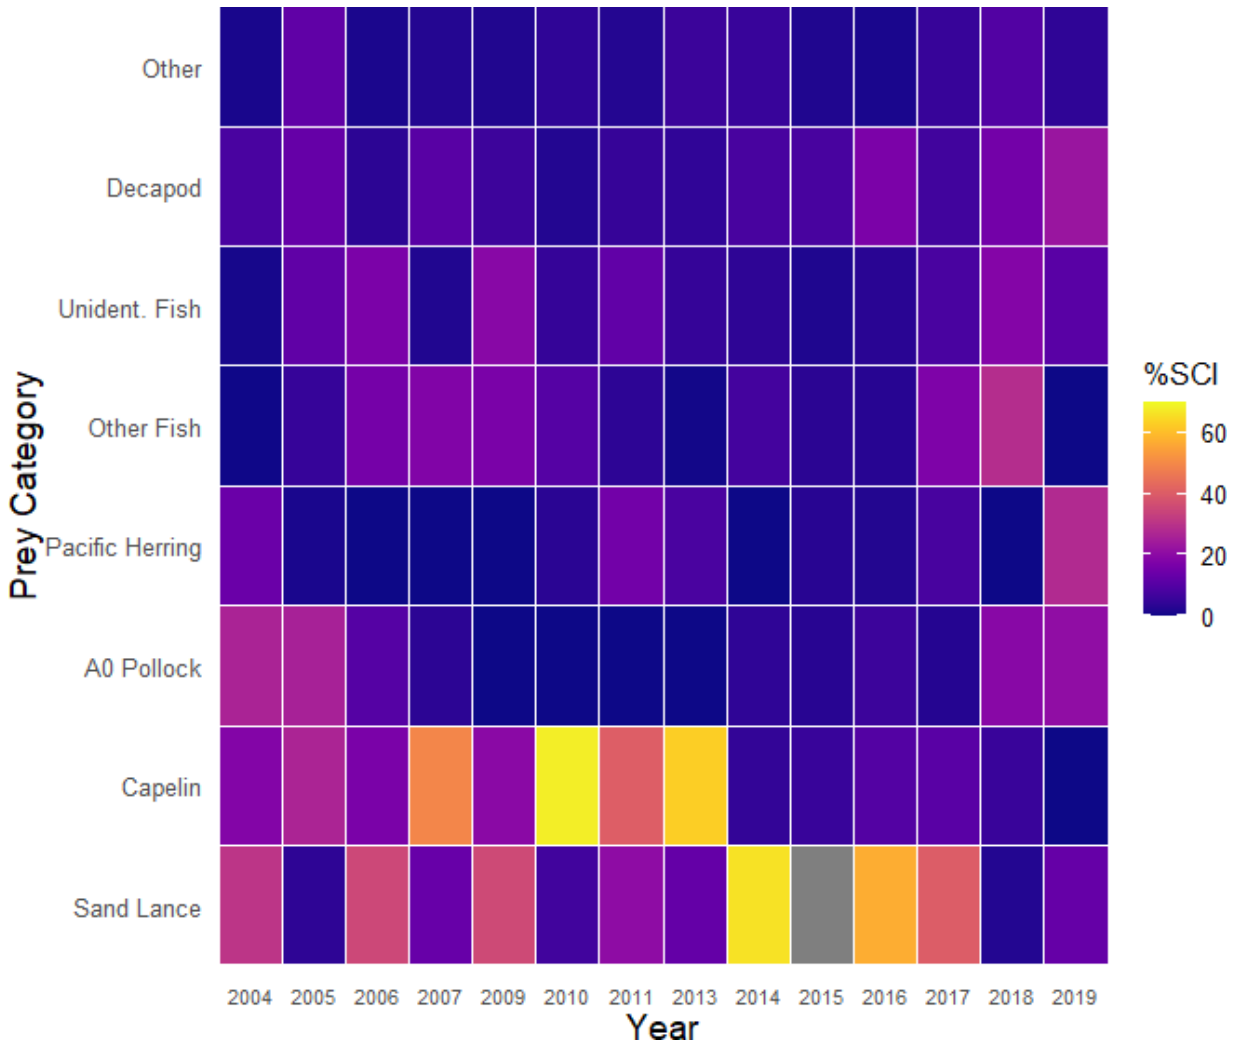

Figure 25. -- The percent of taxonomic prey groups by stomach content index in the stomachs of juvenile Chinook salmon sampled from the northern Bering Sea surface trawl surveys, 2003-2019.

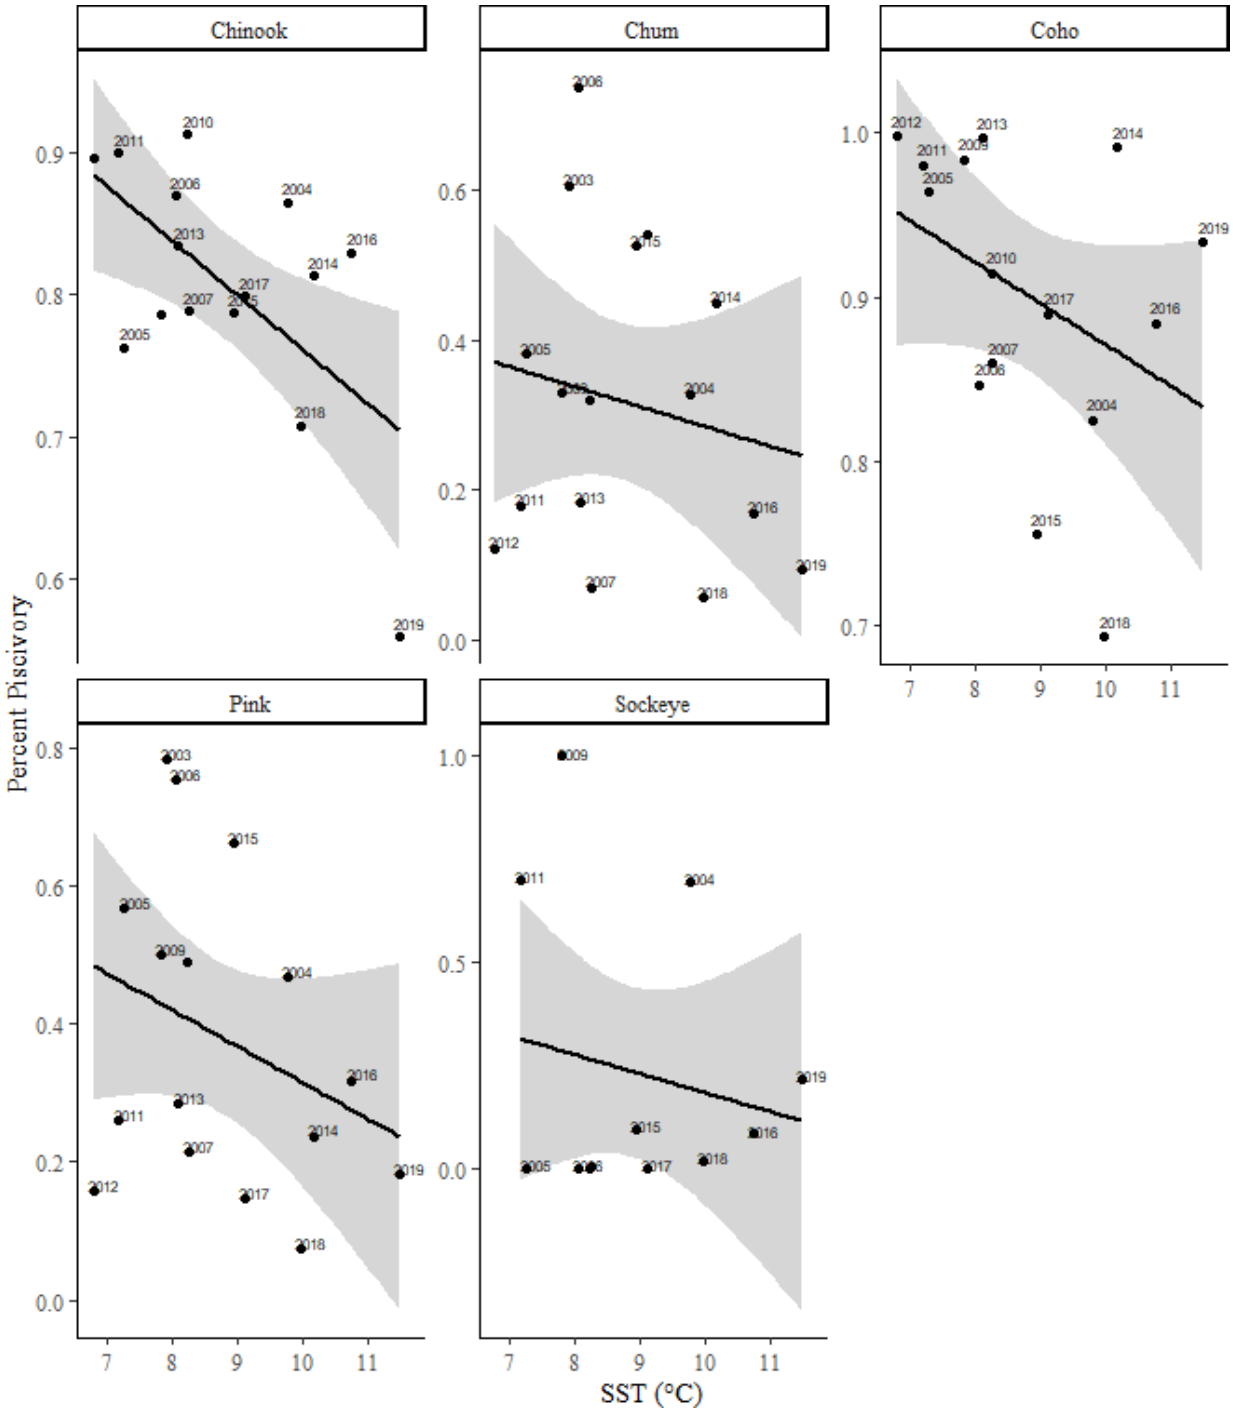

Figure 26. -- Linear regression model fits (black lines) with 95% confidence intervals (shaded regions) between the average percentage of fish in the stomachs of juvenile salmon (piscivory) and sea surface temperature (SST) sampled during the northern Bering Sea surface trawl surveys, 2004-2019. Each point is labeled with the sample year.

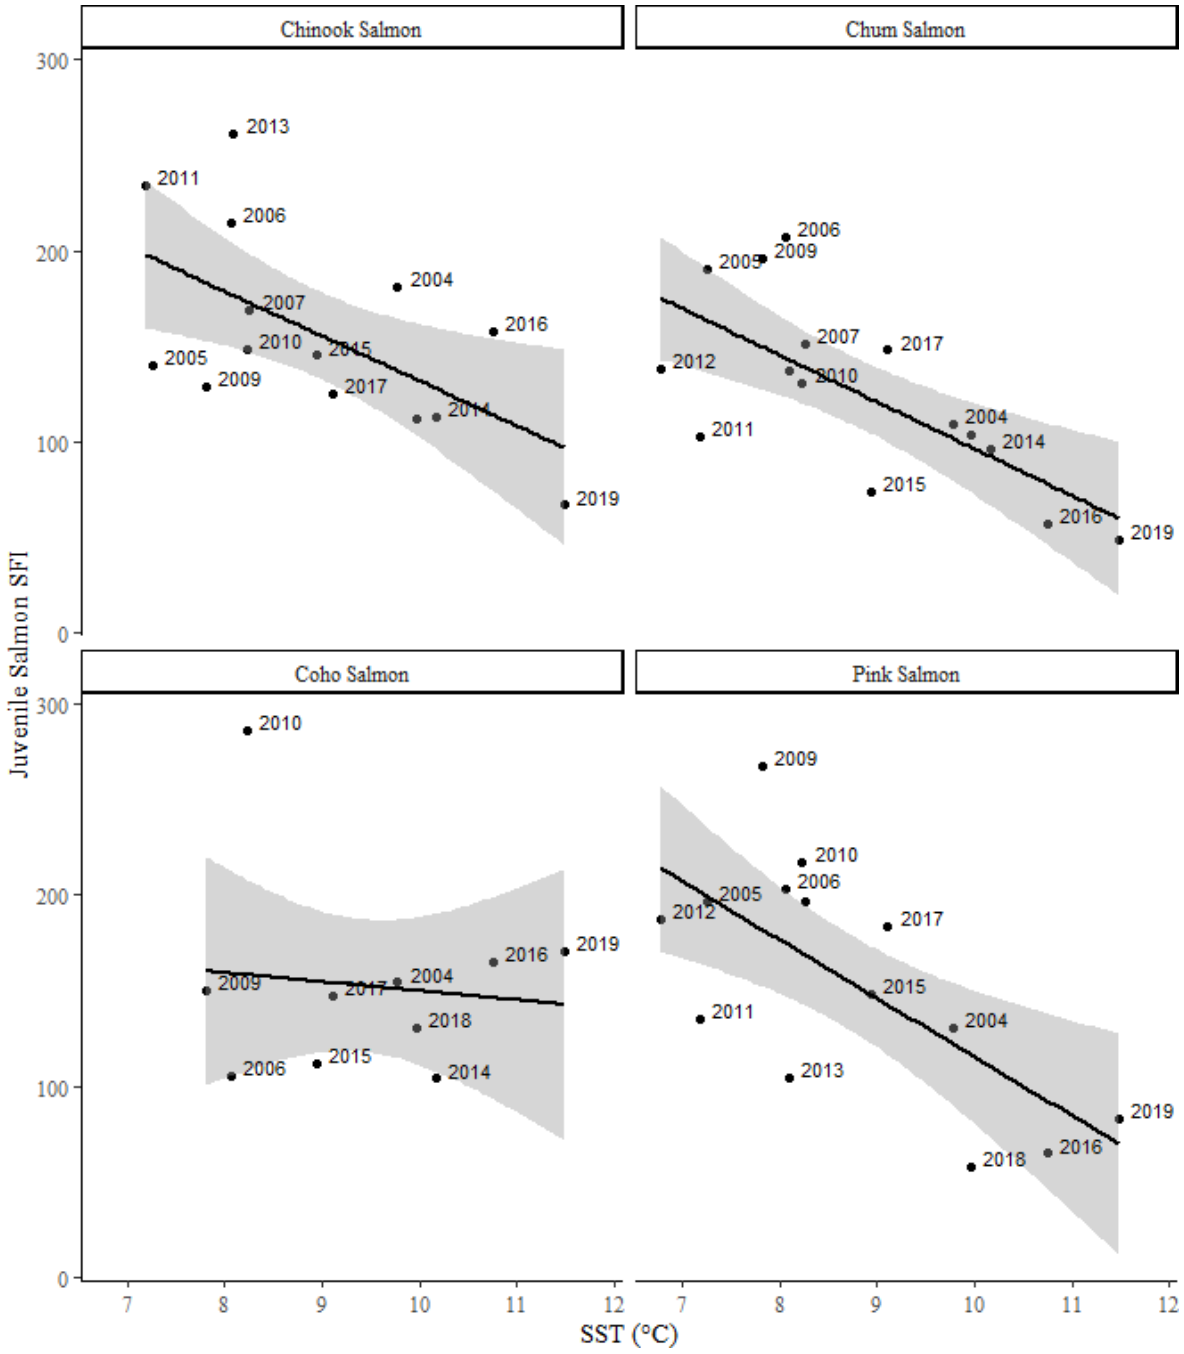

Figure 27. -- Linear regression model fits (black lines) with 95% confidence intervals (shaded regions) between the average stomach fullness index (SFI) of juvenile salmon and sea surface temperature (SST) sampled during the northern Bering Sea surface trawl surveys, 2004-2019. Each point is labeled with the sample year.

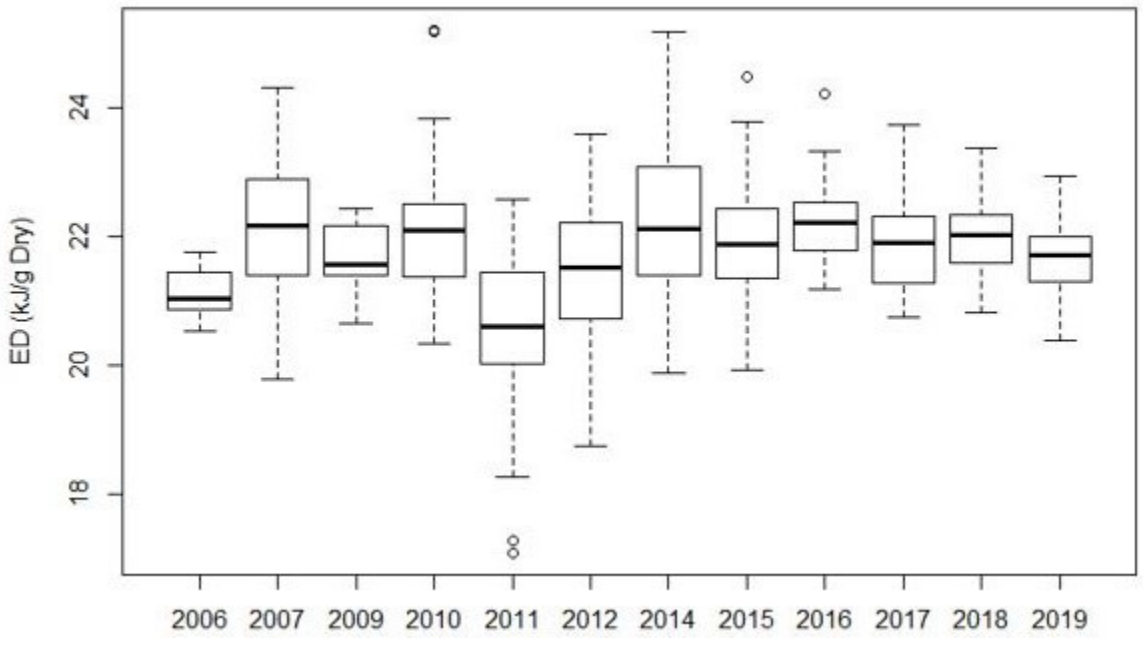

Figure 28. -- Boxplots of juvenile Chinook salmon sampled for energy density (kJ/dry tissue mass, n=575) sampled during northern Bering Sea surface trawl surveys, 2006-2019. Data unavailable for 2008 and 2013. Medians, interquartile ranges (IQR), whiskers (1.5 IQR), and outliers (empty circles, >1.5 IQR) are shown.

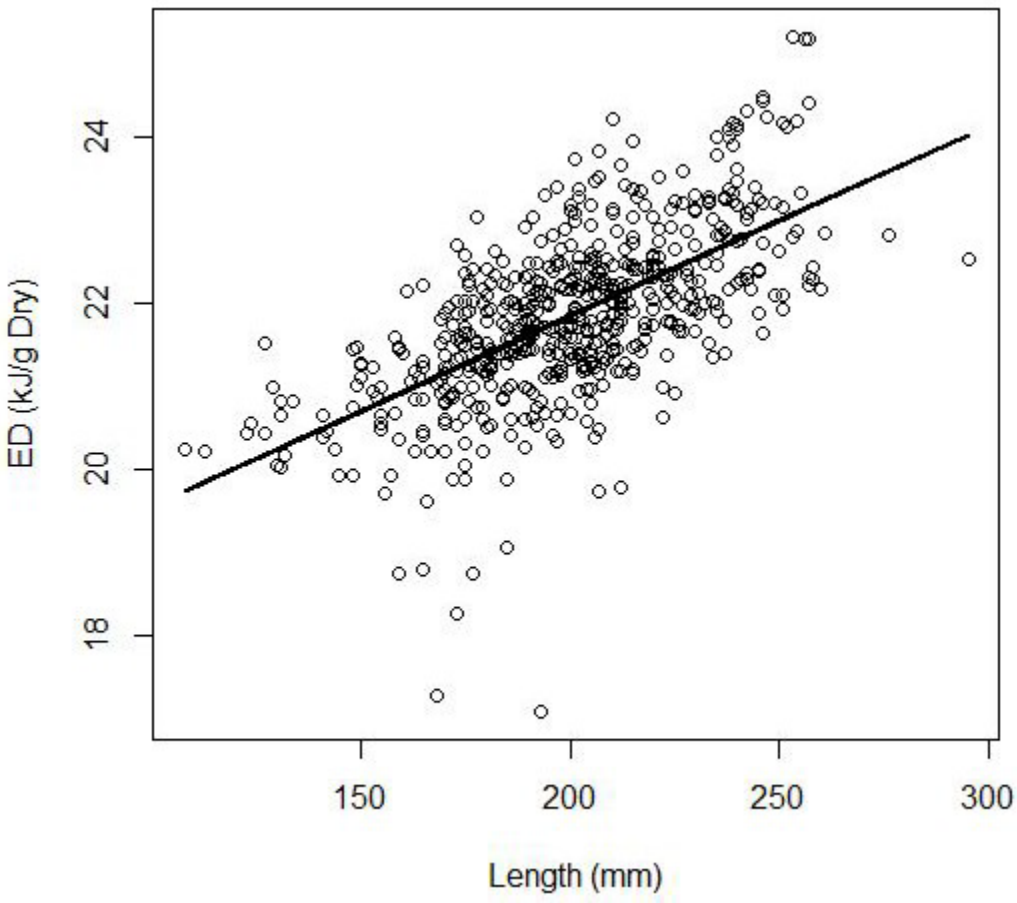

Figure 29. -- Energy density (kJ/g) of dry tissue mass by fork length (mm) of juvenile Chinook salmon caught during the northern Bering Sea surface trawl surveys, 2006-2019. Simple linear regression model fit shown by line (n = 575).

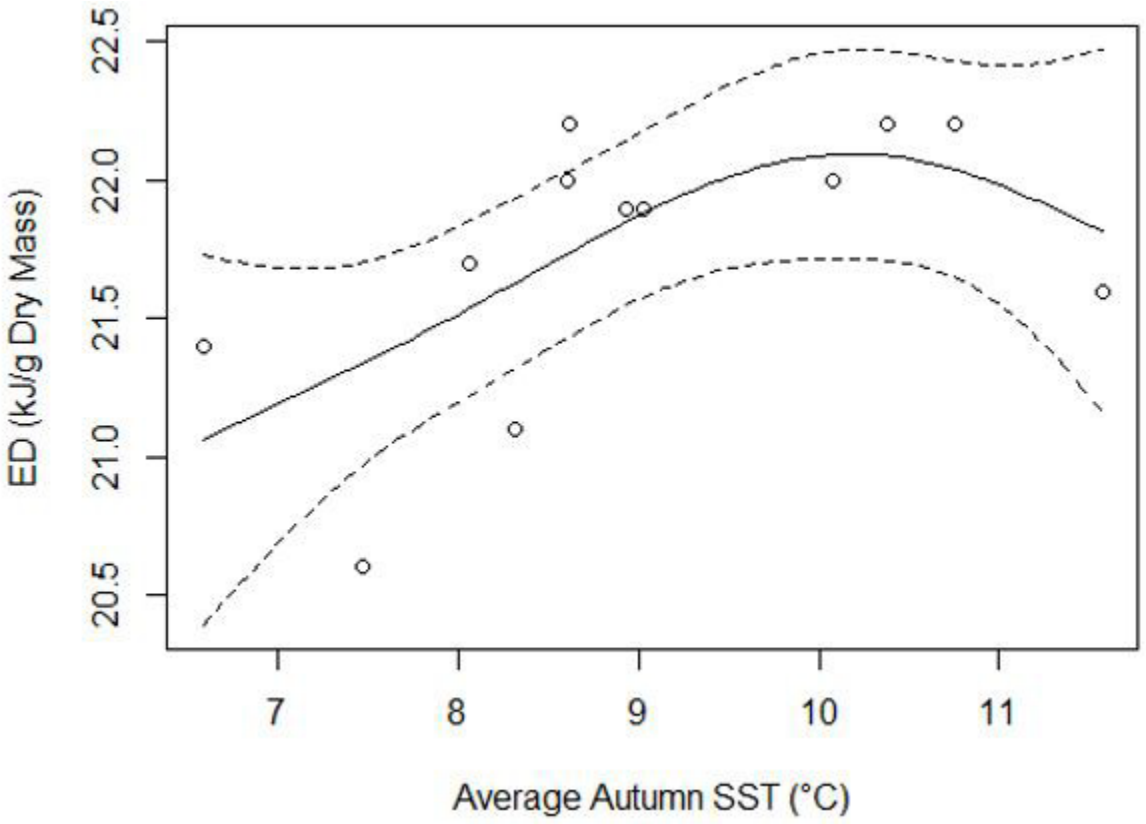

Figure 30. -- Annual mean energy density (kJ/g) of dry tissue mass by average autumn sea surface temperature (°C) for juvenile Chinook salmon caught during the northern Bering Sea surface trawl surveys, 2006-2019. Generalized additive model fit shown by solid line, dashed lines represent ±1 SE. Data unavailable for 2008 and 2013.

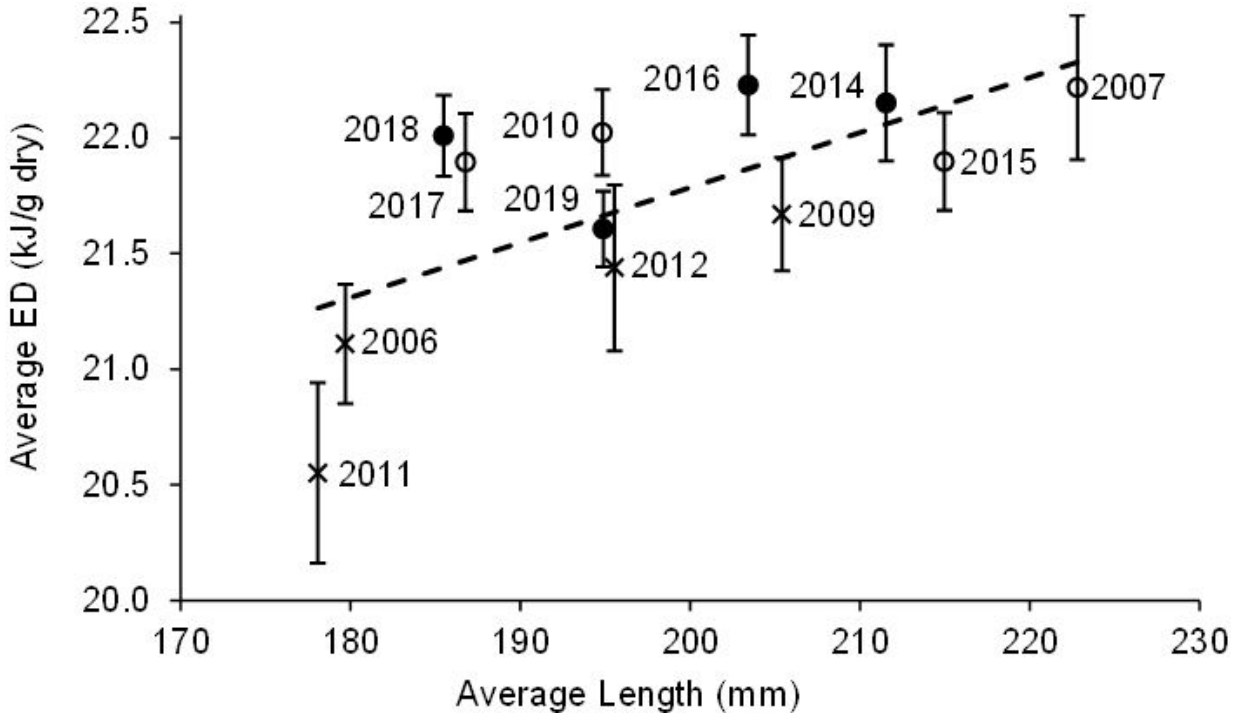

Figure 31. -- Annual mean energy density (kJ/g) of dry tissue mass by fork length (mm) of juvenile Chinook salmon caught during the northern Bering Sea surface trawl surveys, 2006-2019. Simple linear regression model fit shown by dashed line (n = 12 years). Error bars represent 95% confidence intervals. Data unavailable for 2008 and 2013. Symbols indicate four warmest years (filled circles; autumn SST > 9.5 °C), four coldest years (X; autumn SST < 8.5 °C), and four intermediate years (empty circles).

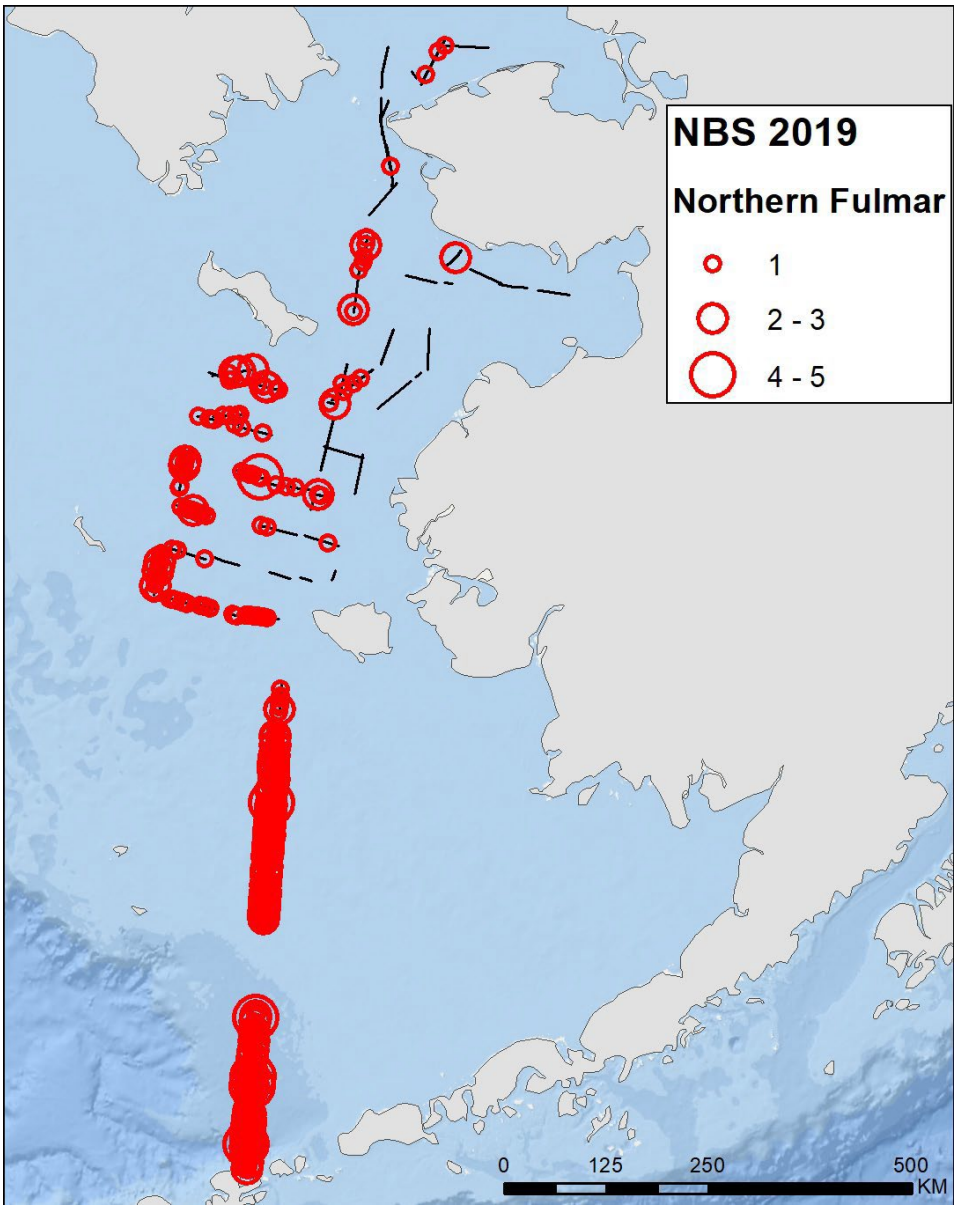

Figure 32. -- Distribution of northern fulmars observed during the northern Bering Sea surface trawl survey, 2019.

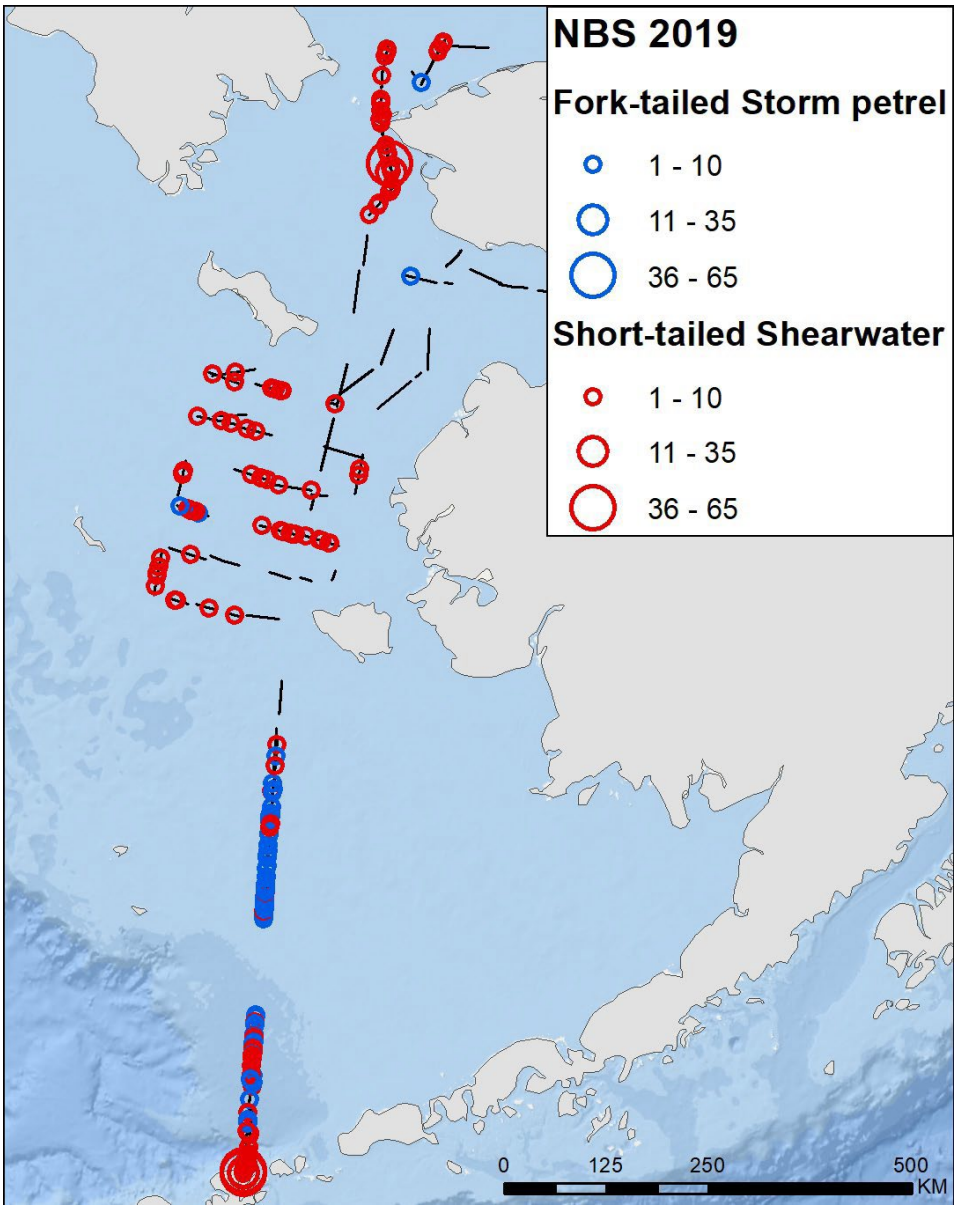

Figure 33. -- Distribution of shearwaters and fork-tailed storm-petrels during the northern Bering Sea surface trawl survey, 2019.

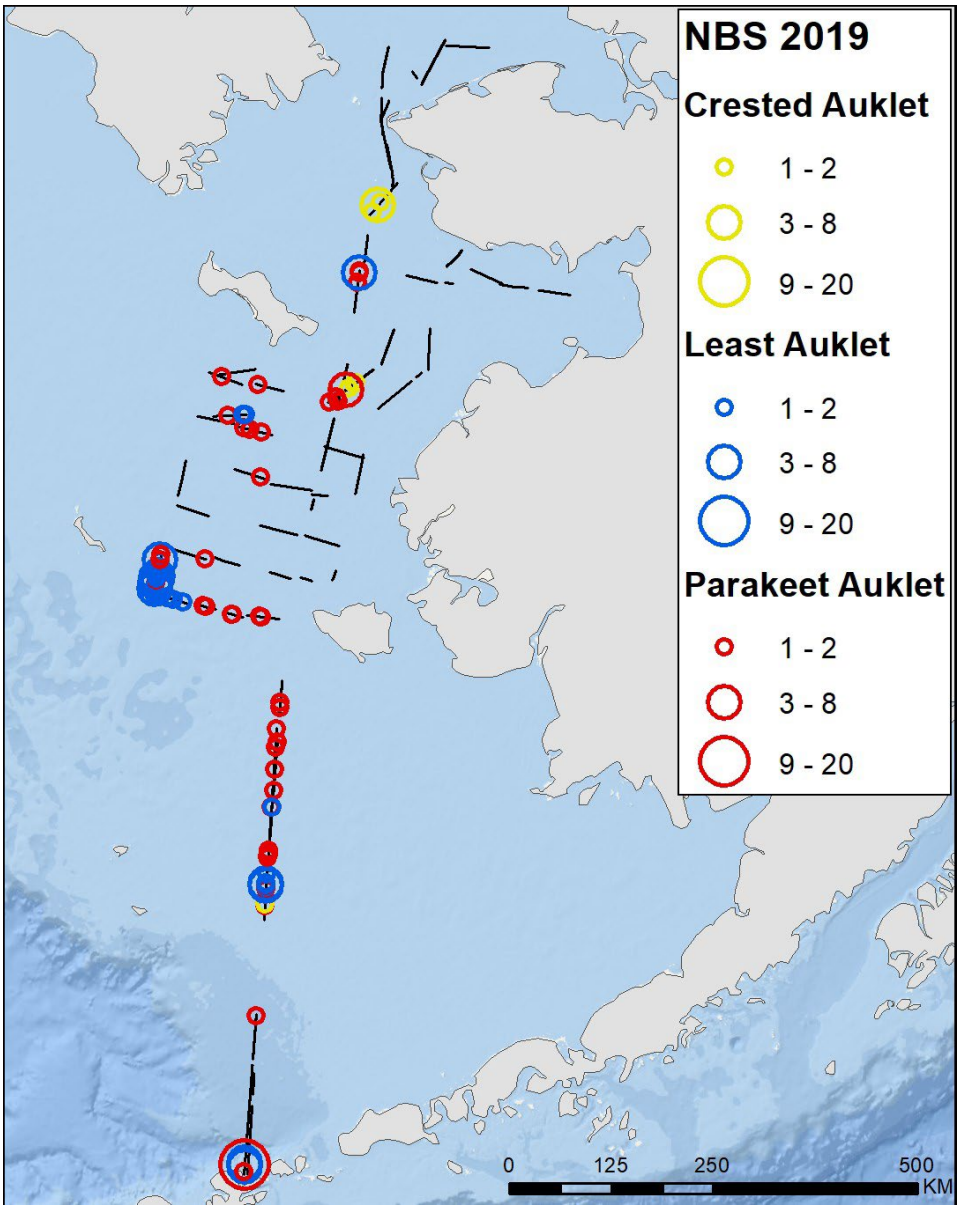

Figure 34. -- Distribution of auklet species during the northern Bering Sea surface trawl survey, 2019.

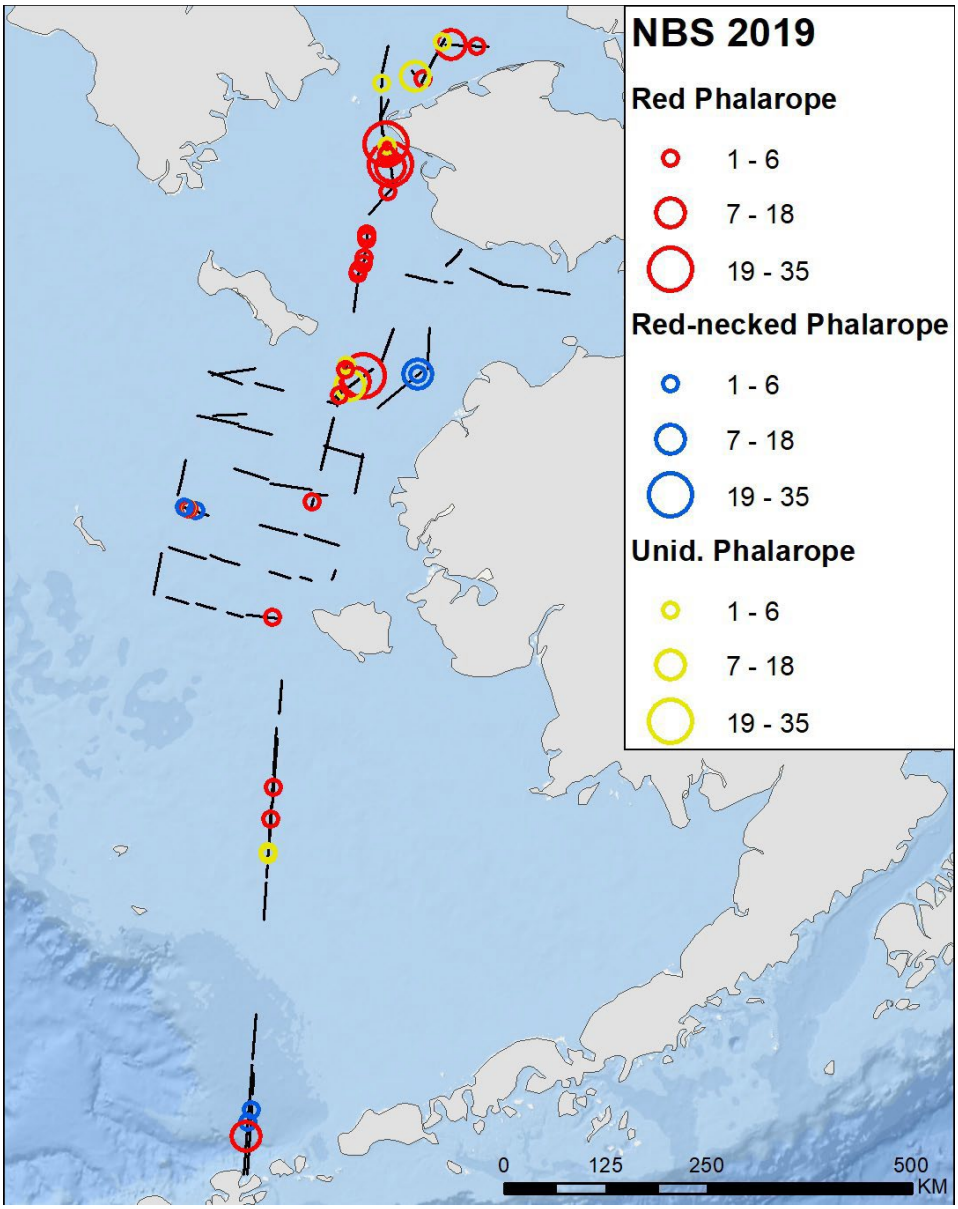

Figure 35. -- Distribution of phalarope species observed during the northern Bering Sea surface trawl survey, 2019.

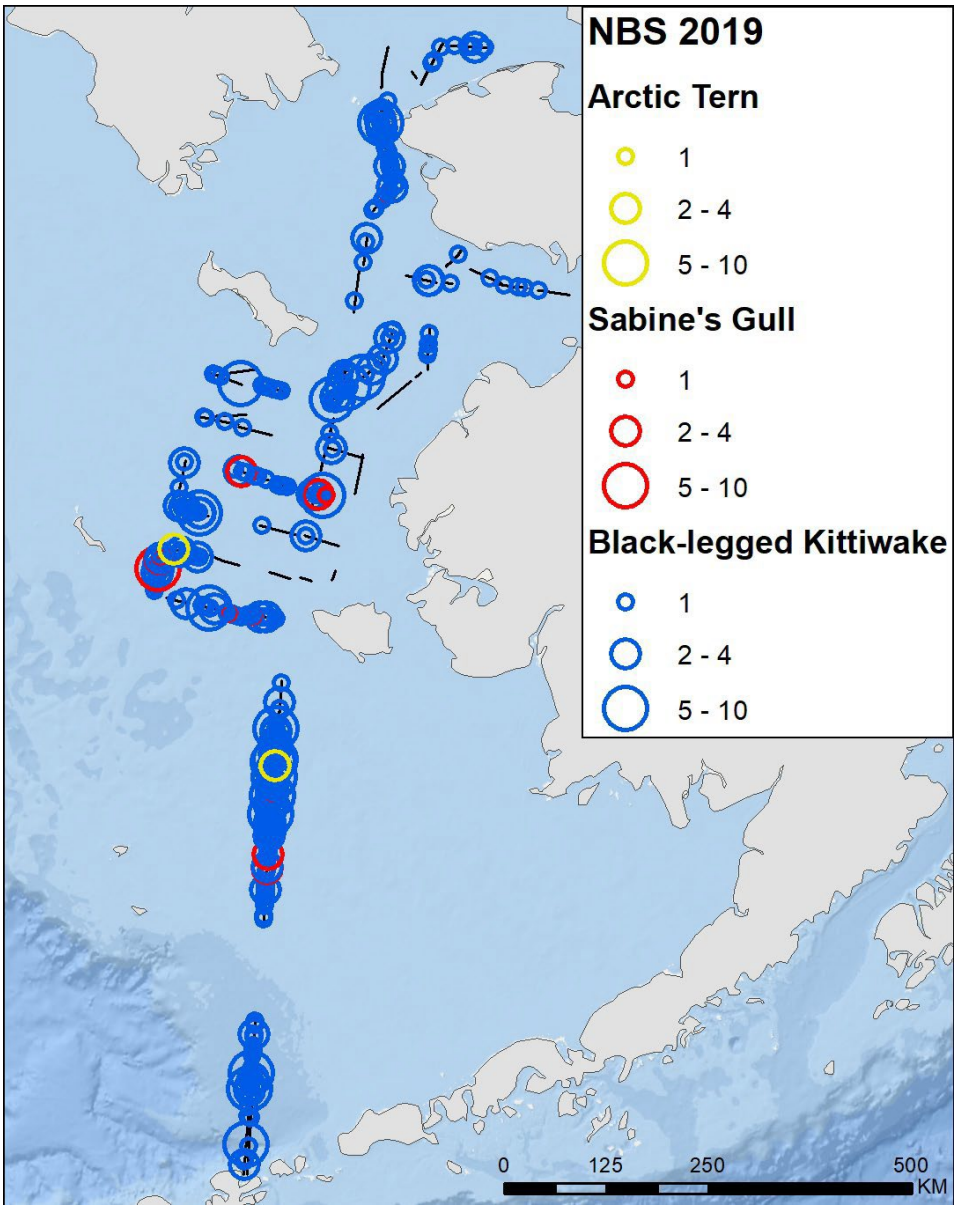

Figure 36. -- Distribution of Arctic tern, Sabine's gull, and black-legged kittiwakes observed during the northern Bering Sea surface trawl survey, 2019.

APPENDIX B. -- Spatial distribution surface trawl catch.

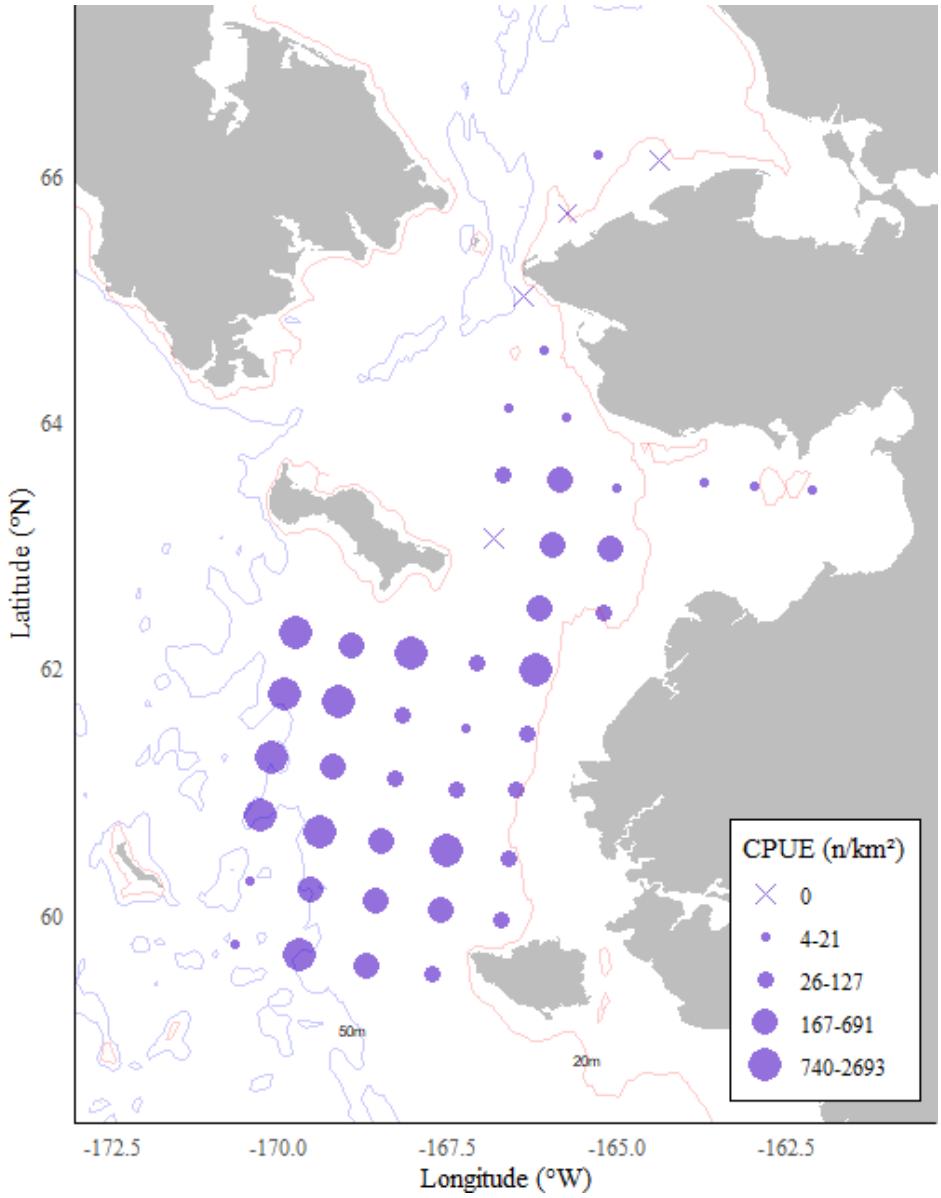

Figure B1. -- Surface trawl catch rates of juvenile chum salmon (CPUE, n/km^2) during the northern Bering Sea surface trawl survey, 2019.

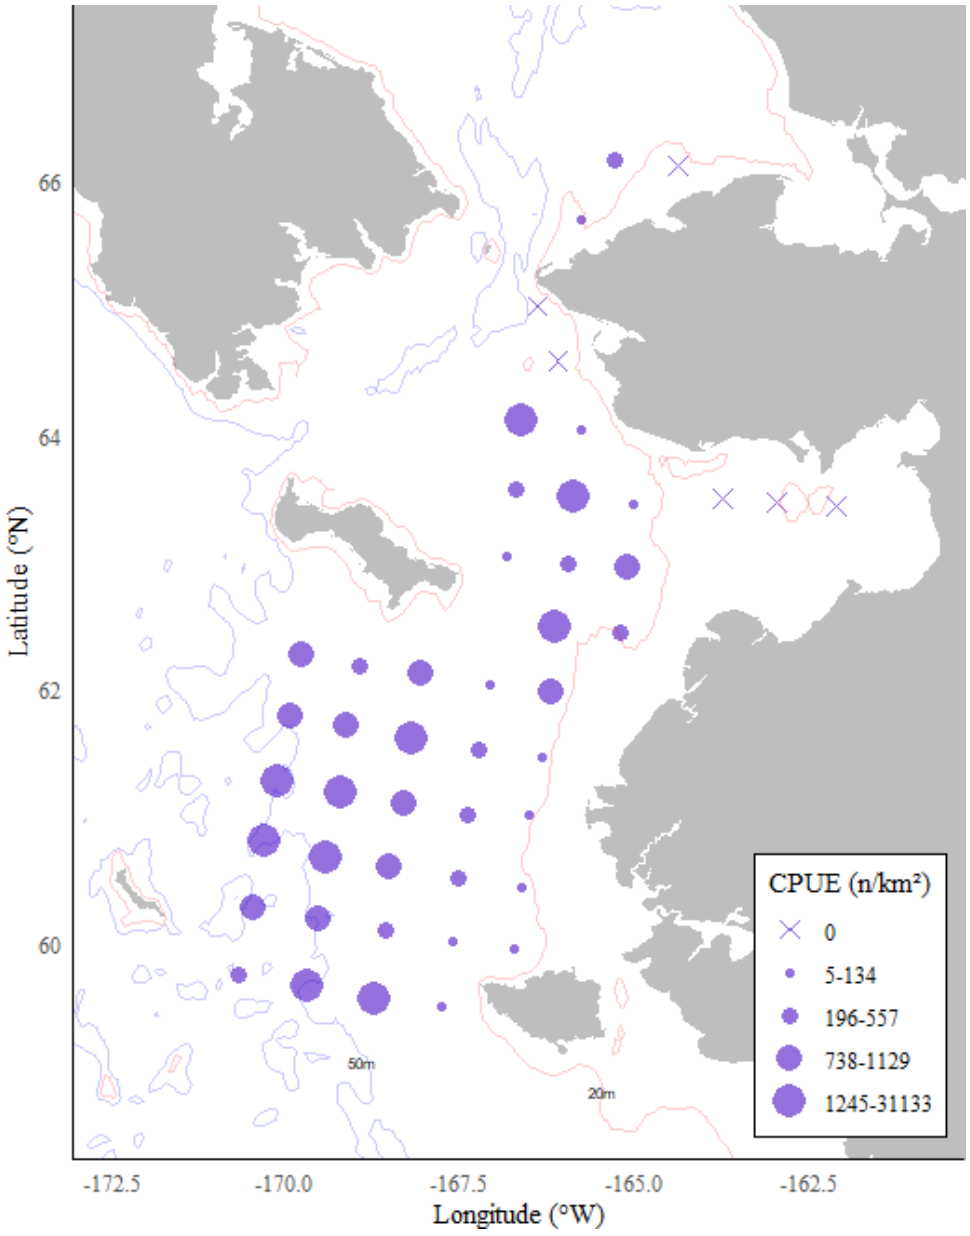

Figure B2. -- Surface trawl catch rates of juvenile pink salmon (CPUE, n/km^2) during the northern Bering Sea surface trawl survey, 2019.

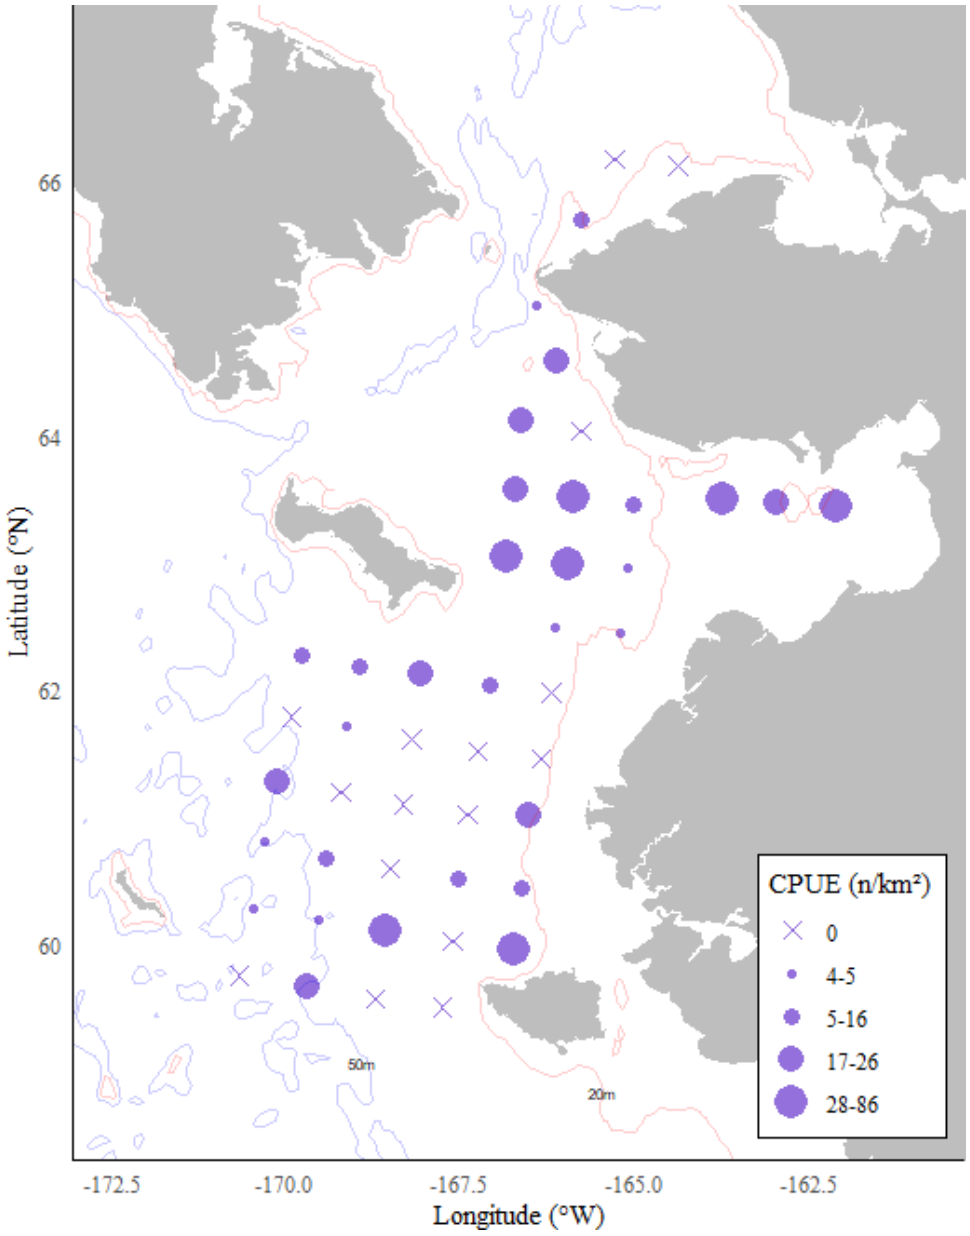

Figure B3. -- Surface trawl catch rates of juvenile Chinook salmon (CPUE, n/km^2) during the northern Bering Sea surface trawl survey, 2019.

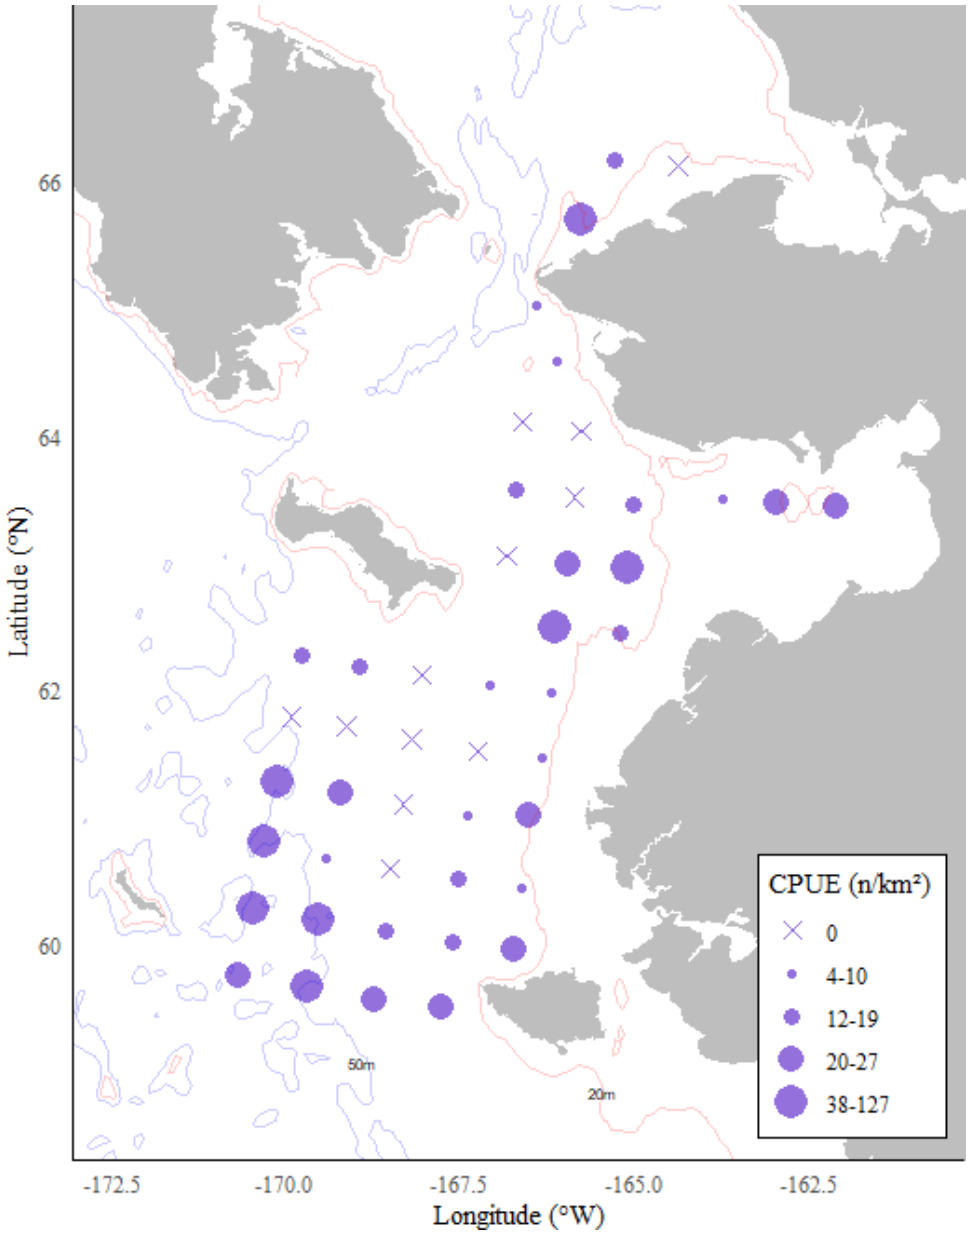

Figure B4. -- Surface trawl catch rates of juvenile coho salmon (CPUE, n/km^2) during the northern Bering Sea surface trawl survey, 2019.

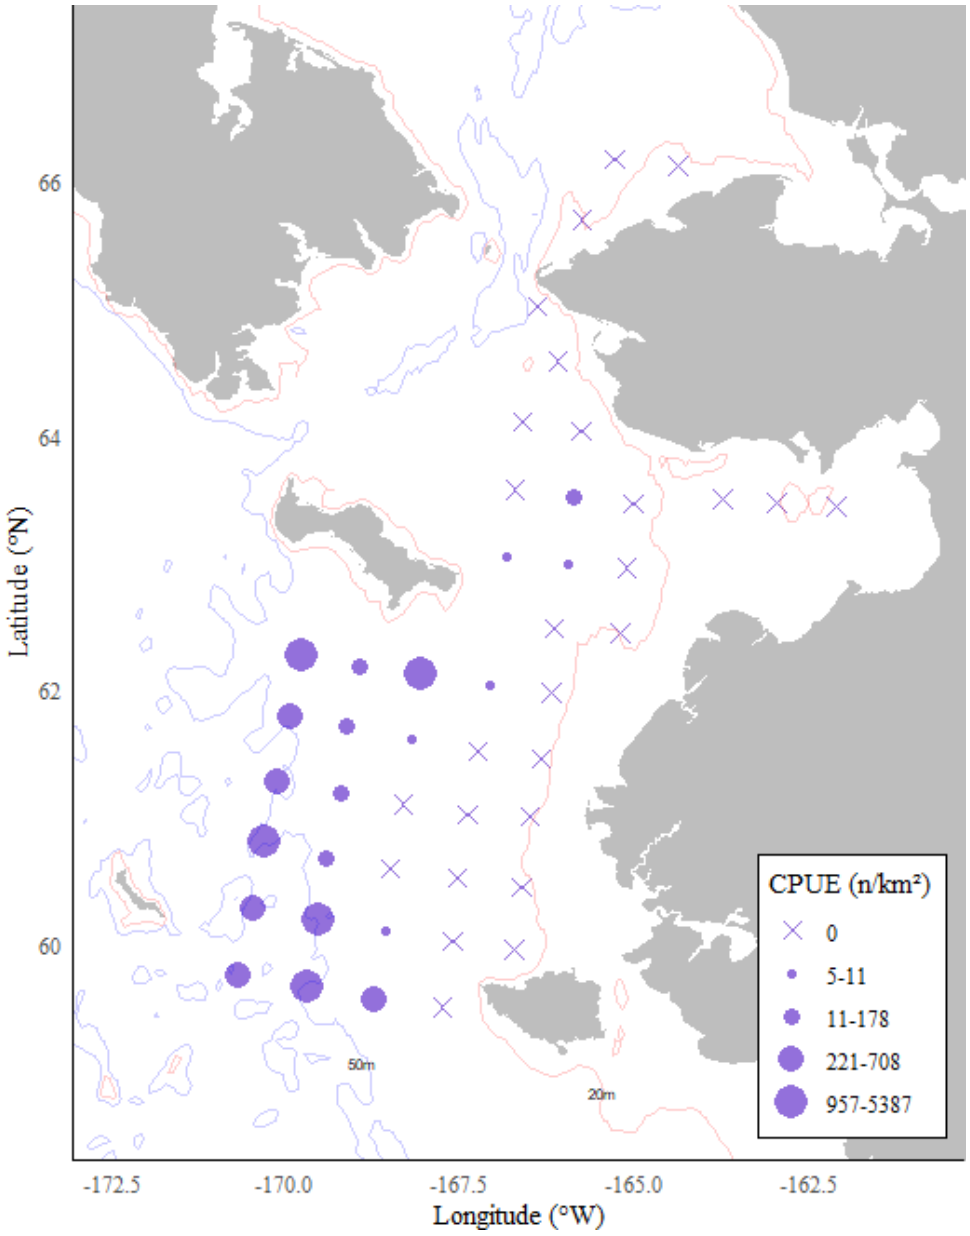

Figure B5. -- Surface trawl catch rates of juvenile sockeye salmon (CPUE, n/km^2) during the northern Bering Sea surface trawl survey, 2019.

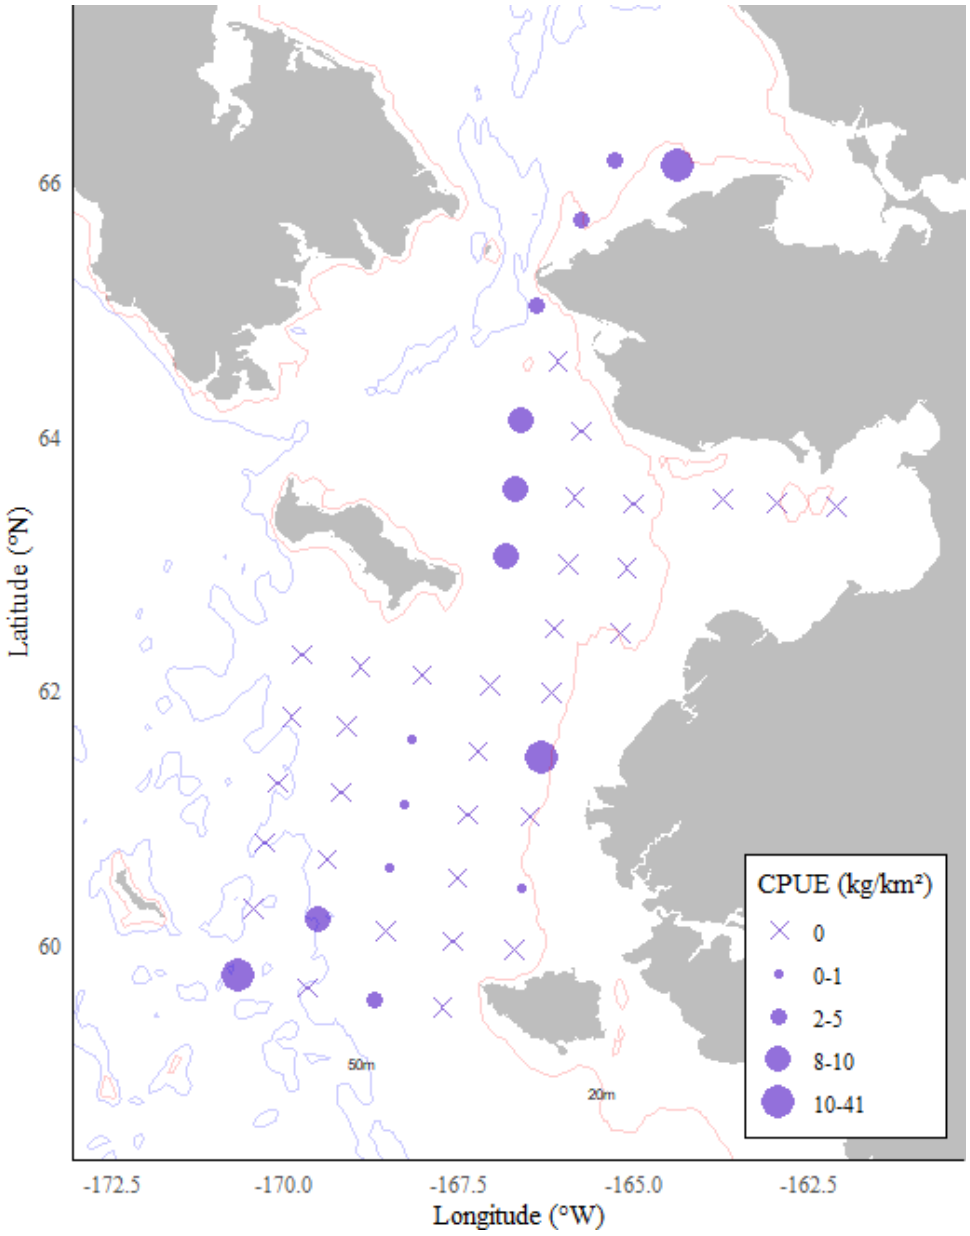

Figure B6. -- Surface trawl catch rates of water jellyfish (*Aequorea* sp.) (CPUE, kg/km^2) during the northern Bering Sea surface trawl survey, 2019.

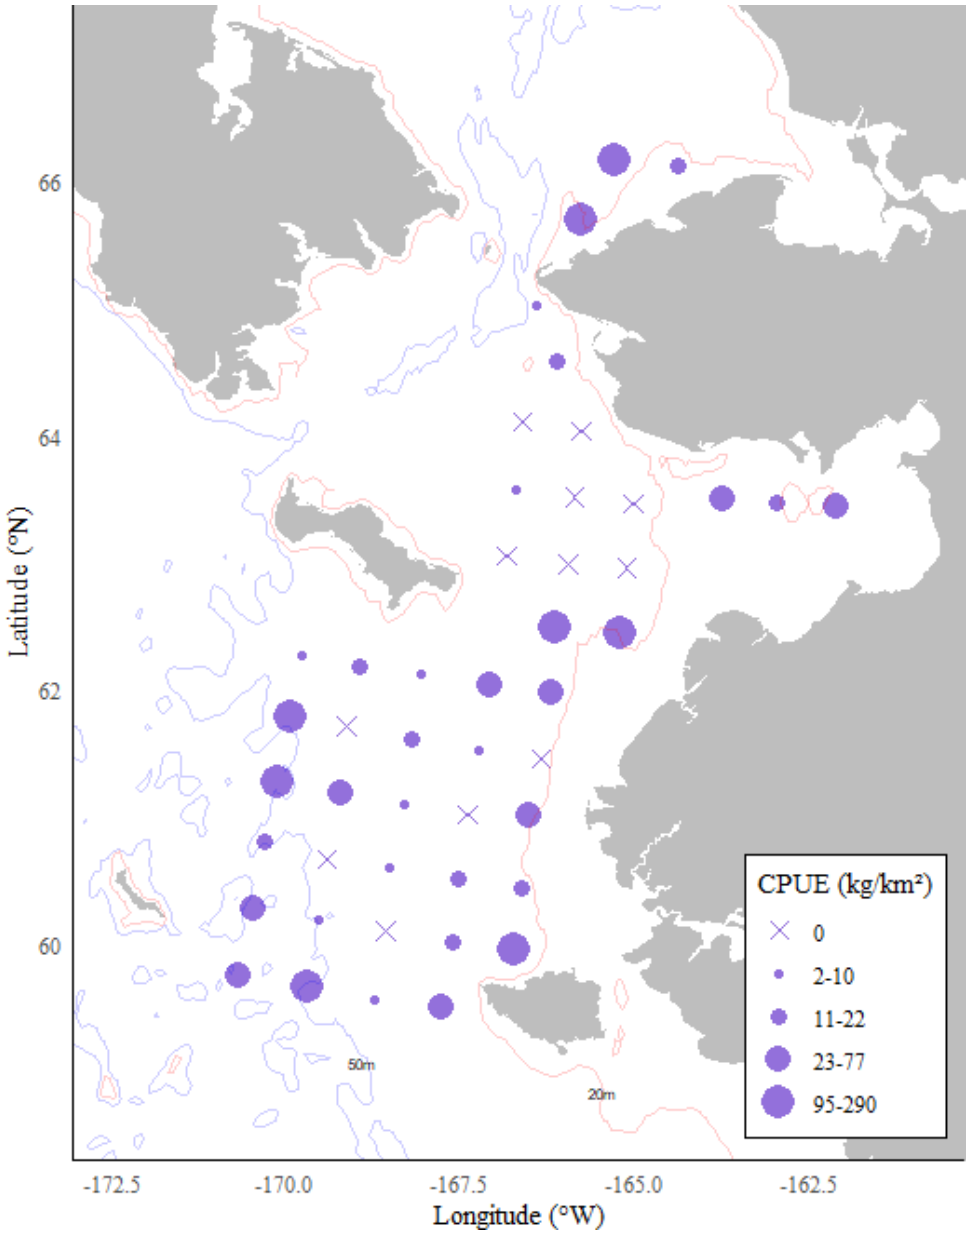

Figure B7. -- Surface trawl catch rates of moon jellyfish (*Aurelia labiata*) (CPUE, kg/km^2) during the northern Bering Sea surface trawl survey, 2019.

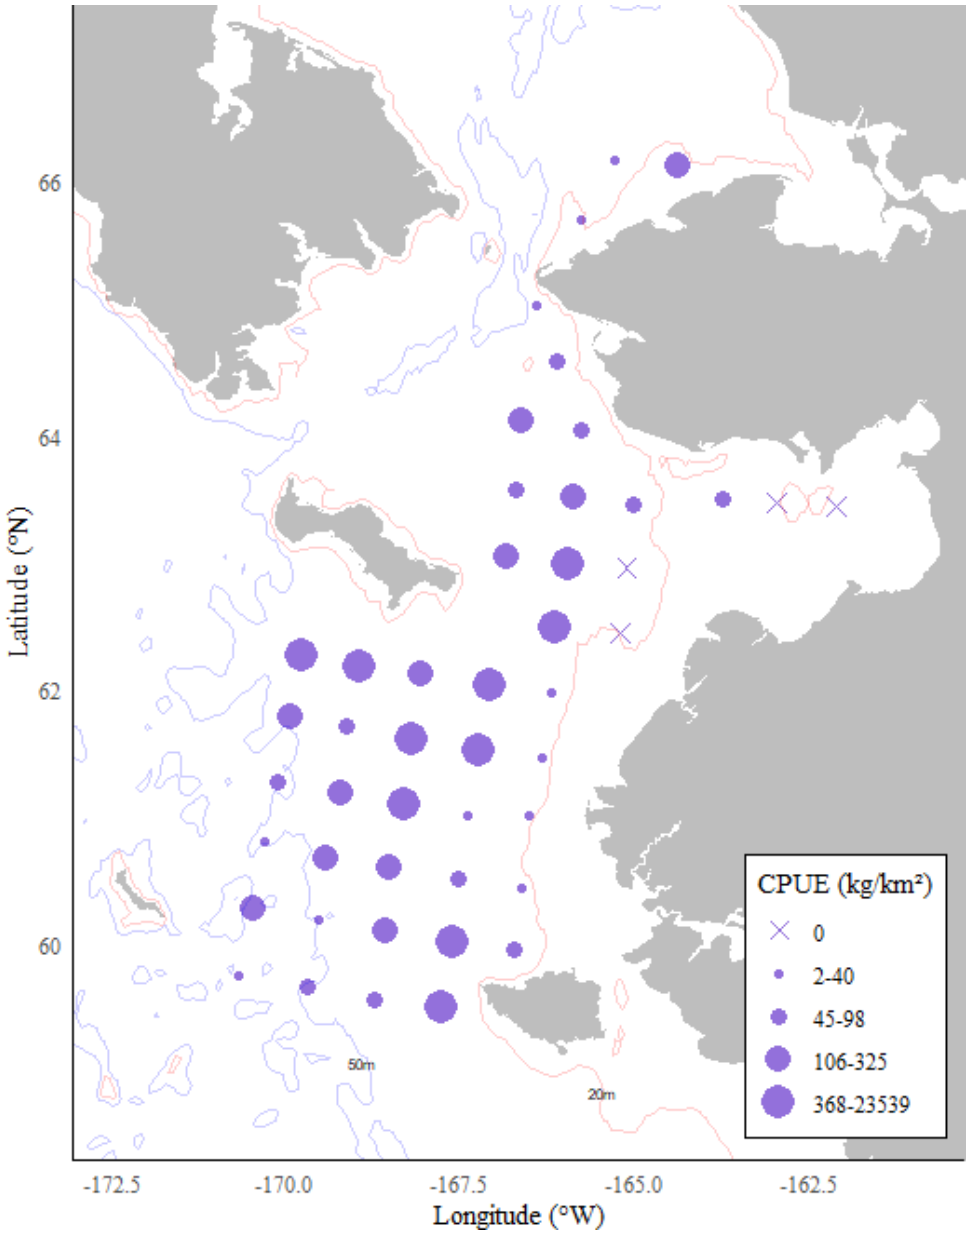

Figure B8. -- Surface trawl catch rates of northern sea nettle (*Chrysaora melanaster*) (CPUE, kg/km^2) during the northern Bering Sea surface trawl survey, 2019.

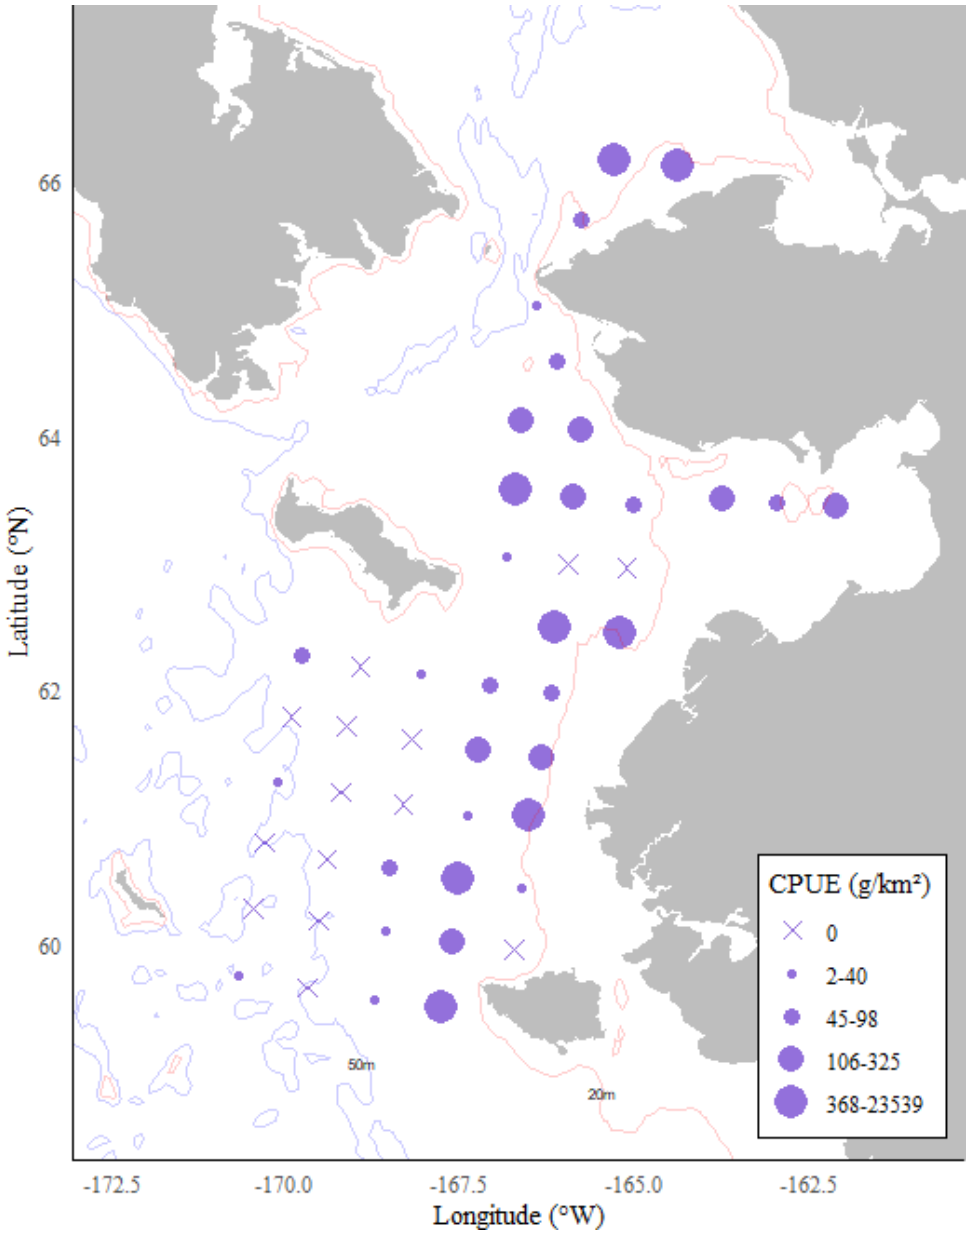

Figure B9. -- Surface trawl catch rates of lion's mane jellyfish (*Cyanea capillata*) (CPUE, g/km^2) during the northern Bering Sea surface trawl survey, 2019.

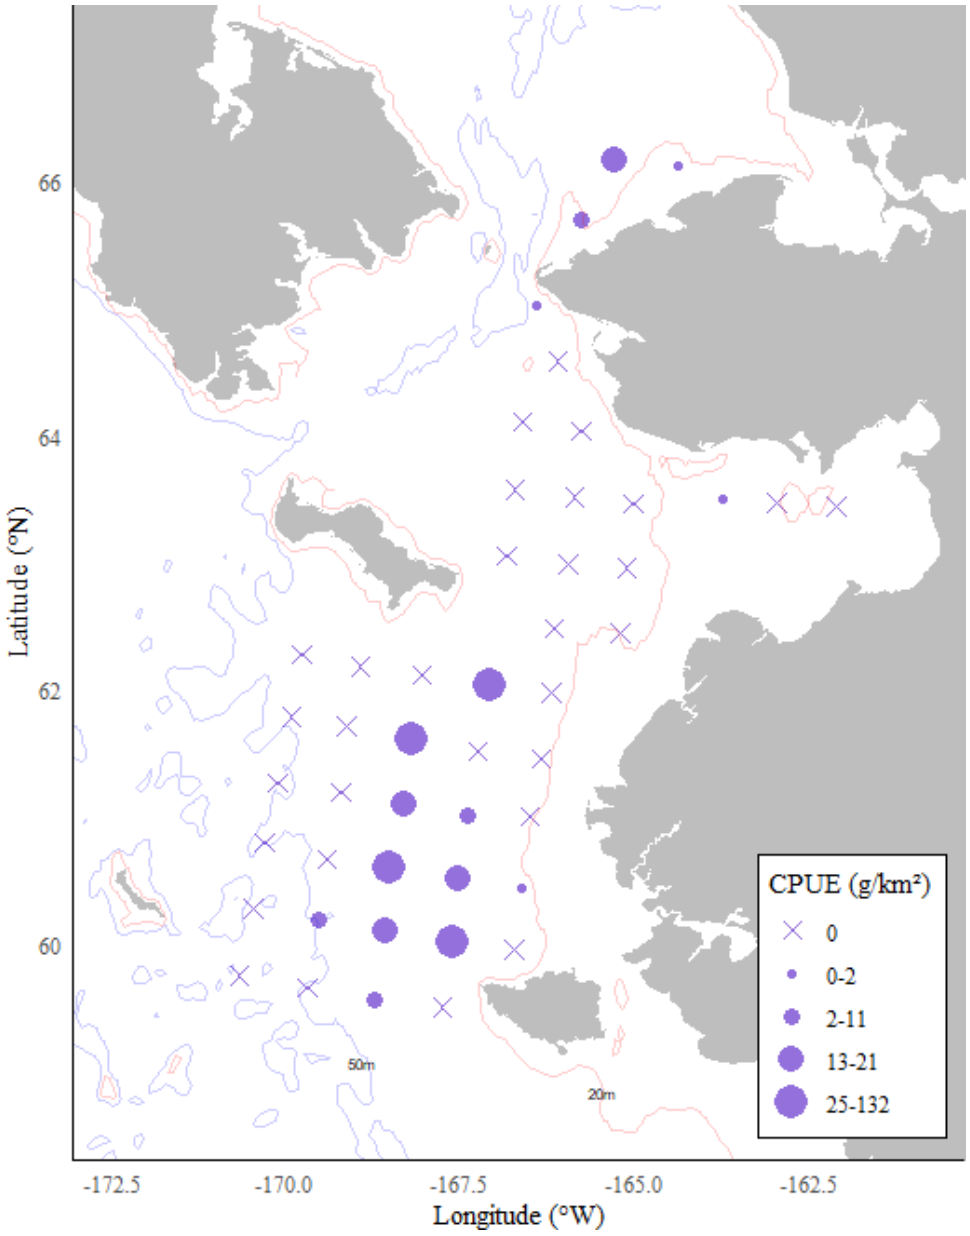

Figure B10. -- Surface trawl catch rates of whitecross jellyfish (*Staurophora mertensi*) (CPUE, g/km^2) during the northern Bering Sea surface trawl survey, 2019.

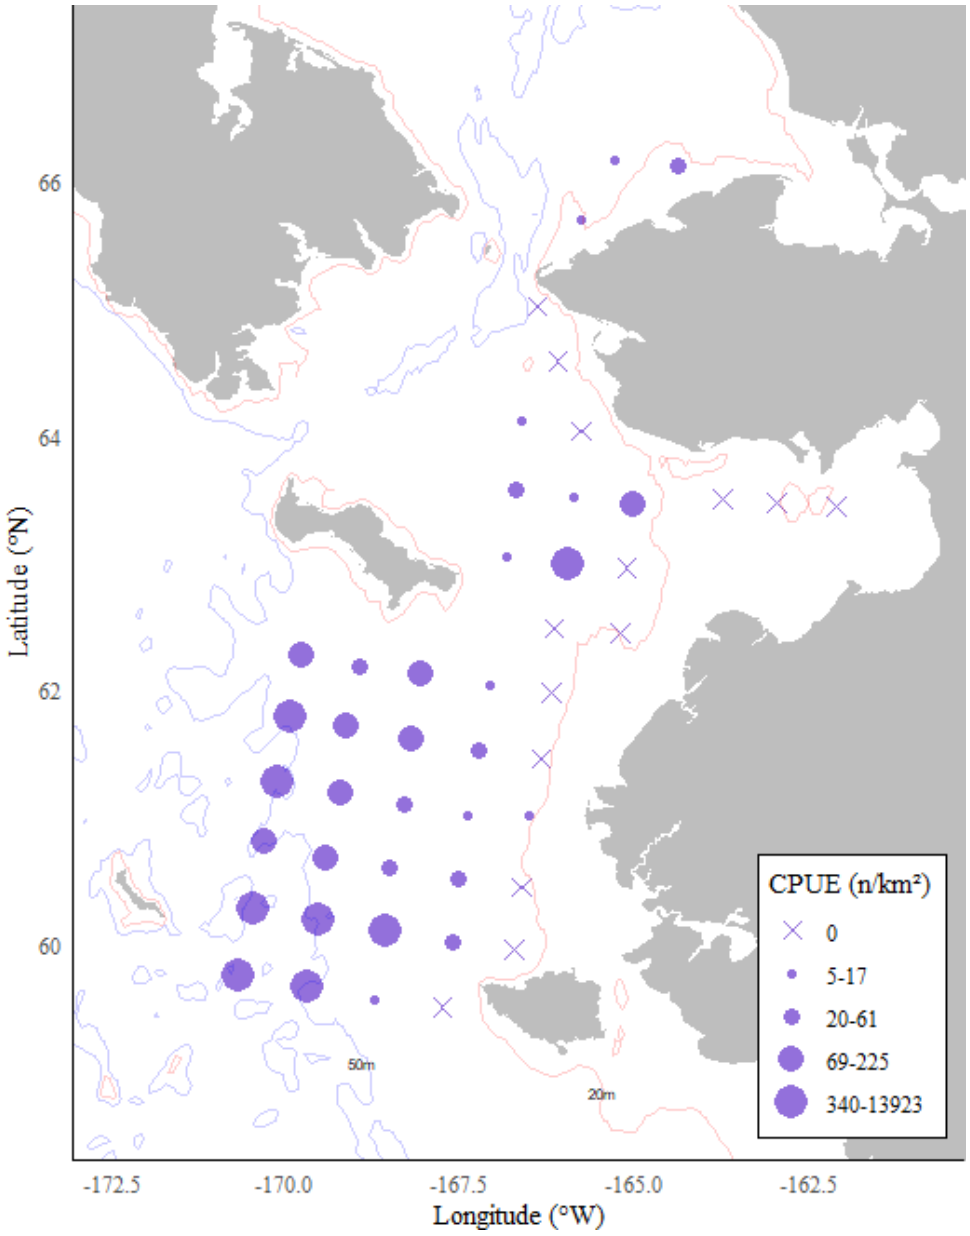

Figure B11. -- Surface trawl catch rates of age-0 walleye pollock (CPUE, n/km^2) during the northern Bering Sea surface trawl survey, 2019.

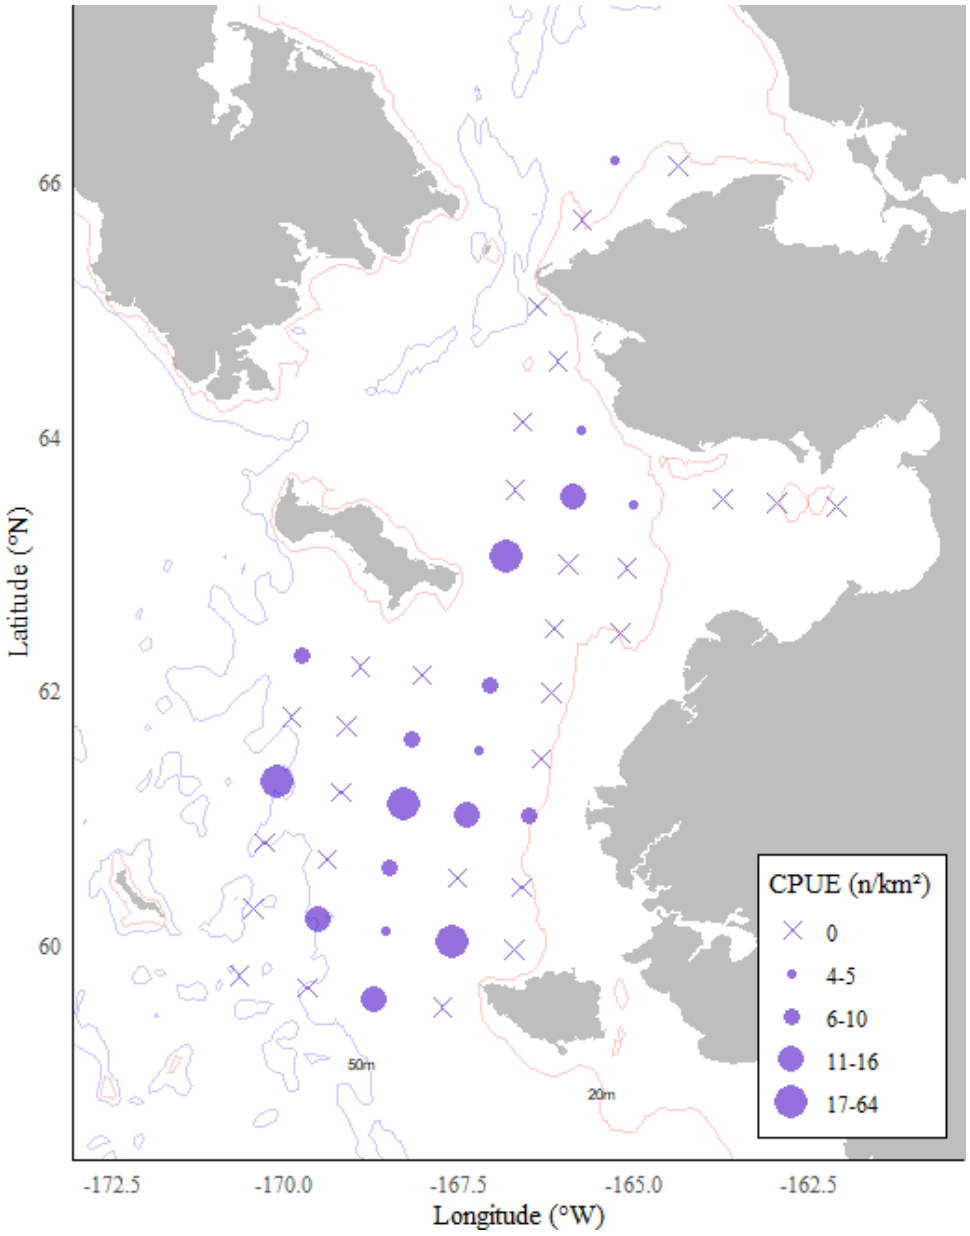

Figure B12. -- Surface trawl catch rates of age-1+ walleye pollock (CPUE, n/km^2) during the northern Bering Sea surface trawl survey, 2019.

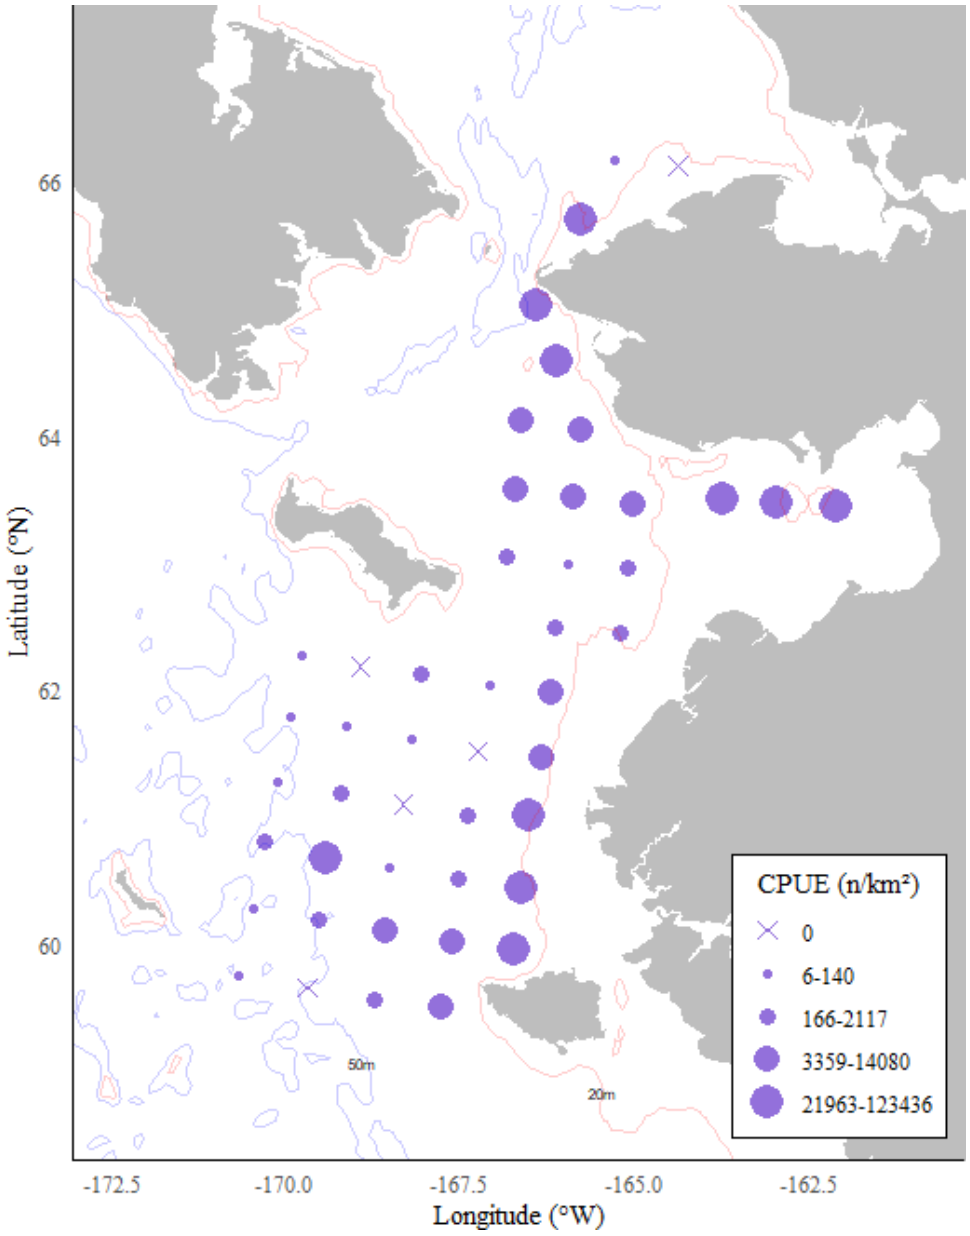

Figure B13. -- Surface trawl catch rates of Pacific herring (CPUE, n/km^2) during the northern Bering Sea surface trawl survey, 2019.

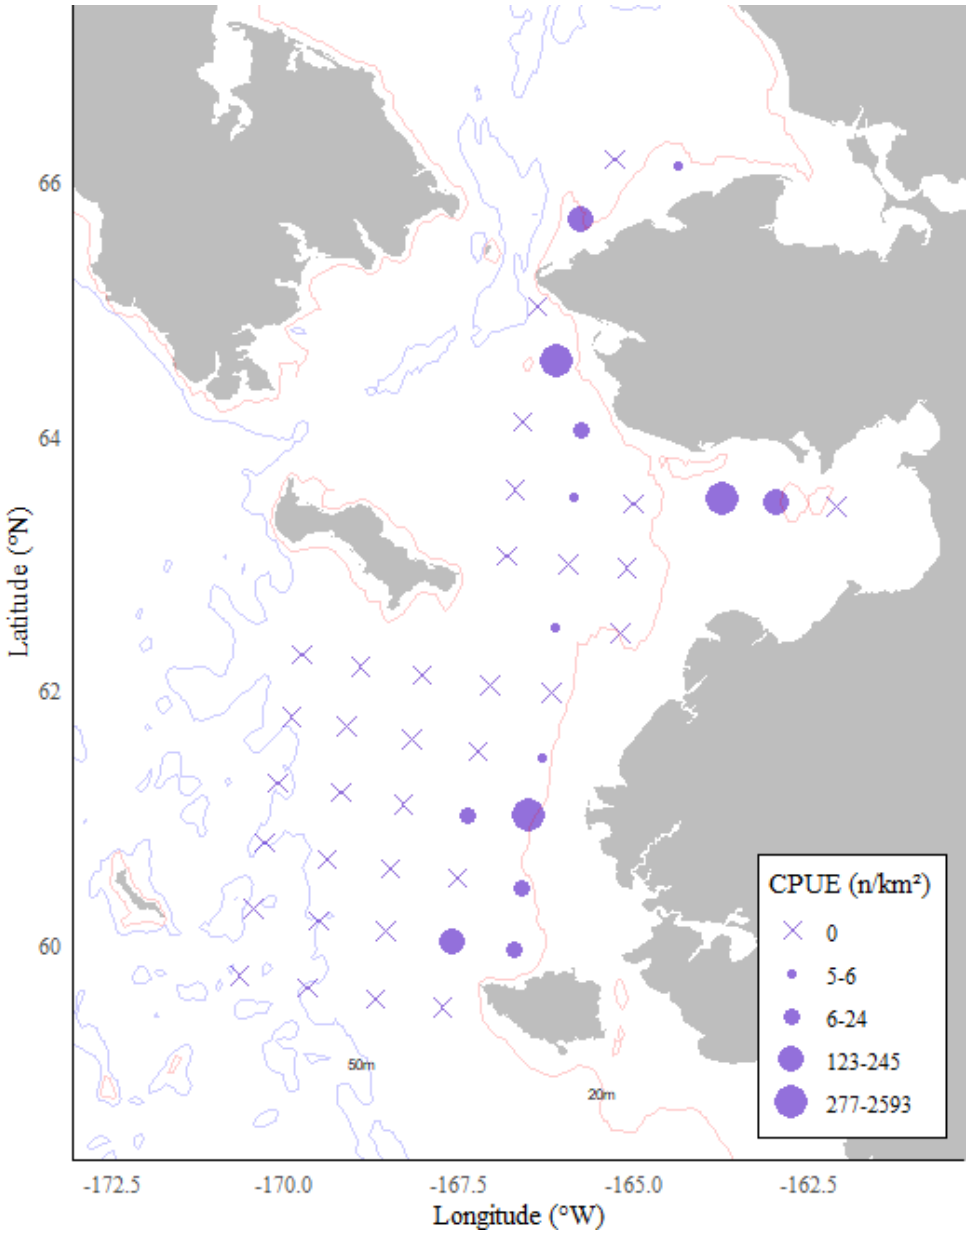

Figure B14. -- Surface trawl catch rates of rainbow smelt (CPUE, n/km^2) during the northern Bering Sea surface trawl survey, 2019.

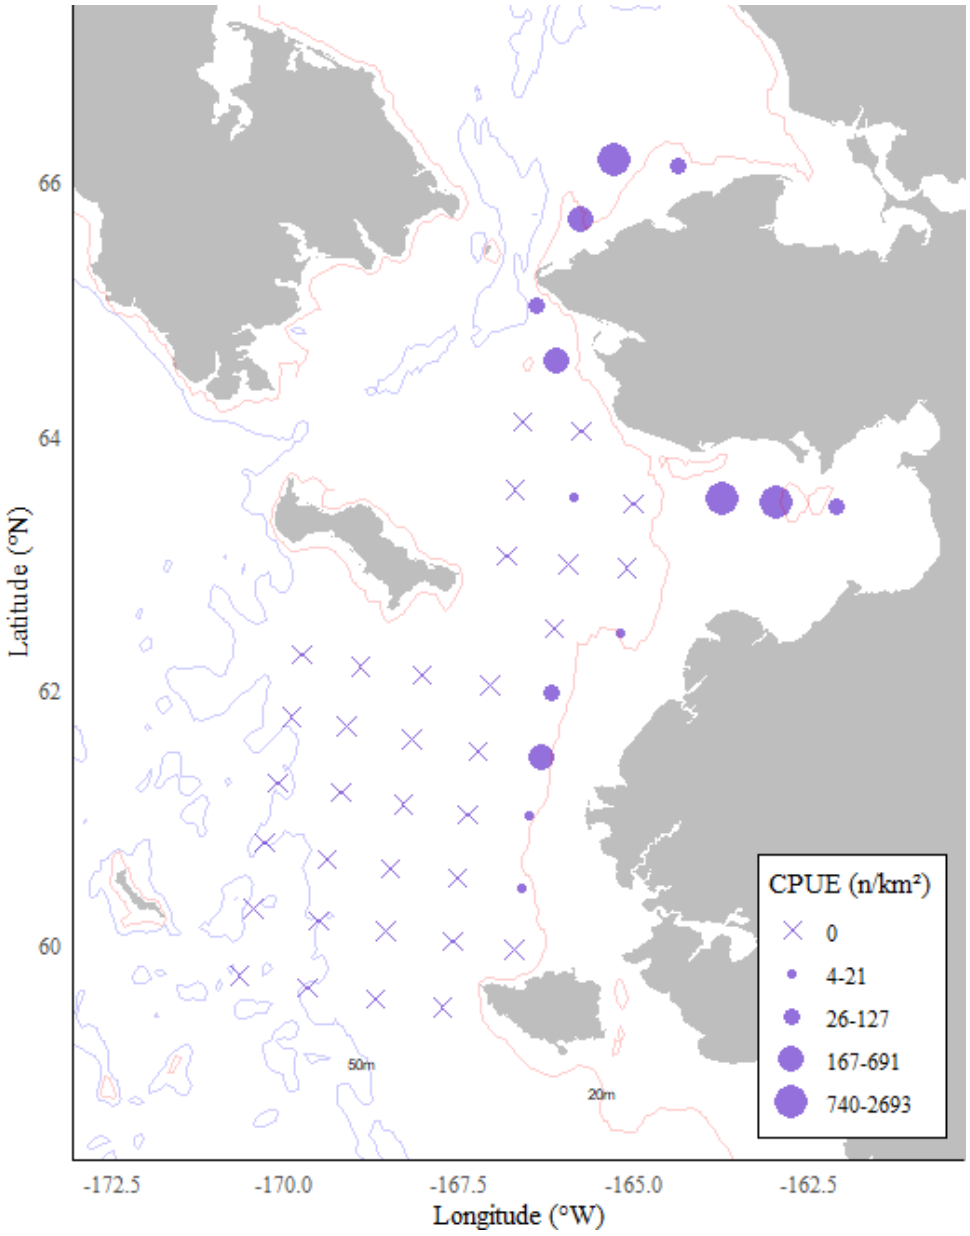

Figure B15. -- Surface trawl catch rates of ninespine stickleback (CPUE, n/km^2) during the northern Bering Sea surface trawl survey, 2019.

APPENDIX C. -- Length-weight relationships.

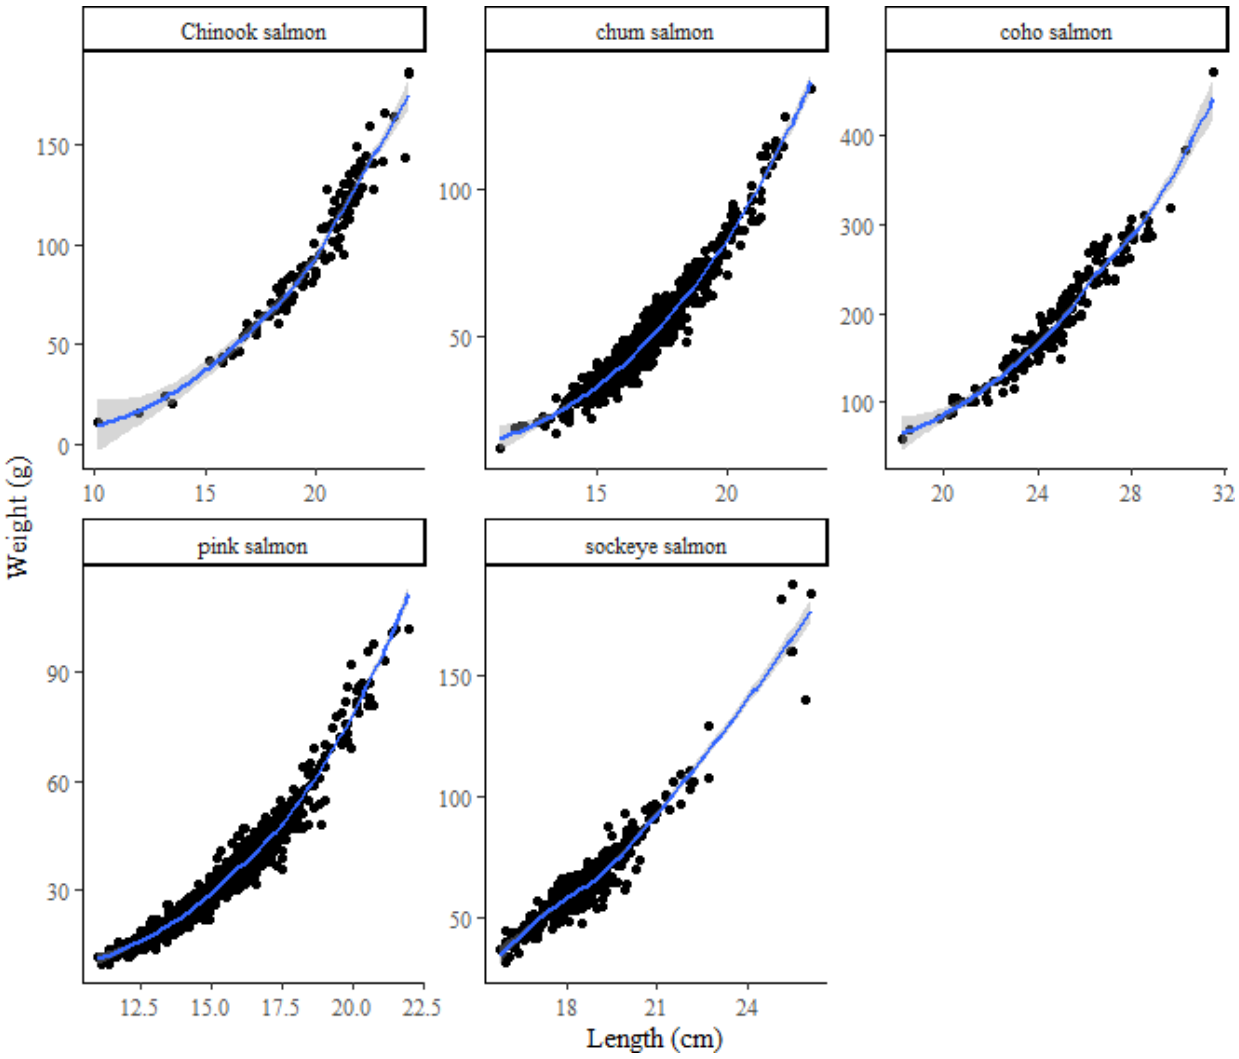

Figure C1. -- Length weight relationships of juvenile salmon species sampled during the northern Bering Sea surface trawl survey, 2019. Lines and shaded regions are from a local regression model (loess) fit and standard error.

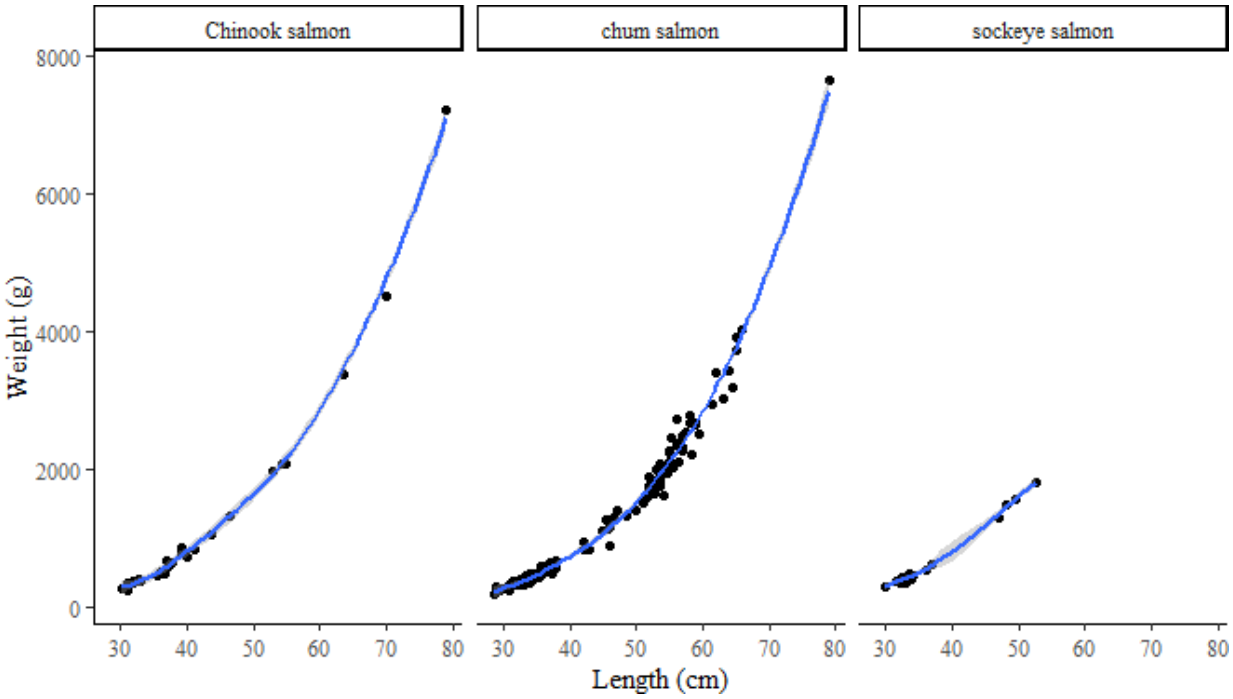

Figure C2. -- Length weight relationships of immature salmon species sampled during the northern Bering Sea surface trawl survey, 2019. Lines and shaded regions are from a local regression model (loess) fit and standard error.

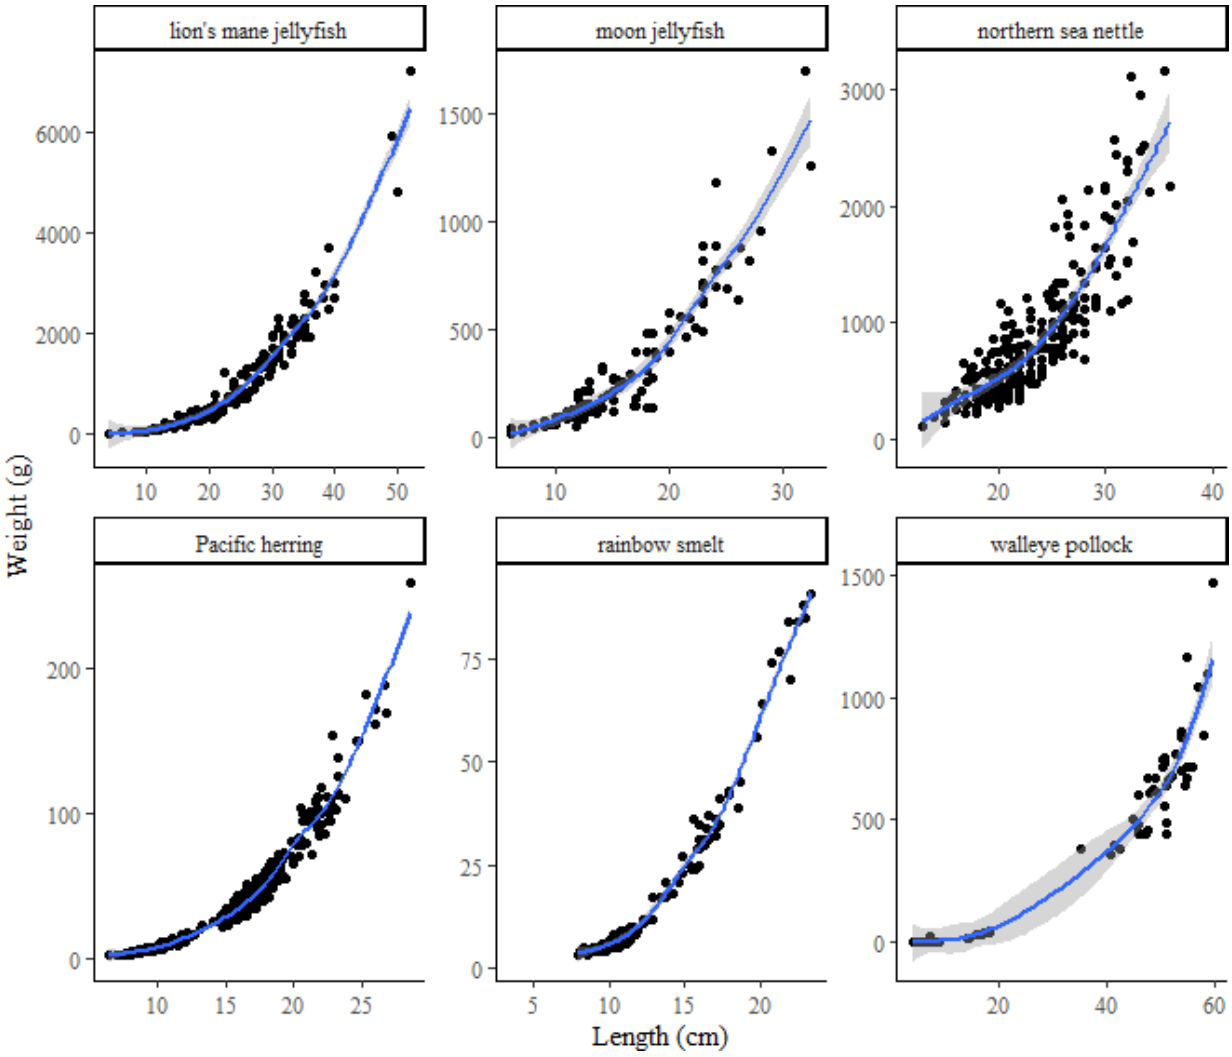

Figure C3. -- Length weight relationships of other key non-salmon species sampled during the northern Bering Sea surface trawl survey, 2019. Lines and shaded regions are from a local regression model (loess) fit and standard error.

APPENDIX D. – Coded-wire-tag recoveries.

Table D1. -- Coded-wire-tag (CWT) recovery information from Whitehorse Rapids Fish Hatchery Chinook salmon captured during the northern Bering Sea surface trawl surveys, 2003-2019.

CHAPTER 16 - Multi-Year autonomous observations of Seasonality in movement, behavior, and growth of pelagic fishes in the Chukchi Sea

Objective 5: Further resolve early life history characteristics of Arctic cod and saffron cod and their behavior and connectivity between the Chukchi Sea and western Beaufort Sea.

Abstract

Recent summer surveys of the Chukchi Sea determined that pelagic fishes were dominated by large numbers of age-0 Arctic cod and walleye pollock, while adult fishes are comparatively scarce. Transport modeling based on regional currents indicates that these age-0 fishes are likely advected to the north in fall. However, the source and fate of these fishes remains unclear, as sampling in this region is impeded by seasonal ice cover. To determine the movement and seasonal variability of this age-0 gadid population, seafloor-moored echosounders were deployed at three locations in the northeastern Chukchi Sea from 2017-2019. Year-round observations indicate that the abundance and composition of the pelagic community on the Chukchi Sea shelf is highly variable over seasonal time scales. Fish abundance was very low in winter, increased in May, and reached peak abundance in late summer in both years. Fish tracking indicated that fish velocities and headings were strongly correlated with local currents. Two modes of direction were apparent; movement was primarily to the northeast with periodic reversals towards the southwest driven by changes in regional wind. The displacement of age-0 gadids to the northeast is consistent with the dominant patterns of advection on the shelf, and the flux of fishes indicates that a large portion of the population present on the Chukchi shelf in summer is likely transported to the northeast, resulting in low abundances of age-1+ fishes present in summer.

Introduction

The Chukchi Sea is a highly seasonally dynamic region, serving as the pathway for Pacific water into the Arctic basin. The shallow continental shelf is covered by sea ice in late winter and spring before warm water from the south initiates the retreat of ice in spring (Woodgate et al., 2010) leading to a largely ice-free summer. Seasonal sea ice extent in the Chukchi has declined over recent decades (Frey et al., 2015) and is predicted to continue to decrease at a rate of 0.94 days year^{-1} (Wang et al., 2018) as temperatures in the region continue to increase (Danielson et al., 2020). These changes are expected to alter the ecology of endemic Arctic fishes and enable further intrusion of boreal species, moving the southern boundary of Arctic species northward and altering composition of the local ecosystem (Mueter et al., 2021).
Age-0 gadids, particularly Arctic cod (*Boreogadus saida*), dominate the pelagic fish community on the Chukchi shelf in summer (De Robertis et al., 2017). Arctic cod is a circumpolar distributed species found throughout the Arctic basin and surrounding shelves (Mecklenburg et al. 2018). Arctic cod are common throughout the region (Lowry and Frost 1981; Rand and Logerwell 2011; De Robertis et al., 2017), where they are a key pelagic component of energy transfer between lower and upper trophic levels (Whitehouse et al., 2014). However, while large numbers of age-0 Arctic cod have been observed in the Chukchi in summer, adult fishes were comparatively scarce (De Robertis et al., 2017; Levine et al., in review). The

observed density of adult Arctic cod does not have the reproductive potential to produce the population of age-0 fishes observed on the shelf in summer and thus these fishes likely originated elsewhere (Marsh et al., 2019). Arctic cod are known to spawn under sea ice (Ponomorenko et al., 2000). Although the source of these age-0 Arctic cod has not been confirmed, modeling studies of regional advection indicate that these age-0 Arctic cod may originate in the southern Chukchi or northern Bering Seas in winter and early spring (Deary et al., 2021; Vestfals et al., 2021).

The composition of the pelagic community is changing under current warming conditions. Boreal species such as walleye pollock (*Gadus chalcogrammus*) make up an increasing portion of the age-0 gadid community (Wildes et al., in review; Levine et al., in review). As a result of recent warming, the distribution of adult pollock in the Bering Sea has shifted, with high densities of mature adults in the northern Bering Sea (Stevensen and Lauth, 2019; Eisner et al., 2020). The age-0 pollock in the Chukchi Sea are hypothesized to originate from this large population of adult fishes south of Bering Strait (Levine et al., in review). Eggs and larvae from this northern Bering population are likely to be transported north along with the movement of water through Bering Strait (Woodgate et al., 2005).

The Chukchi shelf is hypothesized to be an important nursery area for these age-0 fishes in summer (De Robertis et al., 2017; Levine et al., 2021), where relatively warm temperatures support high growth rates for both Arctic cod and pollock (Laurel et al., 2018) that are necessary to maximize growth prior to experiencing winter conditions. However, it remains unclear whether the abundant age-0 fishes observed in summer provide recruits to other areas or act as an ecological sink with fish not surviving through winter (De Robertis et al., 2017). As development of age-0 gadids is largely temperature-dependent (Laurel et al., 2018), the potential fates of populations observed on the Chukchi shelf may depend on their movement into environments conducive to survival during winter. Identifying the mechanisms and pathways by which these fish are distributed across the Chukchi shelf will help to further constrain the fate of this age-0 population and help predict how ongoing environmental changes will further alter their abundance and distribution in the region.

Advection from the south structures the distribution of the planktonic communities in the Chukchi in summer (Eisner et al., 2013; Danielson et al., 2017; Pinchuk and Eisner, 2017; Spear et al., 2020). Northward currents are also hypothesized to exert a strong influence on the gadid populations, as larvae are likely passively transported (Vestfals et al., 2019; Vestfals et al., 2021). Repeat surveys in 2018 indicated that advection played a key role in the distribution of age-0 gadids on the Chukchi shelf in summer (Levine et al., 2021). Periods of on-shelf retention of the population were likely important for growth for these small fishes, prior to their being transported off the shelf towards the Beaufort Sea and Central Basin in fall (Levine et al., 2021). While modeling studies based on summer distributions have hypothesized the passive northward movement of fishes (Deary et al., 2021; Vestfals et al., 2021), there are no direct observations to validate whether the large age-0 population observed in summer is transported to other areas or if this region serves as a sink with fishes failing to survive through winter conditions. If advection is the primary mechanism of distribution, mooring and radar observations and model output of currents provide opportunities to predict changes in distribution of these age-0 fishes on the Chukchi shelf.

Historically, direct observations of fishes in ice covered areas have been rare. Because access to ice-covered areas is limited and traditional trawling gear cannot be used, sampling has been restricted in spatial and temporal extent (Lønne and Gulliksen, 1989; Gradinger and Bluhm, 2004; Melnikov and Chernova, 2013). To monitor fishes during periods of ice cover, acoustic observations of pelagic fishes have been collected from ships (Benoit et al., 2008) and autonomous underwater vehicles operating under sea ice (Fernandes et al., 2003). Net systems designed to sample in ice have made it easier to collect specimens under sea ice over a greater area (Flores et al., 2012; David et al., 2016). However, these methods are logistically difficult and expensive. Winter surveys rely on ships with ice-strengthened hulls to provide access to areas that are seasonally inaccessible, and the deployment of autonomous platforms

or net systems are typically limited to a few discrete locations and collect observations over relatively short periods of time.

In seasonally ice-covered regions, moored instrumentation can be deployed during the ice-free period and left to collect data year-round. In these seasonal ice zones, acoustic doppler current profilers (Wallace et al., 2010) and echosounders (Miksis-Olds et al., 2013; Darnis et al., 2017; Kitamura et al., 2017; Gonzalez et al., 2021) have used acoustic observations to study zooplankton and fish dynamics during extended periods of ice cover. However, moorings have not been previously used to collect long-term observations of fish population movements through ice-covered regions. Moored echosounders can be used to collect continuous data to study fish abundance and fine-scale behavior (Trevorrow, 2005; Kaartvedt et al., 2009; Urmy et al., 2012; Ross et al. 2013; De Robertis et al., 2018). Detection of individual scatterers from split-beam observations can also be used to infer the size composition, transport, and behavior of fishes from moored platforms. While acoustic observations offer limited capacity to identify sound-scattering organisms, in low-diversity regions where backscatter is dominated by a single species or group, moorings can be used to infer information about the population as the primary species are known and interpretation of the acoustic signal is less dependent on the collection of biological samples. For example, if the species of the primary scatterers is known, length can be inferred from acoustic target size using established target strength-length (Traynor, 1996; Geoffroy et al., 2016). Angular information can be used to assess the location of a fish in the water column, and over sequential observations can be used to infer swimming speed and direction (Ehrenberg and Torkelson, 1996).

This study presents two years of near-continuous observations of age-0 gadids collected by seafloor-mounted echosounders at three sites in the northeastern Chukchi Sea. The primary objectives of this study were to characterize the seasonal patterns in pelagic fish abundance in the Chukchi Sea, and to determine the role of advective transport and fish behavior in the movement of age-0 gadids. Year-round observations enabled us to resolve the timing and seasonal dynamics of the pelagic ecosystem, helping to constrain the potential spawning region and determine the fate of the large juvenile population of fishes present during the summer months.

Methods

Mooring deployments

Three moorings were deployed in the northeastern Chukchi Sea in locations where fish densities had previously been observed to be high in summer (De Robertis et al., 2017). The moorings were deployed for two years at 71.03N 160.50W (49 m depth), 70.83N 163.11W (44 m depth), and 70.01N 166.85W (47 m depth) (Figure 4.1). The moorings were initially deployed between 08-15 August 2017, recovered and redeployed between 12-15 August 2018 after data recovery and maintenance, then recovered between 26 August and 05 September 2019 at the completion of the field program.

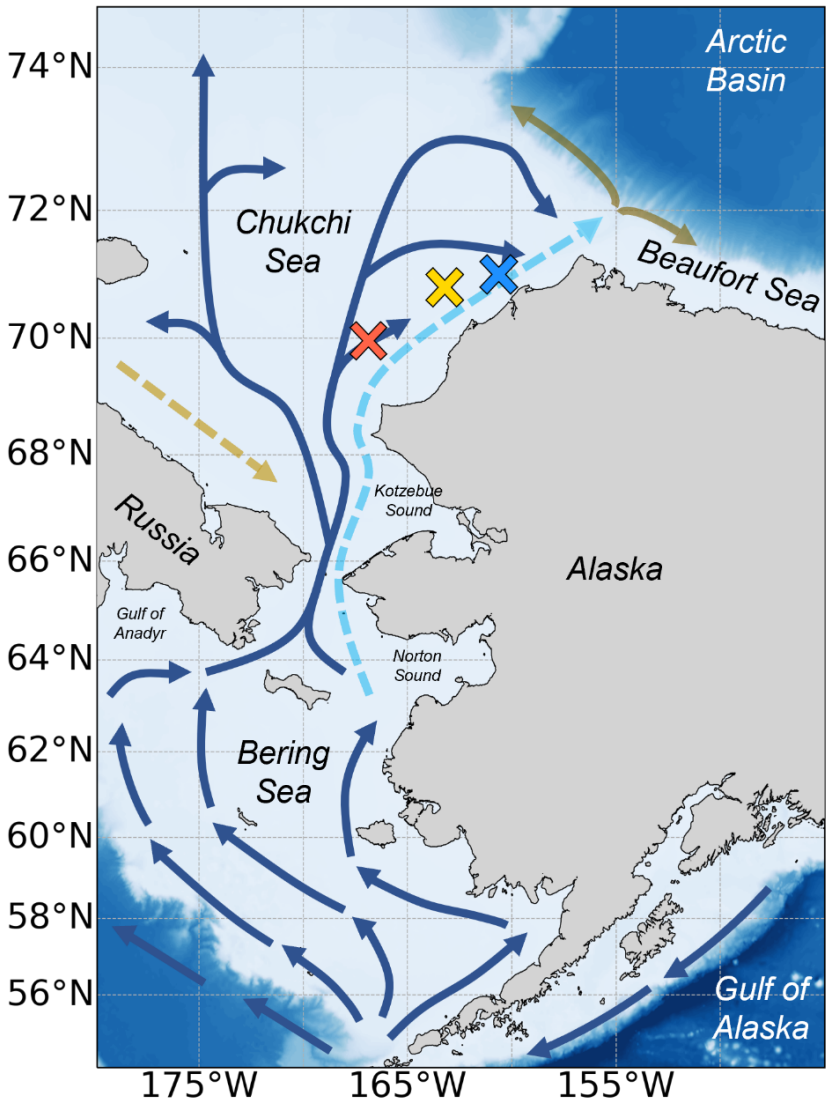

Figure 4.1 Map of the study region, showing the primary transport pathways through the Bering and Chukchi Seas based on Corlett and Pickart (2017) and Levine et al. (2020): Alaskan coastal current (light blue), Bering Sea water (dark blue), Siberian coastal current (gold), slope current (brown, westward) and shelf break jet (brown, eastward). Dashed lines indicate seasonal currents. The locations of the southern (red), central (yellow), and northern (blue) mooring sites are indicated by an x.

Composition of acoustic scatterers

The Chukchi Sea is well-suited for the use of autonomous acoustics. In the low diversity pelagic community of the Chukchi shelf, backscatter is dominated by a single species or group which simplifies the process of inferring species from backscatter. Acoustic-trawl surveys in the northeastern Chukchi Sea in 2012 and 2013 identified age-0 Arctic cod as the primary scatterers (De Robertis et al., 2017). Recent surveys during the mooring deployment period in summer 2017 and 2019 similarly found that age-0 gadids, particularly Arctic cod and walleye pollock, were the dominant pelagic scatters, accounting for 94.3% and 88.3% of the survey backscatter in 2017 and 2019, respectively (Levine et al., in review). Genetic analyses have confirmed that the increase in the proportion of pollock within the gadid community appears to have occurred during the period of these surveys (Wildes et al., in review). Thus,

walleye pollock were likely present throughout the deployment period. Other strong sound scattering pelagic fishes such as capelin (*Mallotus villosus*) and Pacific herring (*Clupea pallasii*) were present only in comparatively low abundances and accounted for < 6% of backscatter during summer surveys in both 2017 and 2019 (Levine et al., in review). Therefore, we assume that the primary contributors to backscatter were age-0 gadids, and that acoustic-based measures of fish density reflect the abundance and distribution of age-0 Arctic cod and walleye pollock.

Mooring Instrumentation

The mooring platforms were designed to be low profile to maximize the range of water column sampled by the echosounder, and to minimize the likelihood of damage due to sea ice. Each mooring was composed of two stacked 1.2 by 1.8 m fiberglass grates, separated with 0.2 m spacers (Supplementary Figure 4.1). The moorings were anchored to the seafloor by 23 kg lead feet positioned on each corner. The feet were replaced with 18 kg steel discs during the second year of deployment to reduce the mooring weight in order to increase the safety margin during recovery. Each mooring contained two acoustic release pop-up recovery packages (EdgeTech PORT-MFE) containing 100 m of recovery line connecting a hoist point on the mooring to a 15.4 cm diameter syntactic foam-filled float. All scientific instrumentation was mounted to the upper grate (Supplementary Figure 4.1).

The moorings were instrumented with battery-powered scientific echosounders (wideband autonomous transceiver, Simrad AS). Each echosounder operated an upwards facing depth-rated 70 kHz 18° split-beam transducer (ES70-18CD), positioned upward in a two-axis gimbal equipped with a 0.7 kg counterweight. Each echosounder also operated a combined 38 kHz 18° split-beam and 200 kHz 18° single-beam transducer (ES38-18/200-18C) mounted to the grating without a gimbal. Both transducer faces were positioned at a height of 0.8 m above the seafloor. During the deployment, the echosounders transmitted an ensemble of 300 pings (200 pings at 70 kHz, 100 pings at 38 and 200 kHz) at a ping rate of 0.4 s every two hours. Data were recorded to a range of 60 m. The echosounders were calibrated at the surface using a 38.1-mm tungsten carbide sphere, following the standard sphere method (Demer et al., 2015; Renfree et al., 2019). Echosounders used in 2017-2018 were calibrated prior to deployment. The echosounders used in 2018-2019 were calibrated following their final recovery, because the transducers recovered in summer 2018 were immediately redeployed. Due to a post-recovery instrument failure, the echosounder and transducer configuration deployed at the southern mooring site could not be calibrated. The average gains of the five other instrument calibrations were used for data processing along with the factory-specified beamwidth. The average gains for each frequency were 19.12 (±0.80 SD) dB at 38 kHz, 19.98 (±0.86 SD) dB at 70 kHz, and 17.98 (±0.55 SD) dB at 200 kHz. These calibrations did not account for potential pressure effects; however preliminary field experiments using the ES70-18CD transducer indicate that targets strength observations vary by <1.2 dB up to 100 m transducer depth (De Robertis, unpublished).

To determine the heading of the transducers when settled on the seafloor, each mooring was deployed with a calibrated compass mounted at a fixed position aligned with the forward direction of the transducers. Deployments used either a custom underwater magnetometer produced by the Engineering Development division of the NOAA Pacific Marine Environmental Lab or an Aaronia GPS Logger (Aaronia AG) sealed in a custom waterproof PVC pressure housing. Measurements were recorded for 0.3 - 385 d of each deployment due to variability in the battery life of each compass. Compasses in four deployments recorded for > 295 d, during which the hourly mean headings varied by < 5° (Supplementary Figure 4.2). These long-duration compass recordings confirmed that mooring orientations were stable throughout the deployment. The mode of all observations collected after deployment, corrected for magnetic declination at each site, was used to represent the mooring orientation (Table S4.1).

Acoustic data processing

Acoustic data were recorded from 8 August 2017 to 26 August 2019 at the southern site, 9 August 2017 to 4 September 2019 at the central site, and 15 August 2018 to 5 September 2019 at the northern site.

Data were not available for the northern mooring site for the 2017-2018 deployment as a result of instrument failure. In addition, the 38 kHz channel at the central mooring site failed during the 2018-2019 deployment. Thus, only the 70 and 200 kHz data were included in analyses. Due to interference (likely from side-lobe reverberation) appearing at 16-20 and 27-30 m depth at 200 kHz at the central mooring site during the 2018-2019 deployment, only data within those ranges where the signal was 10 dB higher than the noise level were included.

Acoustic data were processed using Echoview 12.0 (Echoview Software Pty Ltd). 70 kHz backscatter was used as a proxy for fish abundance. The depth of the sea surface/ice echo was determined by Echoview's threshold offset operator with a minimum detection threshold of -50 dB re 1 m^{-1} below the surface/ice, and manually corrected after visual inspection. The nautical area backscattering coefficient (s_A, m^2 nmi^{-2}; MacLennan et al., 2002) for all frequencies was echo-integrated in 1-m bins from 2 m above the transducer to 2 m below the sea surface/ice echo for every 2-h ensemble. The weighted mean depth ("centre of mass" in Urmy et al., 2012, their Table 1) of s_A was calculated for each ensemble. To investigate seasonality of diel vertical migration, the difference between the weighted mean depth of fishes at maximum and minimum solar altitude was calculated, determined as a function of datetime and location using the Pysolar library for Python (http://pysolar.org/).

The strength of backscatter across frequencies varies as a function of animal scattering properties (reviewed in Benoit-Bird and Lawson, 2016) and can be used to differentiate among key groups of scatterers (Jech and Michaels, 2006; De Robertis et al., 2010). Higher backscatter at 200 kHz than 70 kHz is indicative of scattering from zooplankton, while gadids exhibit higher scattering at 70 kHz than 200 kHz (De Robertis et al., 2010). To investigate potential changes in the composition of acoustic scatterers over the length of the deployment, the difference between the mean 70 kHz and 200 kHz S_v ($\Delta S_{v,70\text{-}200}$, dB) for each ensemble was calculated as used to infer dominant scatterer type.

Fish tracking and flux estimates

Echoes from individual fishes were identified with Echoview's split-beam single target detection (method 2), using a detection threshold of -70 dB re 1 m^{-2}. To minimize the potential bias due to overlapping targets being interpreted as a single fish, single target detection was limited to portions of the water column where density was low. The estimated number of animals per reverberation volume (Nv, Sawada et al., 1993) was calculated in 5-m vertical bins for each ensemble using a target strength of -55.5 dB re 1 m^{-2}, which assumes a mean Arctic cod size of approximately 4.5 cm (Geoffroy et al., 2021; Levine et al., in review). Single targets in grid cells where Nv > 0.04 were excluded as recommended by Sawada et al. (1993). Single targets were joined into individual fish trajectories using Echoview's 4D alpha-beta tracker (Blackman, 1986; see Table S4.2 for parameters). A minimum of 5 single targets was required with a maximum gap of 5 pings (2 s). The mean target strength (TS, dB re 1 m^{-2}) of each tracked fish was calculated as the mean TS of the single targets contained in each track, calculated from the mean of the linear TS values (σ_{bs}, m^2). Fish headings were calculated by fitting a 3-dimensional linear model with respect to time to the single target detections assigned to each fish track. Headings were converted from a coordinate system relative to the transducer into a geographic reference frame based on the compass orientation.

Speed was calculated by dividing the total distance along the model-fit linear track by the duration of the track. In addition to representing the net displacement of tracks through the acoustic beam, the use of the linear model also reduced range-dependent errors associated with the angular resolution of split-beam transducers. As range increases, angular errors as a result of the discrete resolution of 0.1125° in the acoustic data correspond to greater increases in the calculated physical distance between targets, resulting in a range-dependent increase in track speed (Klevjar and Kaartvedt, 2003). This bias was reduced by using a linear model compared with a B-spline or similar curve fitting representations, for tracks in which the distance between control points is likely to be affected by such angular errors (Supplementary Figure 4.3).

Fish density (fish m^{-2}) was calculated at each ensemble using the mean of the observed linear target strengths (σ_{bs}, m^2) and area backscattering coefficient (s_a, m^2 m^{-2}) following MacLennan et al. (2002). The flux of fish (Q, fish m^{-1} s^{-1}) was estimated using the fish density (A) and mean speed and direction of tracks during each ensemble, such that:

$$QQ = AAVV \quad (4.1)$$

Velocity (V) was calculated along the dominant direction of movement, defined as the mode of track headings (in 5° bins) for all tracks observed at each site (hereafter referred to as the reference heading). Thus, flux represents the number of fishes per second crossing underneath a 1 m line of the sea surface perpendicular to the reference heading.

Environmental data

Bottom temperature and salinity were measured using a conductivity, temperature, and depth (CTD, SeaBird 37) sensor mounted on each mooring. Hourly current measurements were derived from acoustic doppler current profilers (ADCP, Teledyne RD Instruments WorkHorse operating at either 300 or 600 kHz varying by site and year) deployed <500 m away from the echosounder moorings (see Stabeno et al., 2018 for details on data processing). To investigate the relationship between currents and fish tracks along a uniform direction, current velocities relative to the reference heading were calculated from the zonal (east-west) and meridional (north-south) components of each depth bin. Fish tracks were matched with the closest ADCP measurement in time and depth.

Sea ice concentrations were obtained from the NOAA/NSIDC Climate Data Record of Passive Microwave Sea Ice Concentration, Version 3 (Peng et al., 2013; Meier et al., 2017). Daily measurements were extracted from the 25 by 25 km grid cell that contained each mooring site. The NCEP/NCAR reanalysis (Kalnay et al., 1996) wind forecasts were used to estimate the wind speed and direction. Near-surface (0.995 sigma level) values of zonal and meridional wind, available in 6-h intervals, were obtained from the 2.5° grid cell nearest to each mooring.

Results

Seasonal characteristics of acoustics scatterers

Backscatter was highest during the late-summer and early fall, decreasing in winter and then increasing the following June/July across all sites during both years of deployment (Figure 4.2). Backscatter was lowest in early spring in all deployments. In early summer of 2018 and 2019, high backscatter first developed in the upper water column, deepening over the course of the summer (Figure 4.2a-c), indicating that the fish increased their depth distribution in summer.

Strong seasonal variability in pelagic community composition is demonstrated by the difference in volume backscatter observed at 70 and 200 kHz ($\Delta S_{v,70\text{-}200}$, Figure 4.3). In winter, $\Delta S_{v,70\text{-}200}$ is consistent with zooplankton-like scatterers at all three sites (blue regions, Figure 3). Fish-like scatterers (red regions, Figure 4.3) appear concurrently with the increase in backscatter in early summer (Figure 4.2). The highest backscatter occurs during periods when $\Delta S_{v,70\text{-}200}$ indicates that the backscatter is dominated by fish-like scatterers ($\Delta S_{v,70\text{-}200}$ > -5 dB, Figure 4.4), consistent with previous summer survey observations of small fishes dominating pelagic backscatter (De Robertis et al., 2017; Levine et al., in review). Thus, further analyses interpreted backscatter as a proxy for fishes (as described in the methods above.)

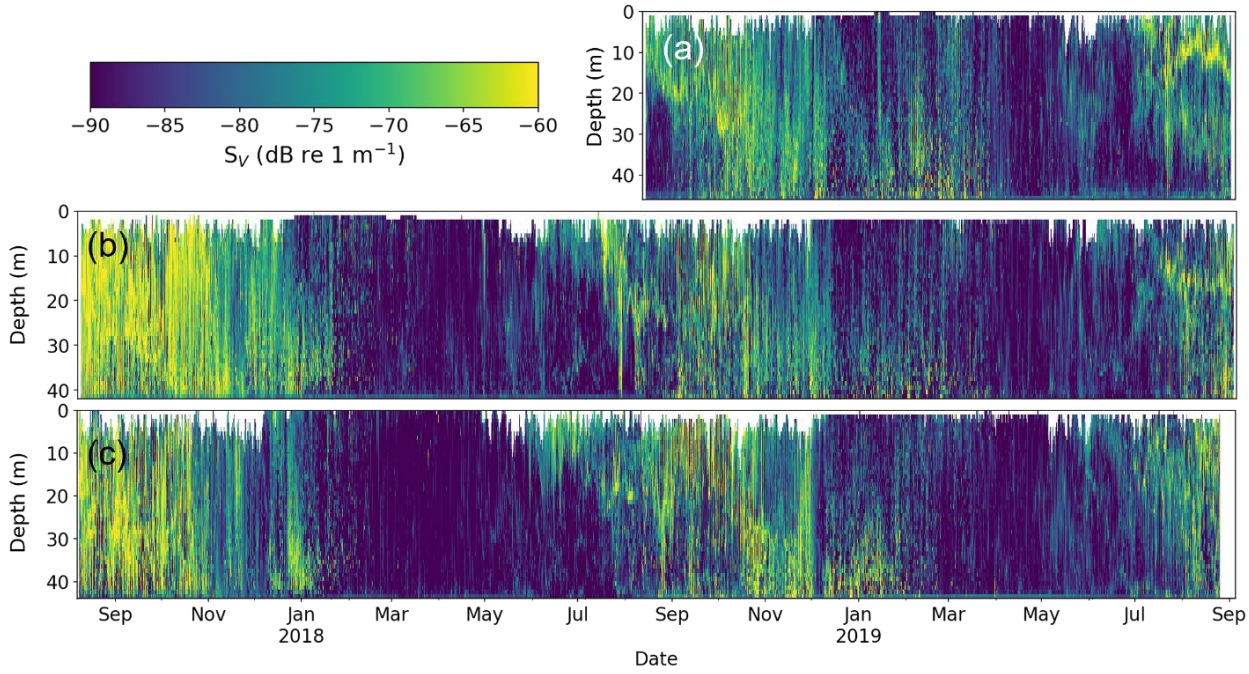

Figure 4.2 Echogram of 70 kHz mean volume backscattering strength (S_v, dB re 1 m^{-1}) recorded during each 2-h ensemble from 7 August 2017 to 06 September 2019 at the (a) northern, (b) central, and (c) southern mooring. Each point represents the mean of all observations in a 1 m depth bin of the water column recorded every 2 hours. White portions of the echogram indicate areas of no data due to the removal of backscatter from the sea surface and ice.

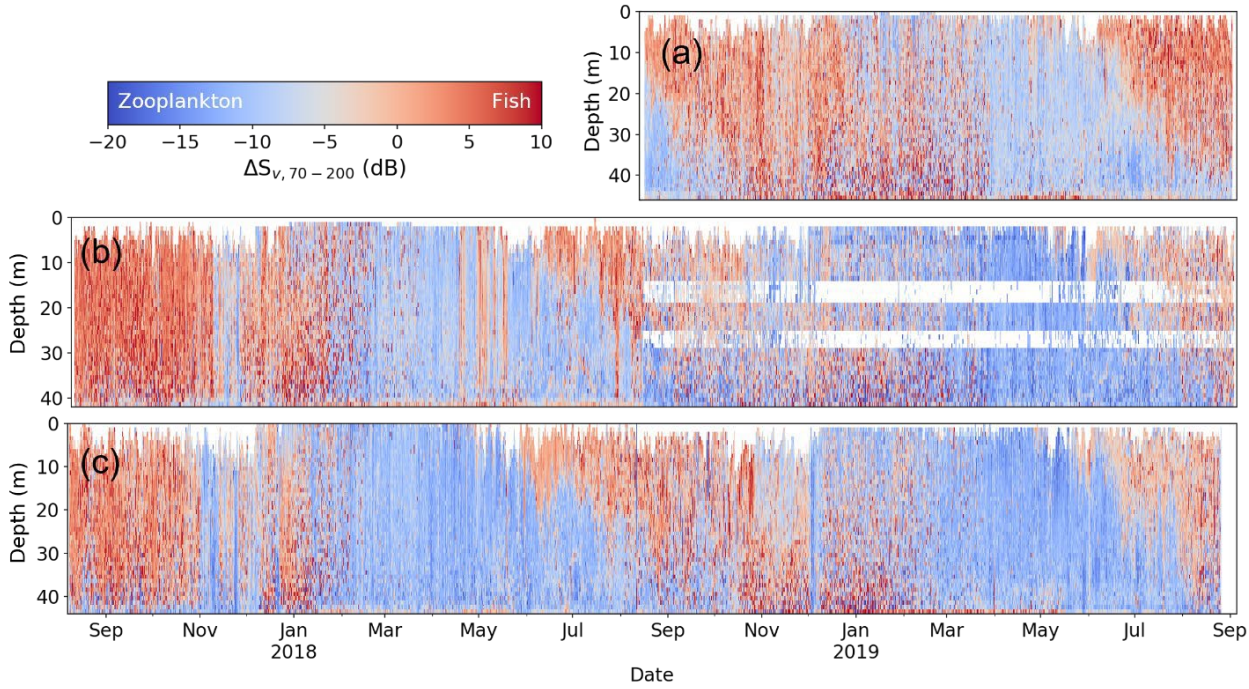

Figure 4.3 Echogram of difference between 70 kHz and 200 kHz volume backscatter ($\Delta S_{v,70\text{-}200}$, dB) for the complete time series at the (a) northern, (b) central, and (c) southern mooring. Red indicates bins where S_v is greater at 70 kHz (fish-like scatterers) and blue indicates bins where s_A is greater at 200 kHz (zooplankton-like scatterers). Each point represents the mean of all observations in a 1 m depth bin of the water column recorded every 2 hours. White portions of the echogram indicate areas of no data due to the removal of backscatter from the sea surface and ice. Due to interference between 16-20 and 27-30 m depth at 200 kHz at the central site during the 2018-2019 deployment, data where the signal was <10 dB higher than the noise level were removed.

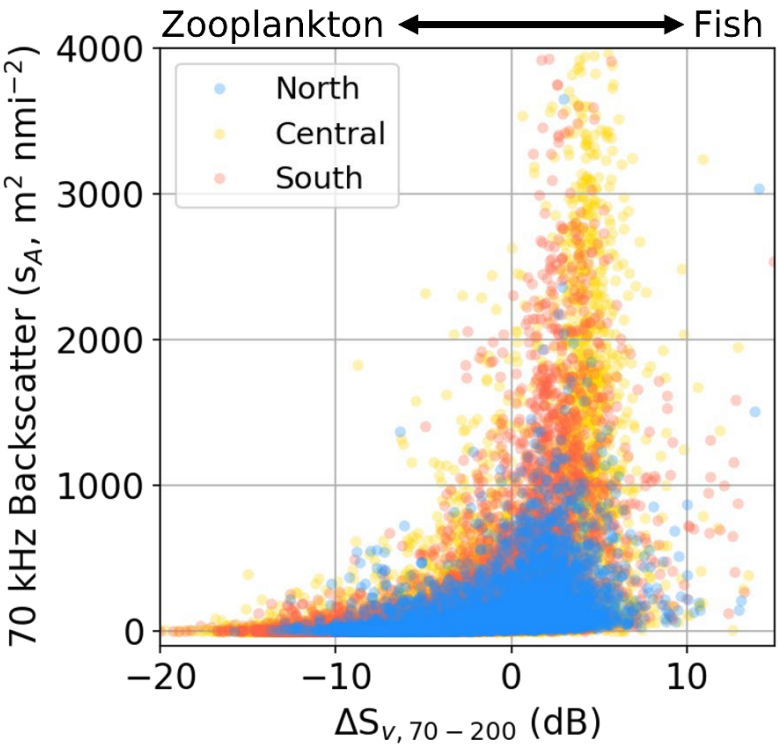

Figure 4.4 Daily mean 70 kHz backscatter (s_A, m^2 nmi^{-2}) as a function of the mean difference between 70 kHz and 200 kHz volume backscatter ($\Delta S_{v,70\text{-}200}$, dB) for each ensemble at the northern (blue), central (yellow), and southern (red) mooring sites. Higher values indicate the prevalence of fish-like scatterers.

Seasonal changes in fish size, abundance, and vertical distribution

Acoustic backscatter indicates that there was strong seasonality in the abundance, size, and vertical distribution of pelagic fishes at all three mooring sites (Figures 4.2, 4.5b, 4.6b, 4.7b). Fish abundance began to increase in July in both 2018 and 2019, peaking in fall. During this period, target strengths were high, consistent with the $\Delta S_{v,70\text{-}200}$ indicating the presence of fishes (Figures 4.5c, 4.6c, 4.7c). Target strengths in summer were consistent with previous observations of scattering from age-0 gadids (TS of ~-55 dB re 1 m^{-2} at 5 cm length, Geoffroy et al., 2016). Given the limited observations of target strengths consistent with large scatterers (e.g., TS ~-35 for a 35 cm adult pollock; Traynor, 1996), there was little evidence of a significant number of larger fishes throughout the deployments (Supplementary Figure 4.4a). Abundance was highest when bottom temperatures were greater than ~1 °C (Figure 4.8a) which was observed at all sites in late summer and fall (Figures 4.5a, 4.6a 4.7a).

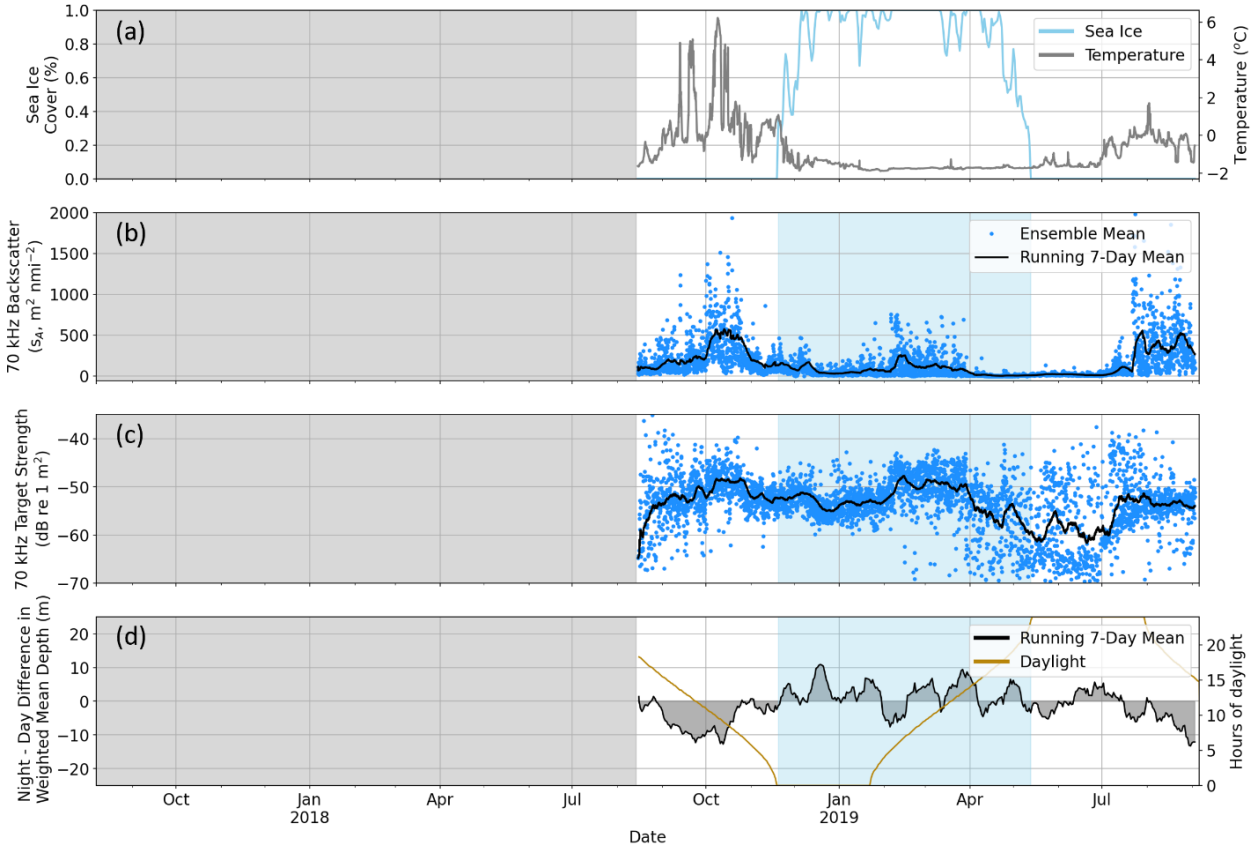

Figure 4.5 Time series of the northern mooring site. (a) Sea ice concentration of the nearest 25 km^2 grid cell of satellite observations (blue line) and bottom temperature recorded by the conductivity, temperature, and depth sensor mounted on the mooring platform (grey line). Mean of each 2-hour ensemble (blue points) and running 7-day mean (black line) of (b) water column 70 kHz backscatter (s_A) and (c) 70 kHz target strength. (d) Running 7-day mean difference in weighted mean depth of 70 kHz backscatter between minimum (night) and maximum (day) solar altitude. The gold line indicates the number of hours of daylight. Blue shading (panels b, c, and d) indicates periods when sea ice concentration was > 20%. Due to instrument failure, data are not available for the northern mooring site from the 2017-2018 deployment (grey region).

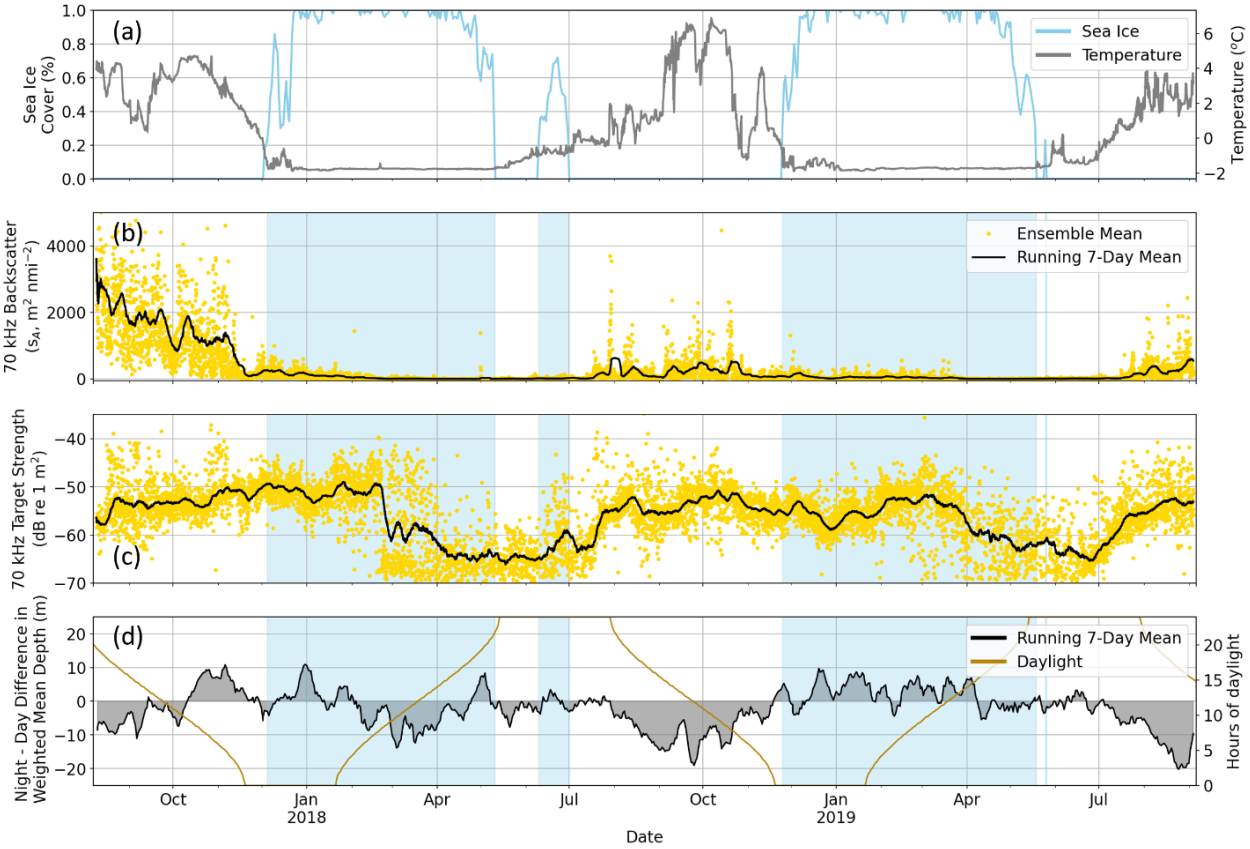

Figure 4.6 Time series of the central mooring site. (a) Sea ice concentration of the nearest 25 km^2 grid cell of satellite observations (blue line) and bottom temperature recorded by the conductivity, temperature, and depth sensor mounted on the mooring platform (grey line). Mean of each 2-hour ensemble (yellow points) and running 7-day mean (black line) of (b) water column 70 kHz backscatter (s_A) and (c) 70 kHz target strength. (d) Running 7-day mean difference in weighted mean depth of 70 kHz backscatter between minimum (night) and maximum (day) solar altitude. The gold line indicates the number of hours of daylight. Positive and negative values are shown in blue and red, respectively. Blue shading (panels b, c, and d) indicates periods when sea ice concentration was > 20%.

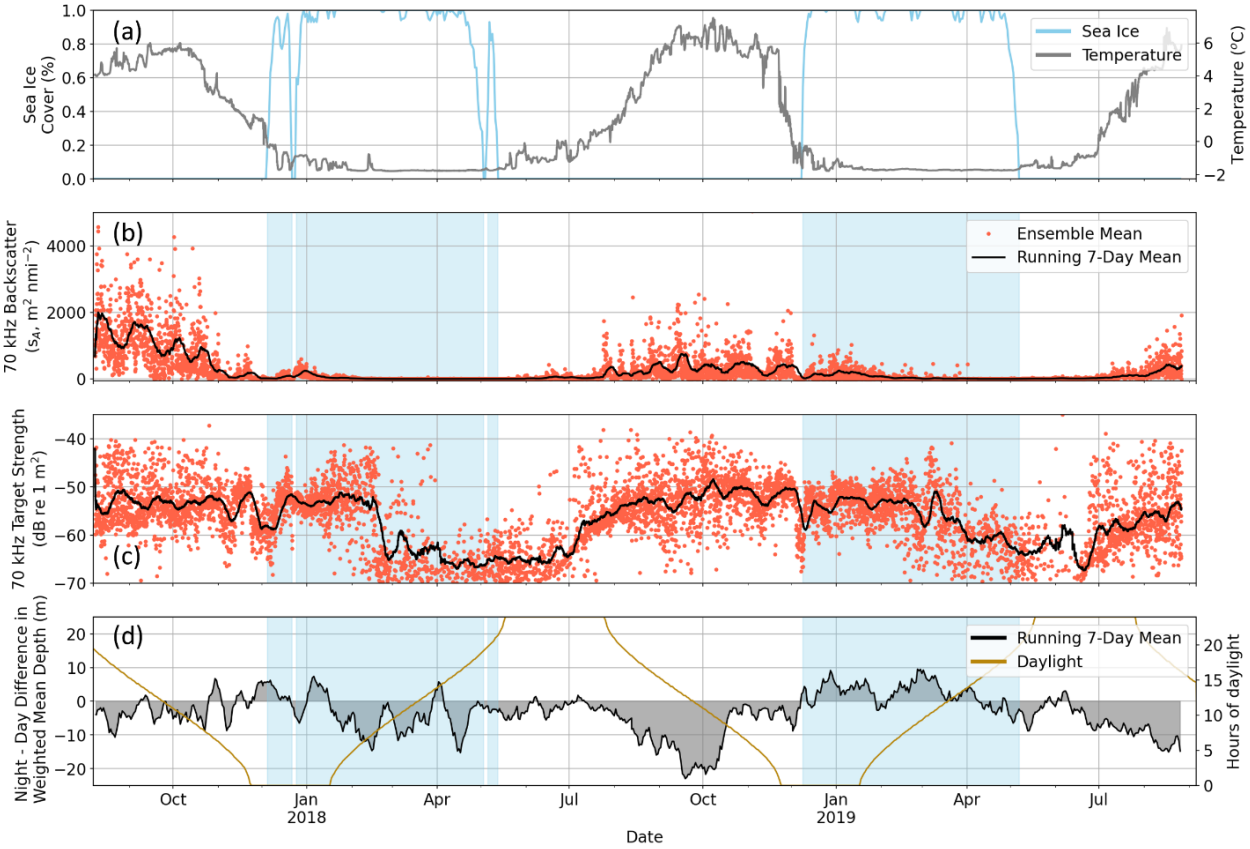

Figure 4.7 Time series of the southern mooring site. (a) Sea ice concentration of the nearest 25 km^2 grid cell of satellite observations (blue line) and bottom temperature recorded by the conductivity, temperature, and depth sensor mounted on the mooring platform (grey line). Mean of each 2-hour ensemble (red points) and running 7-day mean (black line) of (b) water column 70 kHz backscatter (s_A) and (c) 70 kHz target strength. (d) Running 7-day mean difference in weighted mean depth of 70 kHz backscatter between minimum (night) and maximum (day) solar altitude. The gold line indicates the number of hours of daylight. Positive and negative values are shown in blue and red, respectively. Blue shading (panels b, c, and d) indicates periods when sea ice concentration was > 20%.

Between August and October, night-day differences in weighted mean depth of fish increased (Figures 4.5d, 4.6d, 4.7d), with the greatest difference occurring during periods of 14-20 hours of daylight (Figure 4.9). Beginning in October, fish transitioned to be deeper during the day, showing less diel variability as day length shortened (Figures 4.5d, 4.6d, 4.7d, 4.9). As sea ice concentration over the moorings increased in November and December, fish abundance decreased. The onset of sea ice was associated with decreased fish abundance: mean backscatter was 2.8-7.5 times lower at all three mooring sites when sea ice concentration was > 20% (t-test on log-transformed 70 kHz s_A, $p<0.001$ at all sites, Figure 4.8b). However, target strengths remained consistent, indicating that fish of similar size were still present, though in reduced numbers (Figures 4.5, 4.6, 4.7).

In winter, the backscatter observations indicated that fish densities were very low at all three sites, with the lowest abundances occurring in late-winter and early spring. Target strength decreased substantially during this period, reflecting a transition in scatterer type, likely from small swim-bladdered gadids to a zooplankton-dominated pelagic community with lower target strengths (Figures 4.5c, 4.6c, 4.7c). The change in the frequency response also supports this inference. Unlike in summer, where $\Delta S_{v,70\text{-}200}$ was high, higher backscatter was observed at 200 kHz than 70 kHz throughout the water column from

approximately March to May of both years (lower values of $\Delta S_{v,70\text{-}200}$, blue regions Figure 4.3). Among the few periods where fish-like scatterers (> -60 TS) dominated the water column during early winter, vertical distribution remained deep throughout day and night with little evidence of migration (Figure 4.9).

Following the retreat of sea ice in May, bottom temperatures and fish abundance increased. Changes in the $\Delta S_{v,70\text{-}200}$ indicated a transition to fish-like scatterers in June and July beginning near the surface (Figure 4.3). Fishes appeared to grow during this period, as evidenced by increases in target strength (Figures 4.5c, 4.6c, 4.7c). As fish size increased, their night-day depth differences also increased (Figures 4.5d, 4.6d, 4.7d), consistent with the onset of vertical migration behavior. Day-night depth differences peaked in fall when the length of daylight and darkness are approximately equal (Figure 4.9).

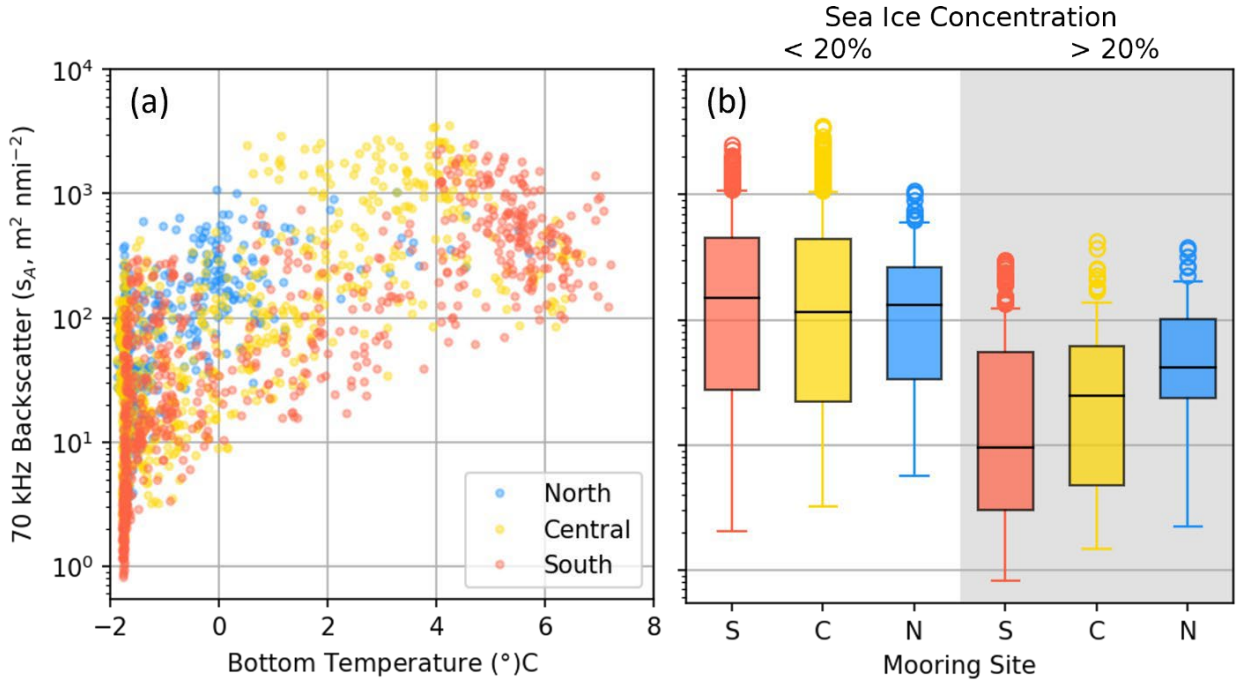

Figure 4.8 (a) Mean daily 70 kHz backscatter (s_A, m^2 nmi^{-2}) as a function of temperature at the northern (blue), central (yellow), and southern (red) mooring sites. (b) Distributions of mean daily 70 kHz backscatter when sea ice concentrations were < 20% (white background) and > 20% (grey background). Boxes indicate the interquartile range, horizontal black lines the median, vertical lines the 5% and 95% intervals. Circles indicate observations beyond the 5% and 95% intervals.

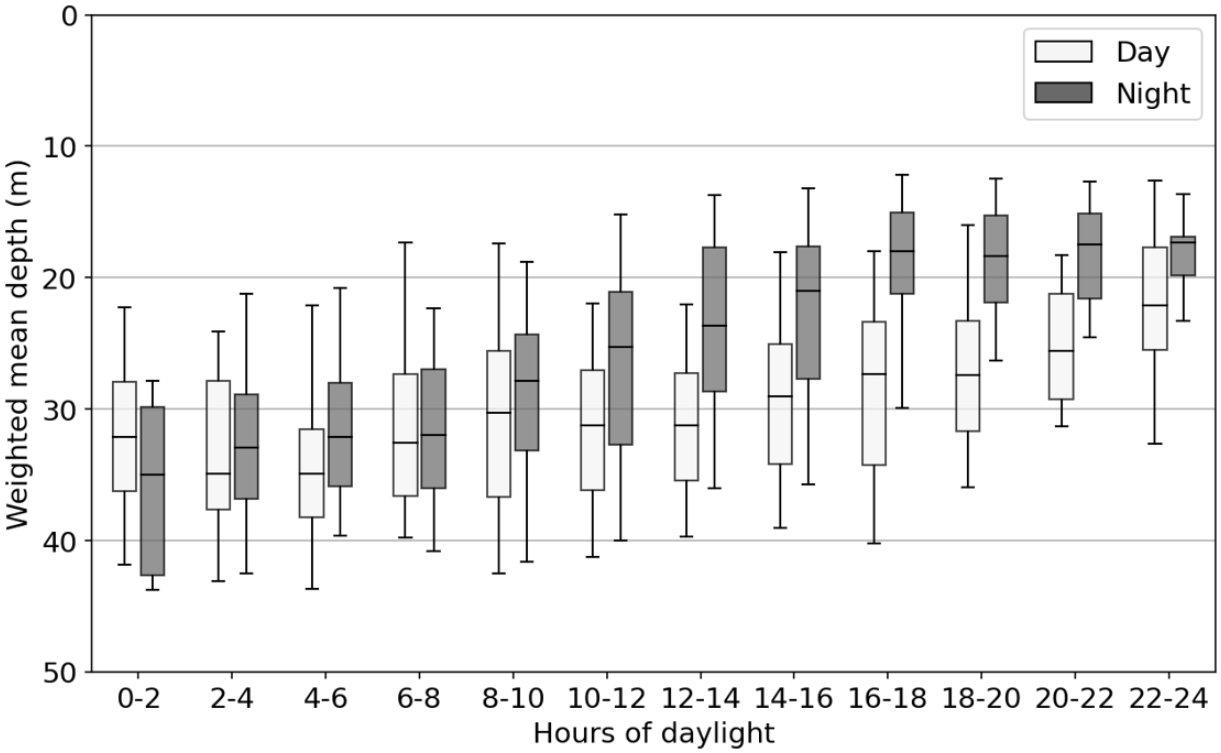

Figure 4.9 Night (minimum solar altitude, grey boxes) and day (maximum solar altitude, white boxes) distributions of weighted mean depth in 2-hour bins of length of daylight. Only ensembles where mean target strength indicate scattering was likely from fishes (TS > -60 dB re 1 m^{-2}) are included.

Drivers of fish movement

Fish tracks and ACDP measurements of currents indicate that fishes were moving largely as passively advected particles. After filtering, a total of 40317, 83024, and 63674 fish tracks were reconstructed from single target measurements at the northern, central, and southern moorings, respectively, during the two years of deployments. The mean track depth was 26.8 (±10.4 SD) m (Supplementary Figure 4.4b). Over the observation period, the majority of track headings were towards the northeast, with the mode of heading distributions (reference headings) for each mooring at 45° (southern), 75° (central), and 65° (northern). The daily mean track heading was correlated to current direction measured independently from the nearby ADCP (R^2=0.58, p<0.001, Figure 4.10a). Two modes were apparent in the current and fish headings corresponding to movement to the northeast and southwest (Figure 4.10a). The mean speed of all individual tracks was 23.4 (±13.5 SD) cm s^{-1}. Daily mean fish track velocities and current velocities calculated along the reference heading for each site were strongly correlated (R^2=0.81, p<0.001, Figure 4.10b), and the mean difference between fish track and current velocities was 0.2 cm s^{-1} (±12.6 cm s^{-1}). Mean track velocities along the reference heading were 8.2 cm s^{-1}, indicating net movement to the northeast.

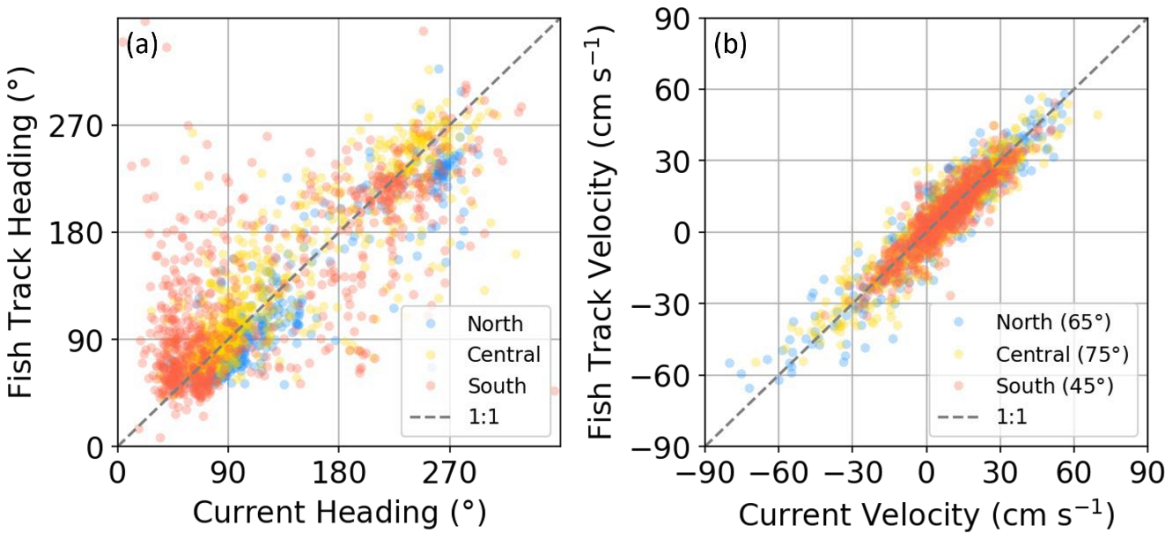

Figure 4.10 (a) Mean daily heading of currents measured from the acoustic doppler current profilers (ADCP) and fish tracks. (b) Mean daily current and fish track velocities along the reference heading (the mode of track headings [in 5° bins] for all tracks observed at each site) indicated in the legend for each site. The 1:1 line on each plot is shown as a reference (grey dashed line).

Table 4.1 Mean flux (Fish m^{-1} s^{-1}) and total cumulative flux over the course of each deployment (Fish m^{-1}) calculated along the reference heading for each mooring.

Deployment	Site	Reference Heading	Mean Flux (Fish m^{-1} s^{-1})	Cumulative Flux (Fish m^{-1})
2017 - 2018	Southern	45°	0.07	1.8×10^6
	Central	80°	0.23	6.8×10^6
2018 - 2019	Southern	45°	0.08	2.8×10^6
	Central	80°	0.09	3.0×10^6
	Northern	75°	0.13	4.4×10^6

The flux of fishes was primarily to the northeast at all three sites (Figure 4.11, Table 4.1). Mean flux was highest at the central site in 2017-2018 and the northern site in 2018-2019, with the lowest estimates of flux at the southern site in both years (Table 4.1). Fluxes were highest during the summer and fall when fish were abundant. The highest mean flux over a 7-day period, 2.6 fish m^{-1} s^{-1}, was observed in September 2017 at the central mooring site (Figure 4.11b). This corresponds with the highest fish abundances observed throughout the deployments (Figure 4.6b). The magnitude of the flux was primarily driven by the abundance (Supplementary Figure 4.5); fluxes were lowest during the ice-covered period when fish were scarce (Figure 4.11). Although current velocities to the northeast were also slower when ice was present at the northern (t-test, $p<0.05$) and central sites ($p<0.1$), velocities did not vary significantly at the southern site ($p=0.8$).

Short episodes of fish movement to the southwest occurred throughout the year (blue bars, Figure 4.11). However, cumulative fluxes indicate net movement of fishes was consistently to the northeast (Table 4.1). These reversals in flux were associated with shifts in wind speed and direction (Figures 4.12, 4.13). Daily mean estimated northward wind speeds during the deployment period ranged from -13.5 to 19.9 m s^{-1} (mean of 0.04 m s^{-1} ±5.5 SD). When wind speeds to the north were high, fish primarily moved to the northeast/east (Figure 4.12). Fish headings became more variable as northward winds weakened, and transitioned to the southwest when winds were strong towards the south (Figure 4.12).

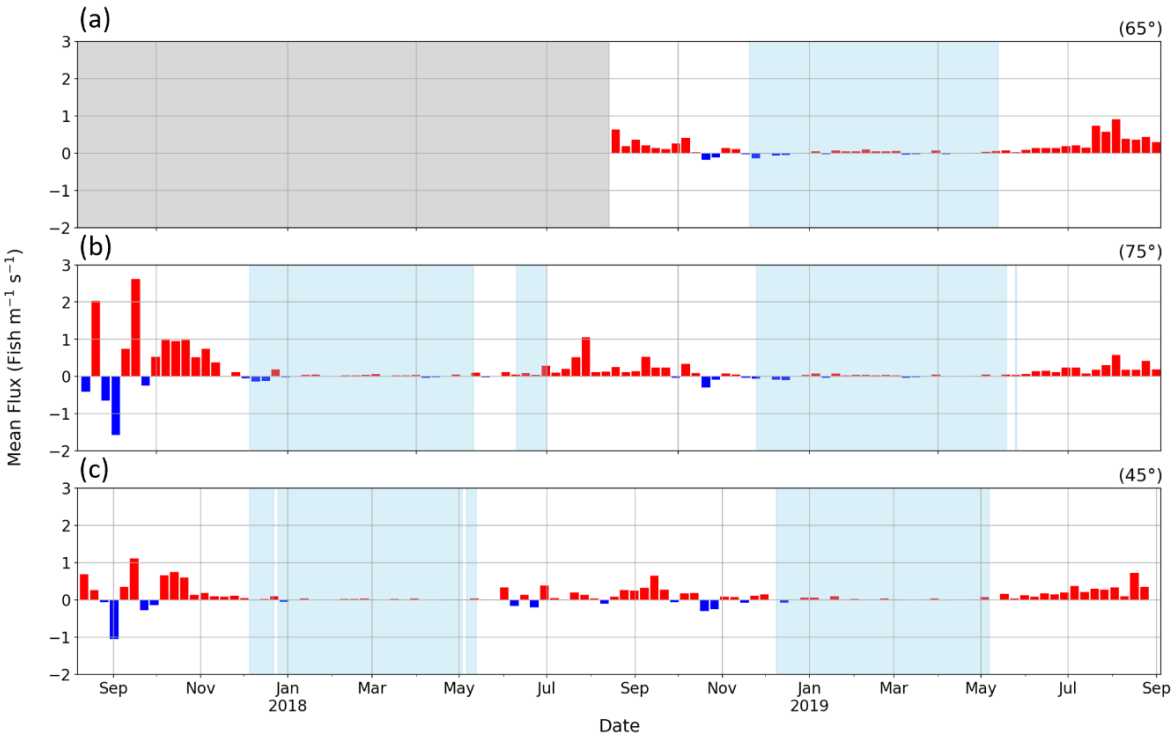

Figure 4.11 Mean flux of fishes (fish m^{-1} s^{-1}) at the (a) northern, (b) central, (d) and southern mooring sites. Each bar represents the mean flux during a single week of deployment. Values represent the number of fish passing through a 1-m line perpendicular to the reference heading (the mode of track headings [in 5° bins] for all tracks observed at each site) indicated in the top right of each panel. Positive (within 90° of the refence heading) and negative (within 90° of 180° from the refence heading) values are shown in red and blue, respectively.

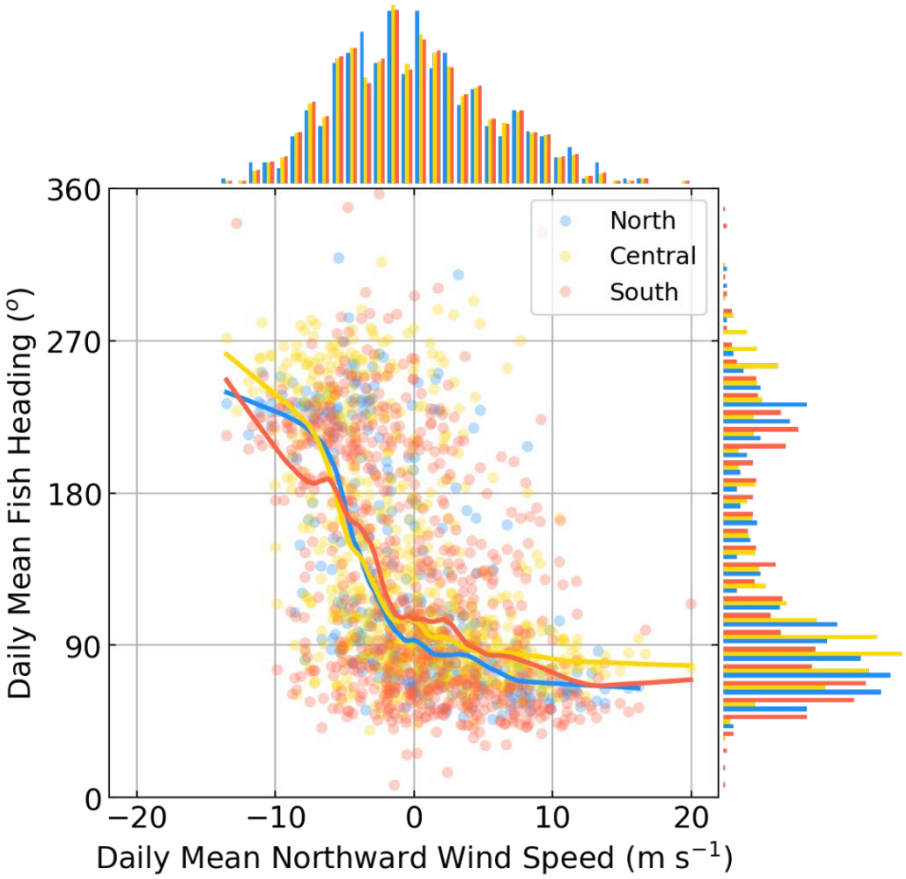

Figure 4.12 Daily mean fish heading as a function of mean northward wind speed at the northern (blue), central (yellow), and southern (red) mooring site. Histograms represent the distribution of wind speeds (top) and fish headings (right) for both years of deployments at each moorings site. The solid lines represent a locally estimated scatterplot smoothing curve (Cleveland, 1979) of the daily means for each mooring to indicate the trend.

Discussion

Seasonality of fishes

The mooring observations provide further evidence of strong seasonality in the composition of the pelagic community on the Chukchi shelf. Large numbers of age-0 gadids have been observed in summer (De Robertis et al., 2017; Levine et al., in review). However, few age-1+ individuals appeared to be present, indicating that either mortality in this region is high or that these fish emigrate to other regions. Using two years of year-round observations from moored echosounders in the northeastern Chukchi Sea, we found that these fishes appear in the region in late summer and disappear in early winter. Using tracking, we found that fish movement correlated with local currents, and estimates of flux indicate that the majority of the age-0 population in summer is likely transported to the north and east off towards the Beaufort Sea and Arctic Basin each fall and winter. These findings support the predictions of passive particle tracking simulations which predict the displacement of the summer age-0 population to the northeast off the Chukchi shelf in fall (Levine et al., 2021).

The presence of fish appears to be strongly associated with seasonal warm waters entering the region. Temperature is a key driver of both Arctic cod and pollock distribution (Sigler et al., 2017; Eisner et al.,

2020; Baker, 2021; Levine et al., in review) and growth (Laurel et al., 2018). The northward transport of warm Bering Sea water in spring and summer into the northeastern Chukchi Sea (Danielson et al., 2017) has been associated with increases in abundance of zooplankton (Eisner et al., 2013; Ashjian et al., 2017; Spear et al., 2020) and fishes (Logerwell et al. 2020; Levine et al., in review). Increases in abundance of fishes in the northeastern Chukchi Sea in summer appear to coincide with the arrival of southern-origin water masses. These flow north into the Chukchi Sea from the Bering Sea shelf (Coachman et al. 1975; Danielson et al. 2017), replacing the colder winter water on the Chukchi shelf (Weingartner et al. 2013). The age-0 gadids observed in the northeastern Chukchi in summer are primarily associated with the warmer (2-8 °C) conditions of these seasonal water masses (De Robertis et al., 2017; Marsh et al., 2019; Levine et al., in review). The observations in this study further indicate that the seasonality of age-0 gadids in the northeastern Chukchi Sea is driven by the advective movement of the fish population within this warm water.

Abundance was much higher in the summer and fall of 2017 than in the following two years at the central and southern sites. This high interannual variability is consistent with survey observations of substantially higher age-0 gadid abundances in 2017 than 2019 (Levine et al., in review). Levine et al., (in review) hypothesized that this increase in gadids was attributed to anomalously warm conditions in spring, resulting in earlier hatch and favorable growth conditions that led to increased length-at-age and thus increased age-0 fish survival. The lower backscatter in both subsequent years is consistent with surveys conducted in 2018 (Levine et al., 2021) and 2019 (Levine et al., in review) which observed similar backscatter during the late summer and fall.

While it was not possible to directly assess the size of fishes, the moorings confirm previous observations that the pelagic community in summer is dominated by small fishes. Mean target strengths during periods dominated by fish-like scattering were consistent with the target strength expected from small (<6 cm) age-0 fishes (Traynor, 1996; Geoffroy et al., 2016; Levine et al., 2021). However, while these reported target strength-length relationships for age-0 gadids are based on ship-based (ventral) observations at 38 kHz (Traynor 1996; Geoffroy et al., 2016), our inferred length from mooring observations are ventral measurements collected at 70 kHz. While target strength of individuals is orientation- and frequency-dependent (Foote 1980; Francis and Foote 2003), the difference in volume backscattering strength at 38 kHz and 70 kHz is small for walleye pollock (De Robertis et al., 2010); we therefore applied the target strength-length relationships estimated at 38 kHz to our observations at 70 kHz with the expectation that the associated error as a result of frequency was minimal. The impact of the use of ventral observations from the moorings is also likely to be low. Most of the variability in target strength of an individual as a result of behavior is due to the change in tilt angle (Horne, 2003) and model predictions estimate that the variability between dorsal and ventral measurements of the same orientation is low (Francis and Foote 2003). Even with these potential sources of variability in the target- strength-length relationship, the scarce observations of high (>-35 dB re 1 m^{-2}) target strengths (Supplementary Figure 4.4a) indicate that larger fishes such as adult pollock were likely not present in significant abundance.

The increase in target strength from July to October, along with the increase in diel vertical migration indicated by increasing difference between day and night weighted mean depth, is evidence of growth in the age-0 population during the late summer (July - October) as observed in summer surveys (Deary et al., 2021; Levine et al., 2021). Arctic cod and pollock are typically surface-associated as eggs and larvae (Spencer et al., 2020). As they increase in size and swimming ability, juveniles begin to move deeper into the water column during the day, a behavioral shift typically occurring at a length of ~ 30 mm in both species (Brodeur et al., 2000; Ponomorenko 2000). The increase in night-day depth difference beginning in July of each year at all three sites is consistent with the onset of diel vertical migration (DVM). The signal of increased diel vertical migration with increasing daylight hours was likely driven primarily by strengthening DVM behaviors, occurring in late summer as the day length is being reduced. We found little evidence of diel vertical migration occurring during polar night and the adjacent periods of minimal daylight, though young Arctic cod have been observed to undergo migration during polar winter in

response to small changes in twilight (Benoit et al., 2010). Thus, the lack of vertical migration observed in winter is consistent with our other observations suggesting that age-0 fishes are virtually absent during March to June.

Fate of age-0 gadids

Advection appears to be the primary mechanism of movement in fishes on the northeastern Chukchi shelf. Fish headings and velocities were consistent with those of the currents, with little evidence of significant horizontal displacement as a result of swimming or other behavior. While age-0 gadids are capable of fast swimming speeds (aerobic threshold of 2-3 body lengths s^{-1}, Hurst, 2007; Kunz et al., 2018), routine speeds are much slower (0.25 – 1 body lengths s^{-1}, Rose et al., 1995; Hurst, 2007). In the fast current velocities observed on the Chukchi shelf, routine swimming behavior is likely to have minimal impact on fish displacement relative to advection. These in situ observations support the assumptions inherent to modelling studies using passive drift to determine horizontal distributions of age-0 gadids in summer (Deary et al., 2021; Vestfals et al., 2021). This work is further evidence that future studies can use direct observations (e.g., ADCPs) or model predictions of regional transport to assess historic and future trends in the source and fate of this age-0 population observed in summer.

We found substantial variability in the flux of age-0 fishes across seasons and between mooring locations. The magnitude of flux was primarily driven by seasonal changes in abundance. However, the variability among sites was likely due to variability in local currents. During 2018-2019, the mean flux was highest at the northern site, although fish abundance was lower than the other sites. Current velocities are typically faster at this mooring site than the central and southern sites (Weingartner et al., 2005; Woodgate et al., 2005; Stabeno et al., 2018), particularly in summer (Stabeno et al., 2018) when we observed the highest fish abundances. Although fish density was comparable between the southern and central sites, (Figures 4.6, 4.7), fluxes were lowest in both years at the southern site. This variability in flux is likely due to the relatively slower velocities typically observed in this portion of the shelf compared to velocities closer in proximity to Barrow Canyon (Stabeno et al., 2018).

The flux of fishes to the northeast provides evidence that the age-0 fishes present in summer are transported out of the ecosystem. This is consistent with particle tracking simulations based on modeled regional advection which predicted that fishes observed in the central portion of the eastern shelf in summer would be transported beyond the shelf break in fall (Levine et al., 2021). If the northern site is representative of the surrounding area of the shelf, we hypothesize that the flux at the northern mooring site may account for a significant portion of the export of age-0 fishes off the shelf. Using the estimate of 4.4×10^6 fish m^{-1} (Table 4.1) observed at the northern mooring site, flux would need to be consistent across <50 km of the eastern Chukchi shelf in order to represent the export of the approximately 1.5×10^{11} fishes reported in the 2019 survey (Levine et al., in review). The ability to extrapolate mooring observations over a wider area is a function of the behavior of the species being observed relative to their environment. When abundances are high, fishes on the Chukchi shelf are relatively evenly distributed over large portions of the shelf (De Robertis et al., 2017; Levine et al., in review), and when moving in a relatively uniform distribution (i.e., large-scale scattering layers rather than discrete schools) moorings are likely to represent abundance over a much broader spatial area than the small area directly observed in the acoustic beam (Brierly et al., 2006; De Robertis et al., 2018). Abundance and distribution of fishes can also be depth-dependent and vary as a function of local topography due to changes in either behavior or advection, therefore extrapolation of mooring observations may only apply within appropriate depth ranges (De Robertis et al., 2018). However, the eastern Chukchi shelf has a relatively consistent depth, thus the moorings may be representative of a larger area.

Age-1+ Arctic cod have been found in low abundance during demersal surveys of the Chukchi shelf in summer (Norcross et al., 2013; Goddard et a., 2014; Logerwell et al., 2017). While the demersal abundances of Arctic cod are significantly lower than pelagic estimates (De Robertis et al., 2017), the presence of these age-1+ fish along the seafloor indicates that Arctic cod likely transition to be more

demersal as they age. Following this transition, these fish would likely not be observable in our mooring data and are inaccessible to pelagic trawls. More work is needed to identify the potential shift of this pelagic age-0 population to demersal habitat on the Chukchi shelf to assess how much of the population remains on the shelf year-round.

Thus, the low densities of age-1+ gadids in the region are likely the result of this continued northward transport of the age-0 population observed in summer. The very low densities of age-1+ gadids in during summer surveys (De Robertis et al., 2017; Levine et al., in review) suggests that the age-0 fishes found in the eastern Chukchi Sea likely originated in other areas. Previous studies using models have hypothesized that the distribution of age-0 fishes observed in summer and fall reflects the northward advection of fishes from southern spawning areas (Deary et al., 2021., Vestfals et al., 2021). Our observations are consistent with these hypotheses: While our study did not observe spawning location, we infer from the strong correlation between fish displacement and currents that age-0 gadids in the Chukchi during summer are likely of southern origin. Larger fish, however, are likely not allowing themselves to be passively transported with their drifting eggs and are more likely to maintain their position in their preferred habitat. Age-1+ fishes have also likely developed the swimming ability required to return to spawning grounds. While we did not identify any high target strength fishes migrating south indicating the return of large fishes to spawning grounds in our observations, some portion of the age-0 population is likely returning as mature adults in order to maintain the spawning population (Forster et al., 2020).

The potential of the age-0 fishes we observed in the Chukchi to survive over winter after being advected into the Arctic remains unclear. Growth and lipid accumulation are temperature-dependent in age-0 gadids (Laurel et al., 2018; Koenker et al., 2018). Based on their body condition, age-0 pollock captured during recent surveys of the Chukchi Sea in summer are unlikely to survive overwinter under Arctic conditions (Copeman, pers. comm.). Thus, while the flux of fishes supports the hypothesis of emigration of the population to other areas as they age, quantifying the mortality of these age-0 pollock in their new environment is still required to address the long-term survival of the population and the ability of boreal species observed seasonally on the shelf to establish permanent populations in the region. However, Arctic cod are widely present throughout the Arctic basin and are capable of surviving Arctic winter conditions. Large aggregations of age-1+ Arctic cod have been observed at depth in Barrow Canyon (De Robertis et al., 2017) and the Beaufort Sea shelf break (Parker-Stetter et al., 2011; Rand and Logerwell, 2011), and genetic studies have not identified any significant population stratification between Arctic cod observed on the Chukchi shelf and those in the western Beaufort Sea (Wilson et al., 2019; Nelson et al., 2020). These populations may recruit from the age-0 Arctic cod being transported off of the Chukchi shelf, though further work is necessary to identify if the western Beaufort is the wintering grounds for the majority of these age-0 fish.

Influence of regional winds

The direction of fish movements appears to be driven primarily by changes in wind speed and direction. On the Chukchi shelf, advective transport that moves water of Bering Sea origin north is driven by the pressure head created by differences in sea surface height between the Pacific and Arctic Oceans (Woodgate et al., 2005; Danielson et al., 2014). This northward flow is restrained by mean winds to the southwest (Pisareva et al., 2019) and variations in the current are primarily wind-driven (Weingartner et al., 2005). Increases in winds to the southwest can slow this northward flow and when strong enough, lead to episodic flow reversals (Woodgate et al., 2005; Stabeno et al., 2018; Pisareva et al., 2019). Conversely, during periods of strong winds to the northeast, the northward flow across the shelf increases. Particle tracking simulations have suggested that this variability in wind and the resulting shift in currents is a major source of interannual variability observed in late-summer distribution of age-0 fishes in the Chukchi Sea (Levine et al., 2021; Vestfals et al. 2021).

We observed two modes in fish displacement, which varied with changes in wind speed on the northeastern shelf. During periods of strong northward wind, current and fish speeds increased, and the

movement of both currents and fish was to the north/east (yellow box, Figure 4.13). When winds were strongly to the south, a reversal was seen in both the currents and fish tracks, with a higher proportion of fish moving to the south/west (purple box, Figure 4.13). During periods of weak and variable winds, fish tracks remained towards the north/east (Figures 4.12, 4.13), consistent with the expected flow on the northeastern shelf (Stabeno et al., 2018). These wind-driven modes of water movement in the northeastern Chukchi have previously been documented and a threshold of 6 m s^{-1} winds towards the southwest (Fang et al., 2017) has been reported as the requirement for transition between states. Our results suggest adjustments to make currents better proxies for fish movements.

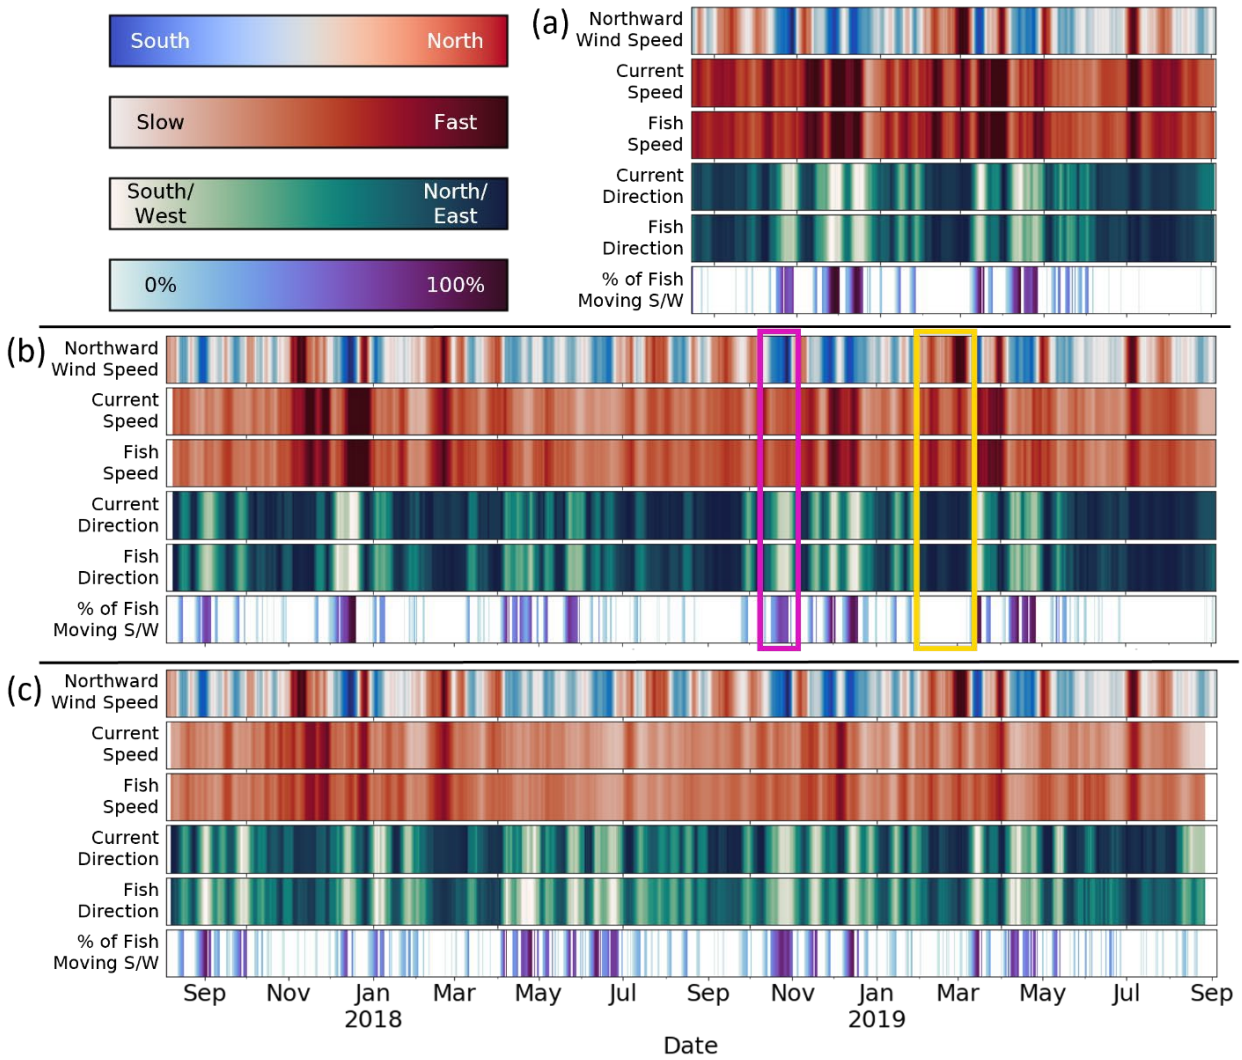

Figure 4.13 Heatmaps of 7-day rolling means of north-south winds, current and fish speeds, and current and fish directions at the (a) northern, (b) central, and (c) southern mooring sites. Within each panel, the top heatmap indicates the northward (meridional component) wind speed, where red indicates strong northward winds and blue indicates strong southward winds. The second and third heatmaps indicate the speed of both the current and fishes, where darker colors indicate faster speeds. The fourth and fifth heatmaps indicate the direction of the current and fishes, where darker colors indicate coherence with the reference heading (towards the northeast, see methods, Figure 4.9). The bottom heatmap shows the % of

fish tracks moving opposed to the reference heading (to the southwest). As examples, the purple box and yellow box highlight a period of strong southward and northward winds, respectively (see results).

Northward winds are expected to increase with future changes in climate. In recent years, the frequency of northward wind events in the region has increased, (Stabeno and Bell 2019). As the region continues to warm, the input of water through the Bering Strait is also predicted to increase (Woodgate, 2018; Danielson et al., 2020), which would increase northward transport across the Chukchi shelf. Transport has already been increasing over recent decades, considerably reducing the amount of time needed to flush and renew the water on the Chukchi shelf (Woodgate et al., 2018). Based on the mean fish track velocity of 8.2 cm s^{-1}, the residence time of fish on the Chukchi shelf is ~85 days (based on ~600 km of transit from Bering Strait to Barrow Canyon). This study occurred during a period of high transport relative to previous decades (Woodgate and Peralta-Ferriz, 2021; Levine et al., in review). This enhanced transport may be more nearly the norm in future decades, and future changes in transport are likely to further decrease the residence time of age-0 gadids on the Chukchi shelf.

Conclusions

The composition of the pelagic community on the Chukchi shelf is highly seasonal. This study provides further evidence that the age-0 gadids observed on the Chukchi shelf in summer are likely temporary residents of the region. Their distribution and movement across the shelf are primarily driven by advection, providing further evidence that these fish are likely originating from the south. However, transport in the region is changing, with potential consequences for the future of this ecosystem and the structure of the summer pelagic community. Enhanced transport from the south is hypothesized to be driving the recent increased presence of boreal species such as pollock in the eastern Chukchi Sea (Levine et al., in review). While these southern-origin species likely cannot survive overwinter in Arctic conditions (Koenker et al., 2018), their increased presence during summer may increase competition with and predation on endemic species, further altering the structure of the summer community. The role of advection in structuring this seasonal population allow us to use observations and predictions of the physical environment to understand how this ecosystem will be structured under future change.

Acknowledgements

This research was conducted under the Arctic Integrated Ecosystem Research Program

(http://www.nprb.org/arctic-program). Funding for the program was provided by North Pacific Research Board, the Bureau of Ocean Energy Management, the Collaborative Alaskan Arctic Studies Program, and the Office of Naval Research. In-kind support was contributed by the National Oceanic and Atmospheric Administration's (NOAA) Alaska Fisheries Science Center and Pacific Marine Environmental Laboratory, the University of Alaska Fairbanks, the U.S. Fish & Wildlife Service, and the National Science Foundation. We would like to thank Ivar Wagnen, Lars Andersen, and Roger Kasinger for their work on the echosounders and assistance with instrument testing and deployment configurations. We would also like to thank Christian Meinig and Steven Anderson for their work in the design and construction of the mooring platform, and Matthew Casari for development of the underwater compasses. The mooring deployments and recoveries would not have been possible without the captains, crews, and science parties of the RV *Ocean Starr* and USCGC *Healy*.

Autonomous vehicle surveys indicate that flow reversals retain juvenile fishes in a highly advective high-latitude ecosystem. Limnol. Oceanogr. 9999, 2020, 1–16. doi: 10.1002/lno.11671

Abstract

Summer surveys of the Chukchi Sea indicate that high densities of age-0 gadid fishes, historically Arctic cod (*Boreogadus saida*) but recently also walleye pollock (*Gadus chalcogrammus*), dominate the pelagic fish community. Adults are comparatively scarce, suggesting that either overwinter survivorship of age-0 gadids is low, or that they emigrate to other areas of the Pacific Arctic. To examine population movement, we conducted repeat acoustic surveys with saildrone autonomous surface vehicles equipped with echosounders throughout summer 2018. The saildrones' range and endurance enabled two large-scale surveys of the U.S. Chukchi shelf. Acoustic backscatter, a proxy for fish density, was highest in regions with sea surface temperatures of 6–8 C, and lowest in areas influenced by recent ice melt. A subarea of the central Chukchi was surveyed a total of four times; backscatter in this subarea increased by > 85% from late-July to mid-September. As summer progressed, fish developed more extensive diel vertical migrations and backscatter from individuals doubled. Both changes suggest increases in backscatter were driven primarily by increasing body size. Particle tracking simulations indicated age-0 gadids were likely retained over the Chukchi shelf by extended periods of wind-driven southward flow during the survey period before strong northward flow in late fall transported them to the north. These findings suggest that in summer 2018, age-0 gadids were advected northward to the Chukchi shelf from the northern Bering Sea, where they were retained during a period of growth until late fall before being advected farther north toward the Chukchi and Beaufort shelf breaks.

Introduction

Arctic gadids, particularly Arctic cod (*Boreogadus saida*), dominate the pelagic fish community in the Pacific Arctic eco- system of the northern Bering, Chukchi, East Siberian, and Beaufort Seas. Arctic cod have a circumarctic distribution and are abundant throughout the shallow shelves of the Arctic marginal seas as well as the Central Arctic Basin (Mecklenburg et al. 2018). Arctic cod are key pelagic secondary consumers that serve as a central trophic link between plankton and higher trophic levels (Bradstreet et al. 1986; Whitehouse and Aydin 2016), supporting large migratory populations of sea- birds (Matley et al. 2012) and marine mammals (Bradstreet et al. 1986). The Pacific Arctic is undergoing rapid changes associated with surface warming and loss of sea ice (Steele et al. 2008; Frey et al. 2015; Woodgate 2018). These changes have the potential to negatively impact Arctic cod growth and survival in this region and alter species distributions.

Recent studies suggest that the warming conditions in the Pacific Arctic are becoming increasingly hospitable for more boreal species such as walleye pollock (*Gadus chalcogrammus*) (Laurel et al. 2016; Huntington et al. 2020). Historically, trawl surveys conducted in the Chukchi Sea have found that pelagic biomass is dominated by age-0 (born within the past year) Arctic cod (Quast 1974; Norcross et al. 2010; Logerwell et al. 2015). Acoustic-trawl surveys conducted in 2017 and 2019 indicate that age-0 walleye pollock have become more abundant on the Chukchi shelf (R. M. Levine unpubl.). As the region changes

due to increasing temperatures, walleye pollock distributions may expand to the north and become a potentially significant component of the gadid community on the Chukchi shelf.

Little is known about the distribution and movements of pelagic fish populations in the region, particularly in the Chukchi Sea. Acoustic-trawl surveys conducted in summer 2012 and 2013 established a baseline of distributions of pelagic fishes in the U.S. northern Bering and Chukchi Seas (De Robertis et al. 2017). These surveys documented large numbers of pelagic age-0 Arctic cod, with the highest abundances in the northern Chukchi Sea where the average length was 3.5 cm and < 0.3% were greater than 6.5 cm (De Robertis et al. 2017). However, this and other surveys in the area indicate that older Arctic cod are comparatively rare on the U.S. Chukchi shelf (Logerwell et al. 2015; De Robertis et al. 2017).

Estimates of the reproductive potential of the Arctic cod population in the survey region indicate that observed densities of adults are likely insufficient to produce the large numbers of age-0 fish observed in the acoustic-trawl surveys (Marsh et al. 2019). It is likely that age-0 Arctic cod observed on the Chukchi shelf in summer are produced by adults that seasonally migrate into the region to spawn, or from eggs and larvae spawned in other areas and subsequently transported into the region. Large-scale horizontal migration of Arctic cod to spawning aggregation sites has been observed in the Barents Sea (Gjøsæter 1995) and Russian Arctic (Ponomarenko 1968). Recent work has hypothesized that a similar pattern of seasonal migration may occur in the Pacific Arctic (Forster et al. 2020). Similarly, walleye pollock have recently become more abundant in the northern Bering Sea (Stevenson and Lauth 2019), and this may have increased the supply of walleye pollock larvae that enter the Chukchi Sea from the south in recent years. The low densities of age-1+ relative to age-0 gadids found on the Chukchi shelf indicate that either overwinter survival of age-0s retained in the area is very low, or that the Chukchi shelf serves only as a summer nursery area, after which age-0s subsequently emigrate or are transported to other areas (De Robertis et al. 2017).

The likelihood of these scenarios is partially constrained by local advective regimes. The Chukchi Sea is a region of seasonally high advection, with strong northward currents that may transport eggs and larvae from the south (Fig. 1). High north- ward transport across the shelf occurs during the summer and fall (Woodgate et al. 2005; Stabeno et al. 2018), yielding residence times of Pacific Waters in the Chukchi of 4–5 months, although this residence time has likely decreased in recent years (Woodgate et al. 2005; Woodgate 2018). This movement of Pacific water toward the Arctic structures the species com- position and distribution of plankton communities in the Chukchi Sea, with many species being transported into the Chukchi Sea from the Bering Sea (Eisner et al. 2013; Ershova et al. 2015; Sigler et al. 2017). Interannual variability in phytoplankton, zooplankton and ichthyoplankton communities is strongly influenced by changes in oceanographic forcing, as indicated by associations between water masses of southern origin and community composition (Norcross et al. 2010; Danielson et al. 2017; Pinchuk and Eisner 2017; Spear et al. 2019).

The reproductive biology of Arctic cod and walleye pollock in the context of the advective regime provides additional clues to the origins of fish observed on the Chukchi shelf. Arctic cod are known to spawn in fall and winter under sea ice on the shallow shelves of the Arctic marginal seas (Ponomarenko 2000). Fertilized eggs are buoyant and develop under ice cover at the ice–water interface (Ponomarenko 2000). Pollock similarly produce pelagic eggs and, as larvae, remain close to the surface (Spencer et al. 2020). Development time in both species is temperature dependent, with time to 50% hatching of Arctic cod in laboratory studies ranging from 31 d at 3.8 C to 67 d at −0.4 C and approximately half of that time across these temperatures for walleye pollock (Laurel et al. 2018). Arctic cod hatching has been observed from December through August, with a peak during May/June (Bouchard and Fortier 2011). Ichthyoplankton surveys and otolith aging of larval and juvenile Arctic cod in other regions of the Arctic indicates that spawning occurs over a period of months, producing an extended distribution of larval fish

throughout the summer rather than a single short pulse or a set of discrete pulses (Bouchard and Fortier 2011; Bouchard et al. 2016). The spawning period of walleye pollock in the Bering Sea extends from early winter into early fall, with spawning in the north- ern Bering shelf highest in early summer (Hinckley 1987).

It is hypothesized that age-0 gadids on the Chukchi shelf are spawned to the south and are advected northward onto the Chukchi shelf in summer. Particle tracking simulations suggest that variations in wind and current patterns drive the interannual variability observed in late-summer distribution in the Chukchi Sea (C. D. Vestfals unpubl.). The age-0 gadids are then advected further to the north in the fall. Observations and modeled transport of larval Arctic cod suggest that spawning occurs at multiple locations in the Pacific Arctic (Vestfals et al. 2019; C. D. Vestfals unpubl.). Three key areas have been proposed as spawning areas for age-0 Arctic cod on the Chukchi shelf: the northern Bering Sea, along the Chukotka Peninsula in western Bering Strait, and the Beaufort Sea (Fig. 1; Kono et al. 2016; Vestfals et al. 2019). Acoustic- trawl abundance estimates in 2012 were lower than those in 2013 which is consistent with the hypothesis that lower annual northward transport in 2012 (e.g., Woodgate 2018) resulted in fewer age-0 Arctic cod originating in the Bering Sea were advected to the northeast Chukchi Sea by the time of the survey (C. D. Vestfals unpubl.). Larval Arctic cod have also been found in the northern Chukchi and western Beaufort Seas, in particular near Barrow Canyon. These fish may have been transported southward via up-canyon advection from aggregations of adult Arctic cod distributed to the north along the Beaufort shelf break (Geoffroy et al. 2011; Parker-Stetter et al. 2011; C. D. Vestfals unpubl.). Although Arctic cod are historically the most abundant species, advective transport is likely the main process driving the presence of all age-0 gadids on the Chukchi shelf. Walleye pollock and saffron cod (*Eleginus gracilis*) are abundant in the northern Bering and southern Chukchi Seas, respectively (De Robertis et al. 2017; Stevenson and Lauth 2019). Eggs and larvae of these species are likely to follow transport pathways similar to Arctic cod on the Chukchi shelf.

In this study, we sought to test the hypothesis that age-0 gadids in the Chukchi Sea are typically advected north during the summer, and that their distribution would shift northward during the open-water season. We used uncrewed surface vehicles (USVs) to conduct repeat acoustic surveys of the northeastern Chukchi Sea to quantify the intraseasonal variability in the spatial distribution of gadids in summer 2018. By conducting repeat surveys, we aimed to: (1) infer the source location of the age-0 gadid population in the northeast- ern Chukchi Sea in summer; (2) evaluate what movements of the fish population may reveal about the role of the northeast- ern Chukchi Sea as a nursery area for age-0 Arctic cod and other gadid fishes; and (3) ascertain whether, when, and how fish were transported out of the study area.

Methods

Survey design and data collection

Two Saildrone generation 5 USVs (SD-1022 and SD-1023, Saildrone, Inc., Fig. 2) were used to conduct an acoustic survey of pelagic sound-scattering organisms on the Chukchi shelf. The vehicles were deployed from Dutch Harbor, Alaska, on 30 June 2018 and recovered in the same location on 06 Octo- ber (98 d). The saildrone is a 7-m long wind-propelled vehicle which uses an actuator-controlled trim tab to manipulate a 5- m wing sail (Mordy et al. 2017; De Robertis et al. 2019). The vehicle autonomously navigates between operator-specified waypoints, with near real-time navigation, data reporting, and instrument control via satellite link. Onboard instrumentation operates on battery power, which is replenished by solar panels on the hull and wing. From 14 July to 24 September 2018 (72 d) the saildrones conducted acoustic surveys of the U.S. continental shelf region of the Chukchi Sea.

To compare the distribution of backscatter during mid and late summer, two large-scale surveys were completed from 20 July to 16 August and 24 August to 11 September. The sur- veys were conducted

between 66.5 N and 72.5 N and 168.6 W and 159.5 W (Fig. 1, area encompassed by the dashed line) along the 0.5 latitude spaced transects as surveyed by research vessels in 2012 and 2013 (De Robertis et al. 2017). Two additional surveys were conducted on a sub- set of four of the transect lines between 69.5 N and 71 N from 20 July to 03 August and from 13 August to 28 August. Along with the two large-scale surveys, this resulted in four replicate small-scale surveys in a region of previously (i.e., 2012 and 2013) observed high acoustic backscatter in the northeastern Chukchi Sea (Fig. 1, area indicated by dotted box). Both large- scale surveys and the additional two small-scale surveys were conducted from north to south along east–west acoustic tran- sects. In total, the two saildrones traveled 7610 nautical miles (14,093 km; hereafter referred to as nmi) in the Chukchi Sea at an average speed of 1.2 m s−1.

To measure backscatter from fishes, each saildrone was out-fitted with a Simrad wideband autonomous transceiver (WBAT-mini) split-beam echosounder with a Simrad ES38-18/200-18C transducer (three-channel split-beam 38 kHz and single-beam 200 kHz, both with a half power beamwidth of 18) gimbal-mounted on the keel at a depth of 1.9 m (see De Robertis et al. 2019 for details on echosounder integration). To manage power consumption, 12-min ping ensembles were transmitted between one and five times per hour (90% of data were collected with the instrument pinging continuously) defined by the operator depending on the battery state. Each ensemble consisted of simultaneous 38 and 200 kHz narrowband pings every 1.5 s using a 0.5-ms pulse duration. Back- scatter was recorded to 75 or 150 m range depending on the bottom depth. Electrical interference from the vehicle's sys- tems precluded the use of the 200 kHz data (this issue has since been resolved by Saildrone). The echosounders were calibrated after deployment using a 60-mm copper sphere for the 38-kHz transducer following the standard sphere method (Demer et al. 2015).

Sensors aboard the saildrone monitored environmental conditions throughout the deployment at 1-min intervals (for a full suite of sensors, see Mordy et al. 2017). Water temperature and salinity at 0.5 m depth were measured using a pair of conductivity, temperature, and depth (CTD) sensors (Saildrone3, RBR Ltd. and Sea-Bird SBE-37) on each USV. In situ comparisons between calibrated sensor pairs agreed to temperatures within ~ 0.01 C and salinities to within ~ 0.02 (PSS-78). Photosynthetically active radiation was measured at 2.5 m above the sea surface (LI-192SA, LI-COR, Inc.), and wind speed was measured using an anemometer mounted on the wing at 5.2 m (1590-PK-020, Gill Instruments Ltd.).

Inferring the identity of acoustic targets

In acoustic-trawl surveys, backscatter is attributed to species based on direct sampling (e.g., trawling) of acoustic scatterers, and by applying knowledge of the abundance and behavior (e.g., schooling characteristics and depth distributions) of the species in the study area (Horne 2000). We were unable to conduct any trawl sampling in 2018, and thus had to rely on observations from other years to interpret the acoustic observations. Surveys in 2012 and 2013 found the age-0 Arctic cod population in the Chukchi Sea to be > 35 times larger than any other observed species (De Robertis et al. 2017). Preliminary results from pelagic trawls conducted in 2017 and 2019 also indicate that most of the acoustic scattering at 38 kHz in this area is attributable to age-0 gadids. However, walleye pol- lock have become more abundant in recent years. Age-0 gadids made up > 95% of the trawl catch per unit effort in 2017 (85% Arctic cod and 10% walleye pollock by number) and > 85% of the catch per unit effort in 2019 (45% Arctic cod and 40% walleye pollock; R. M. Levine and S. Wildes unpubl.). As in previous years (De Robertis et al. 2017), other gadids such as saffron cod and Pacific cod (*Gadus macrocephalus*), and other strong sound scattering pelagic fishes such as capelin (*Mallotus villosus*) and Pacific herring (*Clupea pallasii*), were present in comparatively low abundance in 2017 and 2019 (R. M. Levine unpubl.) and occupied only a small portion of the Chukchi shelf. Although trawl sampling was not conducted during 2018, these surveys from previous and subsequent years strongly suggest that age-0 Arctic cod and walleye pollock likely dominated acoustic backscatter. Therefore, our analysis assumed that the acoustic-based measures

of fish density collected by the saildrones primarily reflect the abundance and distribution of age-0 Arctic cod and walleye pollock.

Acoustic data processing

Acoustic data were processed using Echoview 10.0 (Echoview Software Pty Ltd). Mean volume backscattering strength (Sv, dB re 1 m−1) at 38 kHz was used as a proxy for fish abundance. Sound speed and absorption were determined from 128 CTD casts collected during a 2017 survey of the U.S. continental shelf region of the Chukchi Sea between 67 N and 72.5 N. A mean sound speed of 1466.3 m s−1 was used for acoustic data post-processing, comparable to estimates of mean sound speed of the same region in other years (1470 m s−1 in 2013, 1472 m s−1 in 2019). Estimates fish back- scatter were not sensitive to the sound speed used: if sound speed from any individual cast (range of 1454.6–1484.4 m s−1) was used for the analysis instead of the mean value, backscatter changed by < 1%. In previous acoustic surveys, 38-kHz backscatter was dominated by backscatter with a frequency response consistent with that of fish (~ 96% in 2012 and 2013, De Robertis et al. 2017). During periods of elevated sea state, bubble entrainment caused attenuation of the transmitted signal. These pings were removed following the methods in De Robertis et al. (2019). The nautical area scattering coefficient (SA, m2 nmi−2) was integrated from 4 m below the sea surface to 0.5 m above the sounder-detected seafloor (as determined by Echoview's "best bottom candidate" algorithm and manually corrected after visual inspection where necessary) using a −70 dB re 1 m−1 threshold in 0.1 nmi along-track and 5-m vertical bins. SA is a proxy for fish abundance: it is proportional to fish density if the proportion of incident signal backscattered from the average fish in the population remains constant (MacLennan et al. 2002).

To compare backscatter between repeat surveys, the survey area was gridded into 0.5 latitude by 0.5 longitude cells. For large-scale surveys, only grid cells that contained data from both surveys were included (Fig. 3), resulting in 75 valid grid cells encompassing 993 and 805 nmi of acoustic observations from the first and second surveys, respectively. Mean SA was computed from acoustic measurements within each grid cell. The overall mean SA and the standard errors for all valid grid cells were estimated for each survey by fitting a geostatistical model to the gridded data with a separate mean by survey and constant spatial autocorrelation across surveys. The model was fitted via generalized least squares (GLS) using a Gaussian spatial correlation structure with a nugget effect (Wackernagel 2013). The same gridding and GLS model structure were applied to the four small-scale surveys to calculate mean backscatter and identify variability over time. In each of the four small-scale surveys, a subset of 42 grid cells containing 350 nmi of overlapping trackline was used for analysis (Fig. 5). The mean location of the distribution weighted by mean SA (center of gravity, Eq. 1 in Woillez et al. 2007), and the mean square distance between a measurement and the center of gravity (variance of spatial distribution, Eq. 3 in Woillez et al. 2007), were used to describe changes in the spa- tial distribution of the backscatter.

Measurements of backscattering cross-section (σbs, m2) of individual scatterers during the four small-scale surveys were calculated from single targets identified with Echoview's split- beam single target detection (method 2) algorithm. To minimize potential biases introduced by multiple overlapping targets being interpreted as a single fish, single target detection was limited to areas where density was low. The estimated number of animals per reverberation volume (Nv, Sawada et al. 1993) was determined in 100 ping along-track and 5-m vertical bins based on a target strength (TS, dB re 1 m2; TS = 10 log10(σbs), where σbs is the backscattering cross-section, see MacLennan et al. 2002). Based on previous catch results indicating that Arctic cod were likely the dominant scatterer, Nv was calculated using a TS of −57.3 dB re 1 m2 which assumes a mean Arctic cod size of 3.5 cm (De Robertis et al. 2017) and is similarly appropriate for walleye pollock of the same size class (Table S1). Single targets in grid cells where Nv > 0.04 were excluded from further analyses, as recommended by Sawada et al. (1993).

To investigate changes in acoustic strength of targets during the small-scale surveys, the mean σbs of all targets during each day of each small-scale survey was calculated (79–21,542 targets per day, median of 2893 targets). The daily means were used to model the changes in σbs as a linear function of time (yearday). A TS-length relationship developed primarily from age-0 Arctic cod (Geoffroy et al. 2016) was used to infer fish length at the midpoint of each small-scale survey from σbs, defined as

SL = 10 10 log10 ðσbs Þ +65:13 ,

(Hogan et al. 2014). The particles were seeded in areas where the first large-scale survey suggested (from observed grid cell mean SA and survey-wide mean σbs) that fish were abundant. A single particle was seeded at the center of each model grid cell where observed fish density was ≥ 0.1 fish m−2 (96 of 98 model grid cells) on the start date of the first large-scale survey (20 July).

Particle positions were calculated at 3-h intervals. To evaluate the potential for depth-dependent variability in transport, four separate model runs were conducted seeding particles at fixed depths of either 10, 20, 30, or 40 m. This range of depths encompasses the portion of the water column where most of the fish were located (> 85% of backscatter was observed from 10 to 40 m). To evaluate retention in the northeastern Chukchi Sea, we identified the proportion of particles at each time step that were (1) contained within the small-scale survey where SL is standard length (see Table S1 for additional details). Fish density (fish m−2) at the midpoint of each small-scale survey was calculated using model-predicted σbs following MacLennan et al. (2002).

Vertical distributions of age-0 Arctic cod were quantified by calculating the weighted mean depth of the backscatter from the entire water column in 1-h intervals (Eq. 2 in Woillez et al. 2007). Hourly measurements were classified as day or night based on photosynthetically active radiation measurements from the saildrones' sensors, using a day/night threshold value of photosynthetically active radiation of 10 μmol photons s−1 m−2, with 26% of the survey measurements occurring at night. To investigate linear trends in weighted mean depth over the duration of the surveys, an analysis of covariance was used to model the weighted mean depth of backscatter as a linear function of time (yearday), allowing the intercept and slope to differ between day and night. The model was fit via GLS to account for possible temporal auto- correlation, assuming a continuous first-order autoregressive time series structure (corAR1, Pinheiro et al. 2019).

Particle tracking simulations

The potential for physical retention of fishes in the north- eastern Chukchi Sea was examined using calculations completed using the OceanParcels python library (Lange and van Sebille 2017) which simulates the advection of passive particles from results of a numerical ocean model. Particles were tracked using a 1/12 resolution 3D velocity field obtained from the hybrid coordinate ocean model (HYCOM) global analysis output (https://hycom.org), at 3-h time resolution from 20 July to 18 September 2018. This model has 40 depth levels, with 5-m intervals from 10 to 50 m depth. HYCOM uses the Navy Coupled Ocean Data Assimilation system which assimilates satellite altimeter and sea surface temperature data, and in situ temperature and salinity profiles from ship, drifter, and mooring instrumentation. Surface forcing for the HYCOM run is taken from the Navy Global Environmental Model region or (2) found in the Beaufort Sea or on the Chukchi Sea slope (> 100 m bottom depth).

Results

Repeat large-scale surveys

The saildrones successfully completed two large-scale sur- veys of the U.S. continental shelf of the Chukchi Sea (Fig. 3). Sea-ice north of 71.5 N limited the northern extent of the first survey which was completed from 20 July to 16 August 2018 by a single saildrone. The second survey was completed from 24 August to 11 September 2018 by tasking two saildrones independently with the northern and southern portions of the survey.

Although the mean backscatter in the large-scale survey area increased slightly from a mean SA of 144 (± 37 SE) m2 nmi−2 during the first survey to 188 (± 50 SE) m2 nmi−2 during the second survey, the means were not significantly different (GLS, t-test p = 0.37). Fish distributions were similar in both surveys, suggesting there was no large-scale net advection of the population through the area during the survey period. The center of gravity of the backscatter shifted 18.7 km west (−165.79 W to −166.28 W) and 17.4 km north (from 69.77 N to 69.92 N), while exhibiting a slight decrease in variance of spatial distribution (−0.44 and −0.75 in latitude and longitude, respectively; Fig. 3). During both surveys 50% of the total backscatter occurred between 70 N and 71 N.

Temperature and salinity at 0.5 m depth ranged from−0.7 C to 11.4 C and from 26.5 to 32.8 psu during the large- scale surveys (Fig. 4). The coldest water was encountered north of 71 N, where surface conditions suggested recent mixing with sea ice meltwater (< 7 C and salinity < 30 psu). In areas where meltwater was present at the surface, backscatter was low; 92.9% of backscatter was observed in areas where the sur- face temperature was greater than 6 C and salinity was greater than 29 psu (Figs. 4, S1).

Repeat small-scale surveys

The small-scale surveys (four-transect subarea of the large- scale survey from 69.5 N to 71 N) lasted 12–21 d: 20 July–03 August, 23 July–12 August, 13–28 August (including a 5-d gap in sampling from 17 to 21 August), and 30 August to

11 September (Fig. 5). Mean backscatter within the 42 grid cells of the small-scale survey area varied among surveys, increasing from 197 (± 53 SE) to 369 (± 80 SE) m2 nmi−2 over the course of the summer (GLS, t-test p = 0.03, Table 1). The distribution of the population within the small-scale survey region did not shift appreciably among surveys. The center of gravity shifted slightly to the southwest between the first and last survey (19.4 km to the south and 19.3 km to the west, from −165.56 W 70.37 N to −166.08 W 70.19 N, Fig. 5).

The vertical distribution of fish during the small-scale surveys was consistent with the onset of vertical migration behavior. As the summer progressed, the weighted mean depth of backscatter remained shallow at night, but daytime depth increased after the second survey (Fig. 6a–d). Weighted mean depth during daylight hours increased from 17.7 (± 0.2 SE) to 30.0 (± 0.4 SE) m over the period of 53 d between the 1st and 4th survey (Fig. 6a–d). In contrast, weighted mean depth at night showed less variation, ranging from 16.6 (± 0.5 SE) to 19.6 (± 0.5 SE) m during the four surveys. Daylight hours decreased from 24 h per day at the start of the 1st survey to 14 h per day at the end of the 4th survey. Weighted mean depth differed between day and night (significant interaction in GLS, t-test p = 0.01) and this difference increased as a function of yearday (significant difference in slopes, t-test p = 0.005).

Although the placement of the transducer on the saildrone is shallower than typical on most research vessels, measurements of backscatter and individual acoustic targets were restricted to > 4 m depth. We found no significant difference between day and night backscatter (t-test comparing day and night on all sampling days, p = 0.27), indicating that there were not a significant number of scatterers migrating above the sampling range during the surveys. Although it is possible that some scatterers remained shallower than the transducer at all times, it is unlikely that we missed a large portion of the fish population which would have had to remain above the insonified depth throughout the entire survey period.

Backscattering cross-section (σbs) measurements were obtained from 252,949 acoustic single targets detected during the four small-scale surveys. Daily mean σbs was positively related to yearday (σbs = −7.68 × 10−6 + 4.54 × 10−8 (yearday), $p < 0.001$, $r2 = 0.44$; Fig. 6e), which results in a predicted increase in σbs from 1.7 × 10−6 (± 1.4 × 10−6 SE) to 3.5 × 10−6 (± 1.6 × 10−6 SE) between the midpoints of the first and fourth small-scale survey (Table 1). Estimates of standard length derived from σbs correspond to a change in length of 2.1 cm between the midpoints of the first and last survey 3.4 - 5.5 cm). Using the model-predicted values of σbs from the first day and last day of the small-scale surveys (Fig. 6e), the change in length corresponds to a growth rate of 0.54 mm d−1 over the 53-d period (Table S1). This estimate of growth rate is sensitive to the specific TS–length relationship used to convert scattering strength to fish length, and the use of alternative relationships results in a large range of estimates (0.24–0.89 mm d−1; Table S1).

Particle tracking

The passive particles in the simulation were primarily transported to the northeast (Figs. 7a-e, S2). By the end of the 60-d model run, the majority of particles were dispersed along the slope after being transported through Barrow Canyon (Fig. 7e). Initial movement of particles out of the survey region (Fig. 7a,b) was in two directions; particles in the northwest region of the survey area moved north toward Hanna Shoal, while the remainder of the particles followed the Alaska coast- line to the northeast.

From 20 July to 02 August, particles were advected out of the small-scale survey region at a consistent rate, with the pro- portion remaining in the small-scale survey area decreasing from 49% to 33% (Fig. 7f). The rate of advection out of the small-scale survey region decreased from 02 August to 25 August, when the proportion of particles in the survey region increased to ~ 40% and there were periods where particles returned to the region from the north. Thereafter the rate of export increased, with only 11% of all particles remaining in the survey area by mid-September. Through most of the model run, the proportion of particles along the Beaufort/ Chukchi slope steadily increased. By 18 September, or 60 d after the start of the first small-scale survey, 65% of particles had been advected seaward of the shelf break (> 100 m bottom depth) in the Chukchi and Beaufort Seas (Fig. 7e). The model runs produced similar results with particles tracked across depths of 10–40 m (Fig. 7f), indicating that (1) the system is strongly barotropic, that is, there is little vertical shear to the flow; and (2) inferences drawn from the model are not sensitive to fish depth.

Discussion

Acoustic surveys of age-0 gadids

Although the timing and location of spawning events are not known, large numbers of age-0 Arctic cod have been previously observed in the Chukchi Sea in the late summer and fall (De Robertis et al. 2017). The absence of a large population of age-1+ Arctic cod suggests that age-0 fish found in the eastern Chukchi Sea likely originated elsewhere, and that either over- winter mortality is high or they do not remain in place as they grow to maturity. This mortality and/or emigration is likely also occurring for other gadids including age-0 walleye pol- lock, for which large spawning stocks are observed in the Bering Sea but few age-1+ fish have been reported in the east- ern Chukchi Sea (Goddard et al. 2014). We analyzed repeat acoustic surveys and used particle tracking simulations to gain insights into possible directions of arrival and movement of these age-0 gadids through the eastern Chukchi Sea, and whether the absence of older individuals is most likely due to mortality or emigration of age-0 individuals.

Although we were not able to directly sample acoustic tar- gets, acoustic scatterers throughout the areas surveyed by the saildrones have spatial distributions and scattering properties that are consistent with those expected from age-0 gadids. Backscatter was highest in the northeastern Chukchi Sea, consistent

with observations from previous surveys in which trawl samples in that area were dominated by large numbers of age-0 Arctic cod (Quast 1974; Eisner et al. 2013; De Robertis et al. 2017). The large-scale survey estimates of mean SA (144 and 188 m2 nm−2) are similar in magnitude with estimates observed in previous acoustic surveys in the region (63.6 and 164.9 m2 nm−2 observed in 2012 and 2013), in which age-0 Arctic cod < 6 cm in length were the dominant contributors to 38-kHz backscatter (De Robertis et al. 2017). More recently, preliminary data from midwater trawl surveys in 2017 and 2019 indicate that primary scatterers across the shelf are age-0 gadids < 6 cm in length, and that while Arctic cod are the historically dominant scatterers, age-0 pollock may be becoming more abundant (R. M. Levine unpubl.). The σbs measurements observed in the four small-scale surveys (1.7 × 10−6 to 3.5 × 10−6 m2, Table 1) are consistent with observed in situ observations of both age-0 Arctic cod and walleye pollock < 6 cm (Brodeur and Wilson 1996; Geoffroy et al. 2016) rather than the much higher σbs expected for larger individuals. For example, the σbs for a 15-cm Arctic cod is ~ 8-fold greater than for a 3.5-cm fish (Geoffroy et al. 2016), and ~ 14-fold greater for a 15-cm age-1 pollock than a 3.5-cm age-0 (Brodeur and Wilson 1996; Traynor 1996). Although estimates of length are sensitive to the choice of TS–length relationship (Table S1), the σbs-derived lengths are consistent with the length distributions of age-0 gadids observed in previously collected trawl samples in the region (mean length of 3.5 cm, 99.7% of fish < 6.5 cm in August–September reported in De Robertis et al. 2017). These multiple lines of indirect evidence support our assumption that age-0 gadids dominated contributions to backscatter in the saildrone surveys.

The repeat acoustic surveys indicate that, while the spatial distribution of fishes in the northeastern Chukchi Sea did not change significantly from late July to early September of 2018, acoustic backscatter increased by ~ 87% during this period. The observed increase in acoustic backscatter could have resulted from either an increase in the abundance of scatterers, changes in the composition (i.e., size) of the scatterers, or a combination of both. During the small-scale surveys, σbs between the midpoint of the first and fourth small-scale sur- vey increased 104%. This suggests that the size distribution of fishes in the survey region may have shifted toward larger individuals. Over the same period, estimated fish density derived from the acoustic observations remained consistent (2.0–2.5 fish m−2, with overlapping standard errors, see Table 1). These estimated fish densities are similar to those observed in previous surveys (0.6 age-0 Arctic cod m−2 in 2012 and 2.2 Arctic cod m−2 in 2013, De Robertis et al. 2017).

Despite substantial variability, there is a unimodal distribution of σbs which increases over time, consistent with fish growth (Fig. S3). σbs is largely driven by swimbladder size, and although variability is high, average backscattering strength of individuals increases with length (Traynor 1996; Parker-Stetter et al. 2011). The changes in σbs corresponded to an estimated growth rate of 0.54 mm d−1 during the small-scale survey period. This growth rate is larger than measured rates from previous field and laboratory observations of age-0 Arctic cod (0.26 mm d−1 at 50 mm length, Hop et al. 1997; 0.19–0.24 mm d−1 Bouchard and Fortier 2011). However, growth rate is sensitive to the choice of TS–length relationship (0.24–0.89 mm d−1 depending on the relationship used, Table S1). Furthermore, σbs is orientation dependent (Foote 1980), and these estimates of growth assume consistent average orientation distributions over time. Although the uncertainties are large, the increase in σbs is likely related to growth, and it may ultimately be possible to estimate growth rates of Arctic gadids by measuring target strength in some circumstances. In future work, this uncertainty can be reduced by assessing TS–length relationships directly by coupling these observations with direct sampling of fish lengths.

The observed changes in vertical distribution (change in mean nighttime depth from 17.7 to 30.0 m during small-scale surveys) provide further evidence that growing age-0 gadids may have dominated the acoustic observations. As eggs and larvae, both Arctic cod and walleye pollock are predominantly surface associated (Spencer et al. 2020), drifting until their swimming ability develops and their swimbladder fills. Individuals exhibit an ontogenetic migration, descending deeper in the water column as they age. This transition in Arctic cod and walleye pollock occurs at a length of > 30 mm, when pelagic juveniles

vertically shift to deeper water during day- time, typically observed in late summer (Brodeur et al. 2000; Ponomarenko 2000; Bouchard and Fortier 2011). In the saildrone surveys, diel vertical migration behavior was initiated when mean TS-derived lengths were > 30 mm. This behavior also coincided with the onset of night in late-July during both the first and second small-scale surveys. This change is consistent with expected behavior for gadids as individuals increase in size over time. Together, the observed σbs and increased vertical migration suggest that increasing back- scatter may be due to individual growth.

Suitability of the Chukchi Sea as a nursery

Minimal changes were observed in the spatial distribution of fish during the survey period, which is inconsistent with a single, spatially restricted pulse of fish being advected across the Chukchi shelf. If there was a continuous northward transport, a single short spawning pulse from the south would result in a northward shift in the center of gravity of the population over time, and/or large changes in abundance between surveys. We hypothesized two alternative mechanisms to account for our observations: (1) a greatly extended spawning period that continues late into summer, with fish continuously transported north at a steady rate with balanced immigration and emigration; or, (2) retention of a population established by mid-July for most of the summer. The latter of these scenarios would be consistent with Arctic cod in other regions of the western Arctic where the majority of hatching occurs during a ~ 2-month period in late spring (Bouchard et al. 2016).

Age-0 fish populations may be enhanced by being be retained on the Chukchi shelf in summer to use the region as a nursery. Predation from piscivorous fish is likely low, as large fishes are scarce in the region (Sigler et al. 2011; De Robertis et al. 2017). Piscivorous seabirds are widely distributed and abundant throughout the Bering, Chukchi, and Beaufort Seas (Kuletz et al. 2015), and thus seabird predation pressure during open-water season is relatively consistent throughout the region. In summer, seabird foraging hotspots occur on the boundaries of the Chukchi shelf near Bering Strait and to the north along Barrow Canyon, where there is also a seasonal increase marine mammal presence (Kuletz et al. 2015).

Water temperatures on the Chukchi shelf are also likely to be more conducive for growth than conditions farther north (Laurel et al. 2016). Saildrone measurements of temperature and salinity were limited to the upper 0.5 m, thus it was not possible to directly assess the conditions at the same depths as the fish. However, backscatter was lowest in the northernmost areas of the large-scale survey area (Fig. 3), where low surface water temperatures and salinities suggested recent mixing with the meltwater which typically overlays cold winter water (Weingartner et al. 2013; Danielson et al. 2017). De Robertis et al. (2017) observed that Arctic cod on the Chukchi shelf were largely present at intermediate temperatures (3.4–6.6 C) and high salinities (> 30.4 psu) typical of Bering/Chukchi Summer Water. The Bering/Chukchi Summer Water flows north into the Chukchi Sea from the northern Bering Sea shelf (Coachman et al. 1975; Danielson et al. 2017) and gradually replaces the surface meltwater and deep winter water on the Chukchi shelf (Weingartner et al. 2013). The warmer Bering/ Chukchi Summer Water is within the temperature range (2–8 C) observed for maximum growth in Arctic cod and positive growth potential in both walleye pollock and saffron cod (Laurel et al. 2016).

Advective influences on age-0 fishes

The low backscatter in areas near meltwater indicates that these fish are unlikely to be originating from the north or areas influenced by recent ice melt and are either passively or actively remaining in warmer conditions. The Chukchi shelf is a highly advective environment, where advection is likely to dominate over the directed swimming movements of small fishes. The association of age-0 gadids with warmer water conditions supports the hypothesis that the age-0 gadids observed on the Chukchi shelf are likely advected northward from spawning areas to the south. Advective transport north across the Chukchi shelf

is generally attributed to both local winds and a far field forcing relating to a sea level difference between the Pacific and the Arctic (see Woodgate et al. 2005 for discussion). Since 1990, the annual mean northward velocity of the flow through the Bering Strait has ranged from ~ 18 (± 2) cm s−1 in 2001 to ~ 28 (± 3) cm s−1 in 2014 (lowest and highest annual mean velocities of the 1991–2015 period; Wood- gate 2018). This includes periods of southward flow and thus the northward mode speed is higher (from 20 to 40 cm s−1, Woodgate 2018 their Fig. 4). In the northeastern Chukchi Sea, the mean velocities of the upper 10 m of the water column in summer average 8 cm s−1, ranging from 0.5 to 22.8 cm s−1 from 2010 to 2015 (Stabeno et al. 2018). In respiration experiments, maximum aerobic swim speeds of Arctic cod were 3 to 3.6 body lengths s−1 (12–14 cm s−1 for a 4-cm fish) during burst swimming activity (Kunz et al. 2018). In studies of related gadid species, routine swimming speeds of juvenile fish were 0.5 to 0.6 body lengths s−1 (2–2.4 cm s−1 for a 4-cm fish, Peck et al. 2006). For age-0 gadids of 3.5 cm length, this suggests a routine swimming speed of approximately 1.9 cm s−1, which is an order of magnitude lower than typical advective currents. These estimates support the hypothesis that passive transport likely plays a dominant role determining the distribution of age-0 gadids on the Chukchi shelf, and that swimming behaviors have relatively small impacts on long-term distributions.

In late summer 2018, transport simulations suggest that age-0 gadids were advected northward, likely to the Beaufort and Chukchi slopes and Arctic basin. As expected, the model indicated that net transport was northward, with 90% of modeled particles released in the large-scale survey area dispersed along the shelf or slope to the north of the survey area at the end of the 60-d model run. However, during the month of August, only a few particles left the survey area, and during some periods transport reversed to increase particle abundance within the small-scale survey area (Figs. 7f, S2). The decrease in the rate of particles leaving the survey area and subsequent return of particles suggests that age-0 gadids are retained on the Chukchi shelf by episodic flow reversals. Estimates of retention based on particle transport from the survey area are consistent at 10, 20, 30, and 40 m depth (depths where the bulk of the backscatter occurred throughout the survey period). This suggests that variations in horizontal advection of fishes are likely insensitive to vertical movements or water column position.

Flow reversals similar to those occurring in the 2018 particle tracking model are commonly observed in the northeast- ern Chukchi Sea, and are associated with strong southward winds (Woodgate et al. 2005; Stabeno et al. 2018; Pisareva et al. 2019). De Robertis et al. (2017) speculated that difference in age-0 Arctic cod distribution between 2012 and 2013 may be linked to variability in currents and prey availability, and recent work has proposed variation in wind-driven retention as an explanation (Vestfals et al. 2019). Woodgate et al. (2005) developed a linear model for determining water velocity in the northeastern Chukchi Sea as a function of the pressure head forcing and surface wind speed. Offshore of Cape Lisburne, assuming a baseline pressure head velocity of 9.4 cm s−1 (see Table 3 in Woodgate et al. 2005), surface wind speed would need to exceed 7.2 m s−1 to the south to balance the pressure head forcing, temporarily stopping northward transport. Wind speed measurements from the saildrones indicate that from 01 August to 30 August, the mean velocity of the north–south wind component was 2.3 m s−1 to the south, with 21 days having mean southward winds (Fig. S4). How- ever, during 10.3% of August, wind velocity to the south was 7.2 m s−1, during which predicted net northward transport would be near zero or negative. This simplistic calculation is supported by the particle tracking model which shows this wind reversal was sufficient to account for the particle retention on the shelf. We hypothesize that wind-driven relaxation in northward transport may be responsible for, and predict, retention of age-0 gadids in the northeastern Chukchi Sea.

It also seems reasonable to hypothesize that interannual variations in circulation influence advection and subsequent retention of age-0 gadids in the Chukchi Sea. Transport through the Bering Strait (which is generally indicative of the northward flux through the Chukchi Sea, Woodgate et al. 2005) estimated from near-bottom velocity data indicates that monthly mean transport during summer 2018 (R. A. Woodgate pers. comm.) was similar to the 1990–2004 climatology (Woodgate et al. 2005), even though in the

annual mean, 2018 was higher in flow than the climatology. Thus, as it is summer that most concerns us, it is likely that the observed summer residence time of age-0 gadids in the Chukchi in 2018 is fairly typical, and suggests a hypothesis that cold-adapted species such as Arctic cod may have adapted to spawn at a time and place that more or less reliably places larvae in this apparent nursery area.

The Pacific Arctic is currently undergoing rapid changes, including increased northward transport through Bering Strait in recent decades (Woodgate 2018). These changes in advection, temperature, and ice cover have the potential to alter Arctic gadid populations. Bouchard et al. (2017) proposed that an initial decrease in ice cover, resulting in warmer conditions, would increase survival and growth of larval Arctic cod. However, continued temperature increases beyond their preferred growth range could depress physiological condition and sur- vival of larval Arctic cod, while enhancing conditions for larval walleye pollock (Koenker et al. 2018). Winter spawning provides a lengthy growth period for Arctic cod, during which maximizing prewinter size may be important for survival (Bouchard and Fortier 2011). Increased northward transport in summer may more quickly transport Arctic cod off the shelf and into the Arctic basin, shortening time available for growth in this potentially favorable nursery environment.

Increased input of Pacific water onto the shelf may also increase the presence of subarctic and boreal gadids, increasing competition and predation among pelagic species (Sigler et al. 2011). This transition has already been observed in the Barents Sea, where larger boreal species have expanded their distribution, increasing predation on and competition with smaller Arctic species (Fossheim et al. 2015). Subarctic gadids of high abundance in the Bering Sea such as walleye pollock and Pacific cod may be more likely to be transported north, following the same advective pathways across the Chukchi shelf as Arctic cod. Evidence from recent midwater surveys conducted in the region (R. M. Levine unpubl.) suggest other broadly distributed fishes such as walleye pollock or saffron cod have the potential to move further north, increasing in abundance on the Chukchi shelf as conditions warm (Huntington et al. 2020). The potential for these species to survive overwinter in the Arctic, however, is still unknown.

We found that distributions of age-0 gadids in the Chukchi Sea are strongly driven by two factors: advection and retention within specific water masses. Further studies are needed to better understand specific oceanographic features (e.g., currents, fronts, ice presence, water masses) and to investigate their demographic effects on gadids in the region. For example, in situ observations of fish movement and behavior (e.g., target tracking from moored acoustic instruments; Kaartvedt et al. 2009) paired with direct observations of currents have potential to better constrain potential pathways for transport of fishes, resolve the timing and seasonal dynamics of their development from eggs to juveniles, and predict recruitment into downstream populations along the Beaufort and Chukchi Sea slope.

Insights on Arctic fishes from USV observations

Traditionally, acoustic surveys have relied on trawl sampling of species and size composition to convert acoustic back- scatter into abundance estimates (Simmonds and MacLennan 2005). Recent advances in the integration of echosounders into autonomous platforms have increased our ability to measure acoustic backscatter remotely over long periods (Greene et al. 2014; Mordy et al. 2017; Benoit-Bird et al. 2018; Ohman et al. 2019). We used the endurance of the saildrones to collect a large number of acoustic observations over an extended period of time which would have been pro- hibitively expensive and logistically difficult using ships. These repeat acoustic surveys spanning large spatial and temporal scales enabled us to constrain the movement of age-0 gadid fishes on the Chukchi shelf and made it possible to determine a TS and approximate a growth rate. These insights into the transport, growth, origins, and fate of the age-0 gadid population were made possible by the high spatial and temporal coverage offered by autonomous platforms.

However, with current technology, it remains challenging, in most cases, to validate species composition, size, sex, and other organismal properties by acoustic methods alone (Bassett et al. 2018). Thus, the key challenge going forward is not how to measure acoustic scattering from autonomous vehicles, but how best to use these measurements to under- stand the abundance, distribution, and behavior of marine organisms (De Robertis et al. 2019). While autonomous acoustic surveys cannot definitively identify the species and size composition of acoustic scatterers, they can be effective in regions where other data have shown that a single or distinguishable group of dominant scatterers enables interpretation of acoustic data (Mordy et al. 2017; De Robertis et al. 2019). Low-diversity, high-latitude regions may be favorable for autonomous echosounder measurements because backscatter is often dominated by a single species or group (Geoffroy et al. 2011; De Robertis et al. 2019).

With its low pelagic diversity, the Chukchi Sea provides a good ecosystem for the application of autonomous acoustic survey methods. However, Arctic ecosystems are undergoing changes that may alter species compositions (e.g., Fossheim et al. 2015; Huntington et al. 2020), and the assumptions that make these inferences possible are likely to change with time. The increased presence of species with similar acoustic proper- ties will limit the ability to address species-specific questions without additional sampling in rapidly changing ecosystems such as the Arctic, although inference at the community level (e.g., gadids) may be feasible. Future studies of high-latitude marine environments (e.g., Arctic, Antarctic) may benefit from the use of USVs and other autonomous platforms allowing for acoustic measurement of fish and macrozooplankton populations, with the potential to expand into more complex environments and applications as the methodologies for remote species identification improve.

Conclusions

Repeat saildrone surveys indicated that advection resulted in the retention of age-0 gadids on the Chukchi Sea shelf throughout the summer where they underwent in situ growth. These fish likely originated south of the central Chukchi Sea and were advected onto the northeast shelf. In late summer, transport simulations suggest that advection played a larger role than swimming and that these fishes were passively advected further north to the Beaufort and Chukchi slopes and Arctic basin. Variations in transport rate and trajectory may account for the interannual variability in the density and distribution of pelagic fishes on the Chukchi shelf. In a changing climate, changes in circulation and water column conditions may alter the future structure of pelagic communities in the Pacific Arctic and the suitability of the Chukchi shelf as a favorable nursery area. Although Arctic cod are currently the dominant gadid in the region, increasing temperatures and earlier transport off the Chukchi shelf could limit age-0 growth prior to their first winter, and increased subarctic pelagic fishes such as walleye pollock may lead to increased predation pressure and competition that may further limit the Arctic cod population (Fossheim et al. 2015; Huntington et al. 2020). New technologies such as autonomous vehicles are likely to provide opportunities to better quantify perturbations of this rapidly changing ecosystem.

Acknowledgments

This work was funded by the North Pacific Research Board Arctic Research Program, NOAA's Pacific Marine Environmental Laboratory's Innovative Technology for Arctic Exploration program, NOAA's Alaska Fisheries Science Center, and the Joint Institute for the Study of the Atmo- sphere and Ocean (JISAO) under NOAA Cooperative Agreement NA15OAR4320063. The saildrone deployments would not have been possible without the contributions of Richard Jenkins and Dave Peacock (Saildrone, Inc.), and Ivar Wagnen (Kongsberg Simrad). We would also like to thank the Alaska Waterways Safety Committee, Alaska Eskimo Whaling Commission, The North Slope Borough, and members of The Vil-lage of Wainwright, AK for their advice and assistance with saildrone oper- ations. We thank the anonymous reviewers for their suggestions which improved this manuscript. This is contribution No. 5091 for Pacific Marine Environmental Laboratory, contribution No. 2020-1063 for JISAO, and contribution No. EcoFOCI-0947 for NOAA's Ecosystem Fisheries Oceanog- raphy Coordinated Investigations. Bering Strait mooring observations are funded by NSF-OPP (1304052 and 1758565) with data available from http://psc.apl.washington.edu/BeringStrait.html. Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement U.S. Government. Findings of

this paper do not necessarily represent the views of the National Oceanic and Atmospheric Administration.

Table 1. Summary of small-scale survey observations. The mean SA, model-predicted backscattering cross-section (σ_{bs}) at the midpoint of each small-scale survey, abundance from 38-kHz backscatter, and estimated standard length of gadids are given. Standard errors are given in parentheses. Lengths were calculated from the model-predicted σ_{bs} at each survey midpoint using the TS–length relationship defined for Arctic cod (Geoffroy et al. 2016, Table S1).

	20 Jul-03Aug	**23 Jul-12 Aug**	**13-28 Aug**	**30 Aug-11 Sept**
Mean SA (m^2 nmi^{-2})	197 (53)	177 (76)	281 (79)	369 (80)
σ_{bs} (m^2)	1.7×10^{-6} (1.4×10^{-6})	2.0×10^{-6} (1.4×10^{-6})	2.8×10^{-6} (1.5×10^{-6})	3.5×10^{-6} (1.6×10^{-6})
Abundance index (fish m^{-2})	2.5 (0.6)	2.0 (0.8)	2.2 (0.6)	2.3 (0.5)

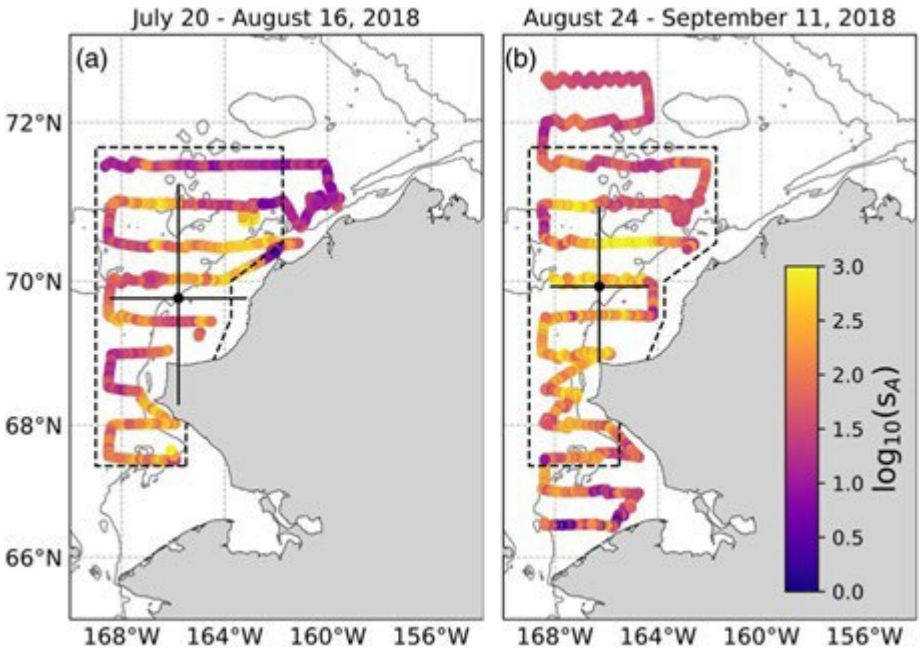

Fig. 3. 38-kHz backscatter (SA, m^2 nmi^{-2}) along the saildrone trackline during the (a) first and (b) second large-scale surveys. Center of gravity and variance of spatial distribution computed from the gridded cells common to both surveys (region encompassed by the dashed line) are indicated by the black circles and lines, respectively. The 40-, 100-, and 1000-m depth contours are shown.

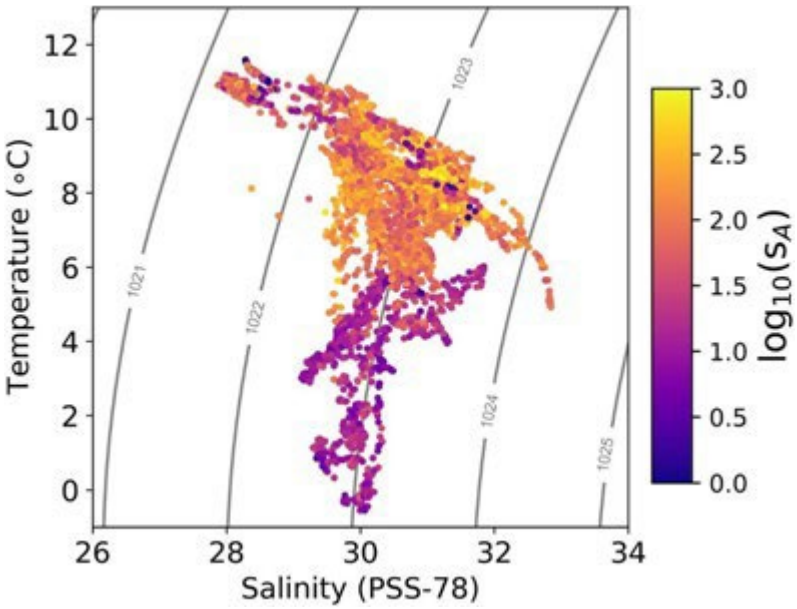

Fig. 4. Ten-minute averaged temperature and salinity at 0.5 m depth measured by sensors on the keel of the saildrone during the large-scale surveys (Fig. 3). Color of points indicates depth-integrated water column 38-kHz backscatter (SA, m^2 nmi^{-2}). Contours indicate potential density.

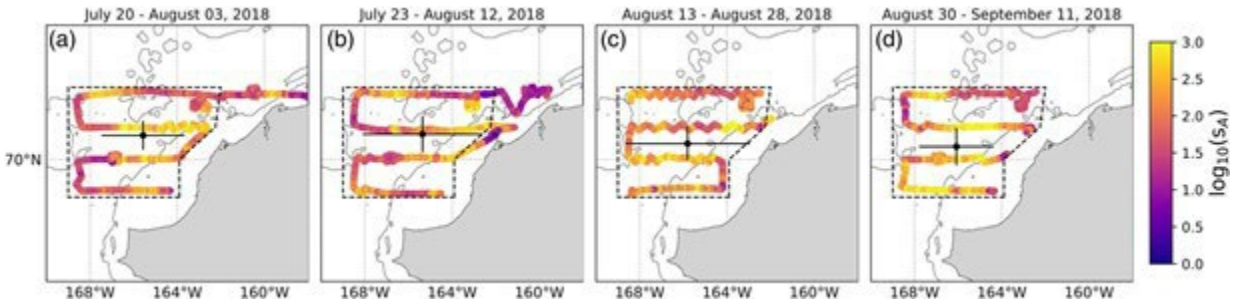

Fig. 5. 38-kHz backscatter (SA, m^2 nmi^{-2}) along the saildrone trackline during the (a) 1st, (b) 2nd, (c) 3rd, and (d) 4th small-scale surveys. The center of gravity and variance of the spatial distribution computed from the gridded cells common to all surveys (region encompassed by the dashed line) is indicated by the black circles and lines, respectively. Note that the first two survey periods overlap in time. The 40- and 100-m depth contours are shown.

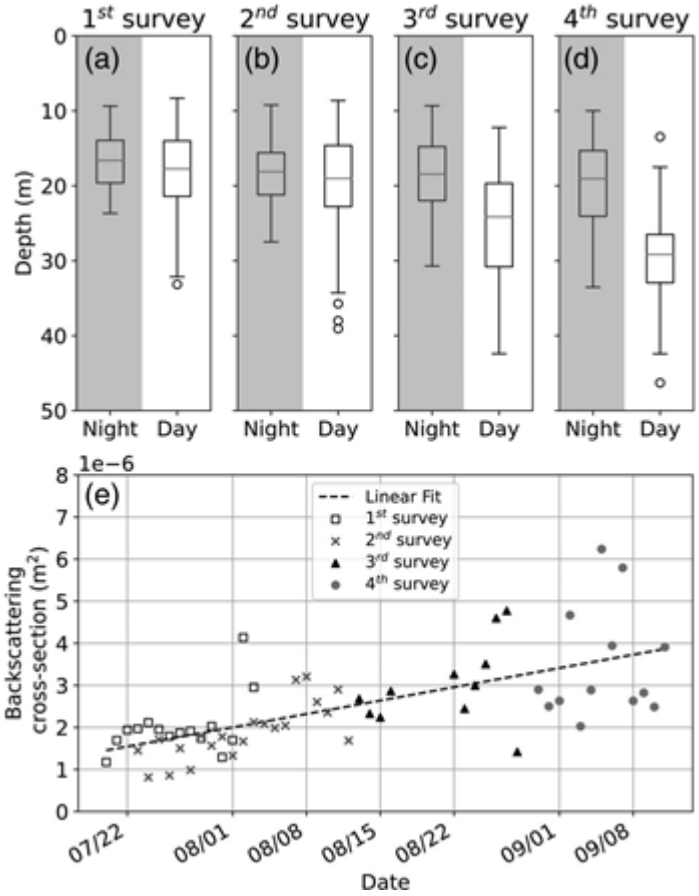

Fig. 6. (a–d) Distributions of nighttime and daytime hourly weighted mean depth of backscatter during the small-scale surveys. Boxes indicate the interquartile range, horizontal gray lines the median, vertical lines the 5% and 95% intervals. Circles indicate observations beyond the whiskers. (e) Daily means of backscattering cross-section (σ_{bs}) of all targets observed in small-scale surveys. Linear fit for the 53-d period is indicated by the black dashed line ($\sigma_{bs} = -7.68 \times 10^{-6} + 4.54 \times 10^{-8}$(yearday), $p < 0.001$, $r^2 = 0.44$.

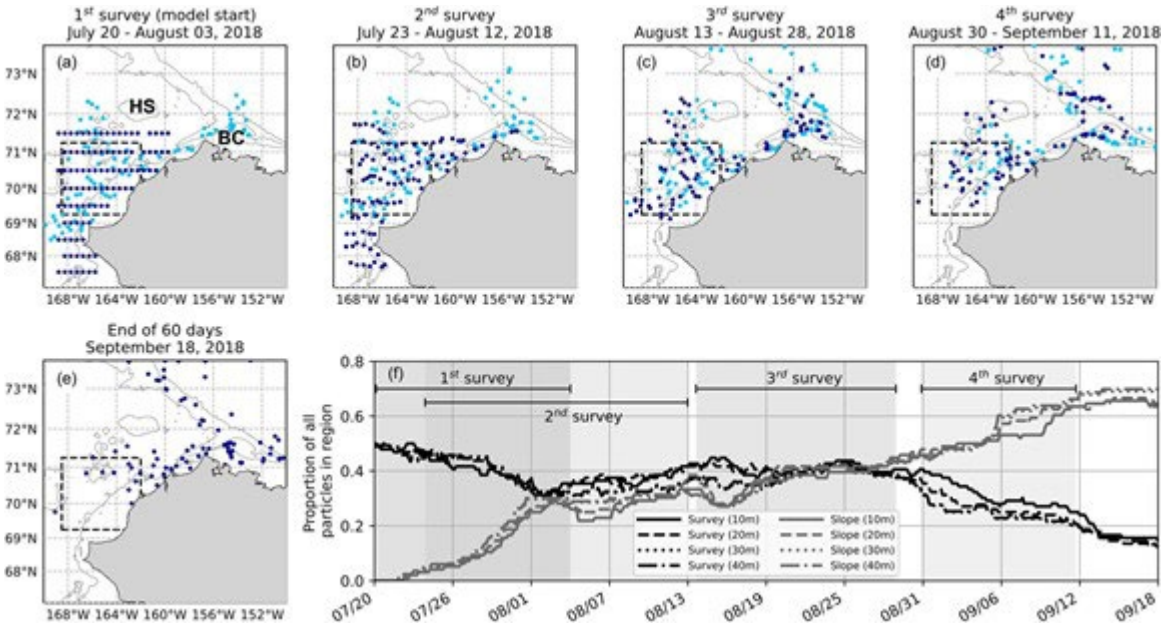

Fig. 7. Results of particle tracking model. (a–d) Locations of particles at 20 m depth at the start (dark blue circles) and end (light blue circles) of the (a) 1st, (b) 2nd, (c) 3rd, and (d) 4th small-scale surveys. Particles were seeded on 20 July at the center of each 0.5 grid cell of the first-large-scale survey (see Fig. S2). The locations of Hanna Shoal (HS) and Barrow Canyon (BC) are indicated in the first panel. (e) Locations of particles seeded at 20 m depth at the end of the 60-d model run. The area indicated by the dashed box represents the small-scale survey region. The 40-, 100-, and 1000-m depth con- tours are shown. (f) Proportion of particles remaining within the small-scale survey region (black lines), and particles transported to the Beaufort Sea and Beaufort/Chukchi slope (> 100 m bottom depth, gray lines) over a period of 2 months from the start of the 1st survey. Model results for particles seeded at fixed depths of 10–40 m are shown. The time periods of the four small-scale surveys are indicated by the gray shaded regions and lines. Note that the 1st and 2nd survey periods overlapped.

CHAPTER 18 - Modeling the dispersal of polar cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*) early life stages in the Pacific Arctic using a biophysical transport model

Objective 5: Further resolve early life history characteristics of Arctic cod and saffron cod and their behavior and connectivity between the Chukchi Sea and western Beaufort Sea.

Cathleen D. Vestfals, Franz J. Mueter, Katherine S. Hedstrom, Benjamin J. Laurel, Colleen M. Petrik, Janet T. Duffy-Anderson, and Seth L. Danielson 2021. Modeling the dispersal of polar cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*) early life stages in the Pacific Arctic using a biophysical transport model. Progress in Oceanography. 196: 102571. ISSN 0079-6611, https://doi.org/10.1016/j.pocean.2021.102571.

Abstract

Polar cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*) are the most abundant and ecologically important forage fishes in the Pacific Arctic marine ecosystem, yet little is known about their spawning locations or the habitats occupied by their early life stages (ELS). We developed a biophysical transport model coupled to a Pan-Arctic hydrodynamic ocean circulation model to identify potential spawning locations and examine connectivity between the northern Bering, Chukchi, and Beaufort seas. We simulated the growth and transport of newly hatched polar cod and saffron cod larvae until the early juvenile stage (to 45 mm in length) using circulation model hindcasts from 2004 – 2015. Analyses identified species-specific differences in dispersal trajectories, despite similar hatch times and locations. Strong interannual variability in growth and dispersal was linked to several global-scale climate indices, suggesting that larval growth and transport may be sensitive to environmental perturbations. Results show that polar cod spawned in the northern Chukchi Sea may be an important source of larvae for the Beaufort Sea and Arctic Basin, while observed larval aggregations in the Chukchi Sea likely originated in the northern Bering and southern Chukchi seas. This study provides new information about potential spawning times and locations for polar cod and saffron cod in the Pacific Arctic and helps to identify important ELS habitat. This knowledge can help improve the management of these species and, by examining how larval connectivity changes in response to changing environmental conditions, improve our ability to anticipate how these species may respond in a rapidly changing Arctic.

Introduction

The Arctic is warming at an unprecedented rate. Surface air temperatures have increased at double the global rate (Screen and Simmonds, 2010) and this warming has also extended to the oceans, resulting in dramatic changes across Arctic ecosystems (Wassman et al., 2011; Huntington et al., 2020). The Pacific Arctic, in particular the Bering Strait region and the Chukchi Sea, is warming rapidly, with water temperatures increasing by 0.43 ºC per decade since 1990 (Danielson et al., 2020a). Sea-ice concentration, extent, and duration have also declined over this period, with an earlier spring ice retreat and delayed fall ice formation increasing the length of the open-water season by ~3 months (Comiso et al., 2008; Stammerjohn et al., 2012). Reduced ice cover, earlier ice melt, and greater freshwater inputs associated with warming in the Arctic are predicted to impact ecosystem dynamics via the poleward movement of boreal species and changes in marine productivity (Meredith et al., 2019). These changes will likely have a profound effect on the distribution and abundance of resident Arctic species. To better understand the consequences of these environmental changes, in this study we examine the early life stages (ELS) of polar cod (Boreogadus saida) and saffron cod (Eleginus gracilis), two of the most abundant and ecologically significant species in the Pacific Arctic marine ecosystem.

Polar cod and saffron cod play an important role in the transfer of energy to higher trophic levels, serving as key prey for piscivorous seabirds and marine mammals, as well as humans, in the northern Bering, Chukchi, and Beaufort seas (Whitehouse, 2011; Moore and Stabeno, 2015). In general, observational data

for Arctic marine fishes are scarce and particularly so for their ELS, such as spawning locations, larval drift pathways, and juvenile nursery areas. Collections are mainly limited to the late spring and summer (but see Lafrance, 2009; Bouchard et al., 2016) due to the challenges and costs of sampling during winter and spring in the remote regions of the Arctic (e.g., difficulties of sampling under the ice, lack of sustained research efforts). As such, identifying major spawning locations of species that spawn under the ice during the winter, such as polar cod and saffron cod, resolving the movement and distribution of their ELS, and understanding their responses to variable climate conditions cannot be achieved through field studies alone.

Advective transport of eggs and larvae is known to play an important role in population regulation of marine fishes and several studies have linked larval transport with variability in year-class strength (Bailey, 1981; Hollowed and Bailey, 1989; Wilderbuer et al., 2002; Govoni 2005; Mueter et al., 2006; Petrik et al., 2015, 2016). Modeling approaches, such as the use of biophysical models that can track and simulate the behavior of eggs and larvae, can provide insights into the movement of ELS and information that would otherwise be unavailable through conventional field sampling. Since eggs and larvae are relatively underdeveloped in the first few months of life, their dispersal is primarily governed by ocean circulation and can be tracked by simulating the transport of passive particles or particles with basic behaviors. Examples include temperature-dependent growth combined with size- or age-dependent vertical migrations, until the larvae grow to a size at which their movements are largely independent of the currents (Leis, 2007). The impacts of circulation on larval dispersal and recruitment has been successfully evaluated using hydrographic modeling approaches in a variety of marine systems (as reviewed in Miller, 2007), including the Gulf of Alaska and the Bering Sea (Hinckley et al., 1996; Parada et al., 2010; Duffy-Anderson et al., 2013; Vestfals et al., 2014; Petrik et al., 2015, 2016; Gibson et al., 2019).

The Chukchi Sea is a broad (> 500 km), shallow (~50 m deep), high-latitude shelf system that extends > 800 km northward from Bering Strait and is highly productive during the spring melt and open-water seasons (Grebmeier et al., 1988). The seasonally fluctuating Pacific-Arctic sea level gradient (Stigebrandt, 1984; Aagaard et al., 2006) drives the northward flow from the Bering Sea through the narrow (~85 km) and shallow (~50 m) Bering Strait. Water entering the Chukchi Sea is often classified into three water masses: cold, relatively saline, and nutrient-rich Anadyr Water (AW) in the west (Coachman et al., 1975; Sambrotto et al., 1984), seasonally present and relatively warm, low-salinity Alaskan Coastal Water (ACW) in the east, and a mixture of the two water masses, Bering Shelf Water (BSW) (Coachman et al., 1975), which originates primarily from 100 m isobath flow (Stabeno et al., 2018). Peak inflow through Bering Strait occurs during summer, bringing relatively fresh water, nutrients, heat, carbon, and organisms into the Chukchi and Beaufort seas (Wyllie-Echeverria et al., 1997; Weingartner et al., 2005; Woodgate et al., 2005a, b; Moore and Stabeno, 2015), while strong southward winds in winter reduce the northward flows (Woodgate et al., 2005a, b; Stabeno et al., 2018).

Inflow through Bering Strait moves across the Chukchi shelf along three main pathways: westward through Hope Valley towards Herald Canyon (Coachman et al., 1975; Weingartner et al., 2005; Woodgate and Aagaard, 2005; Pickart et al., 2010), eastward parallel to the Alaskan coastline into Barrow Canyon (Coachman et al., 1975), and through the Central Channel across the mid-shelf between Herald and Hanna Shoals (Weingartner et al., 2005) (Fig. 1). Flow across the shelf is highly variable and can be modified by local winds and other fluctuations, with particularly strong northerly winds capable of reversing the transport for periods of days to weeks (Coachman and Aagaard, 1981; Weingartner et al., 2005; Woodgate et al., 2005a, b; Danielson et al., 2014, 2017). Flow exits the Chukchi shelf through Barrow Canyon in the east (Coachman et al., 1975; Weingartner et al., 2005) or Herald Canyon in the west (Coachman et al., 1975; Pickart et al., 2010). Water exiting through Barrow Canyon flows either westward along the Chukchi shelf break as the Chukchi Slope Current (Corlett and Pickart, 2017), or eastward into the Beaufort Sea along the shelf break and slope (Pickart, 2004). Low-salinity waters associated with river outflow and solar heating are transported northward during the summer and fall by

the seasonal Alaska Coastal Current (ACC, Coachman et al., 1975). The water column cools to near freezing temperatures in the late fall and early winter and remains near the freezing point until late spring and early summer, when increasing solar radiation and the inflow of warmer water from the Bering Sea leads to rapid warming, melting of sea ice, and increased river discharge (Weingartner et al., 2005; Danielson et al., 2017, 2020a).

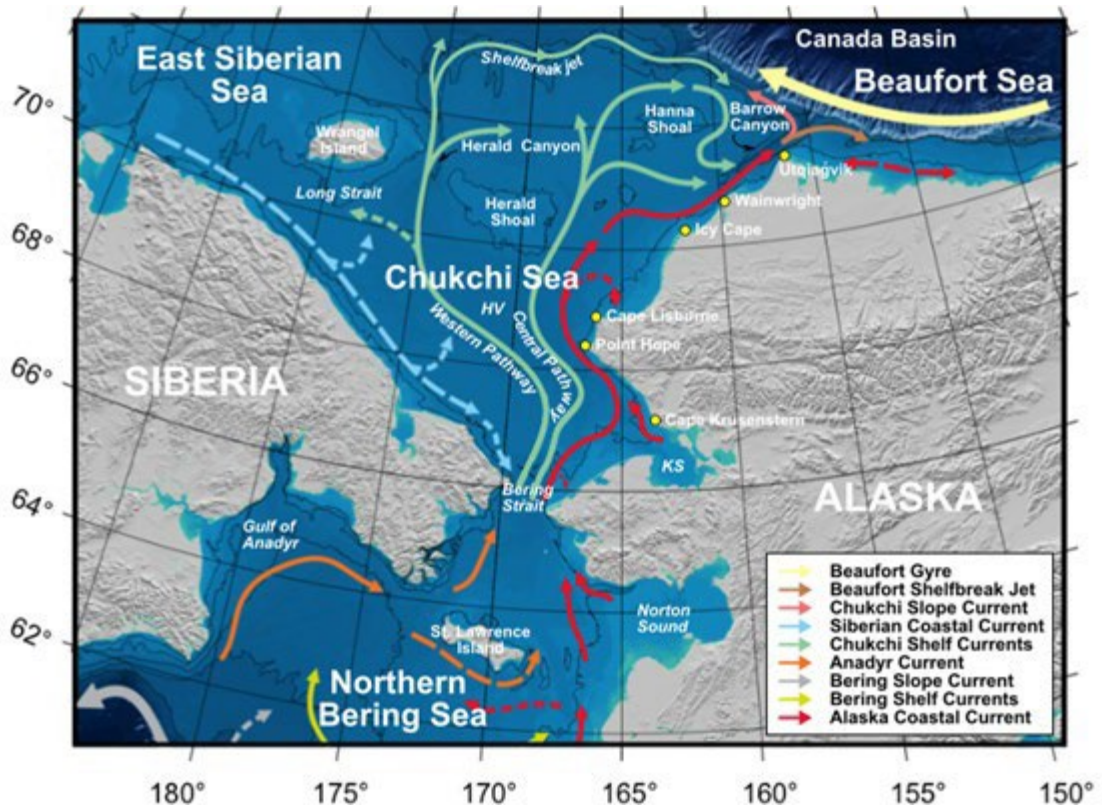

Fig. 1. Map of typical flow pathways of the northern Bering Sea, Chukchi Sea, and western Beaufort Sea based on Danielson et al. (2020a) with water bodies and place names. Persistent currents are shown with solid arrows; intermittent or poorly known flows are shown with dashed arrows. KS denotes Kotzebue Sound and HV denotes Hope Valley. Depth isopleths are contoured with thin black lines at 25, 70, 100, and 200 m.

Building on previous modeling efforts for walleye pollock (Gadus chalcogrammus) in the eastern Bering Sea (Petrik et al., 2015, 2016) and using an ocean circulation model for the Arctic region, we developed biophysical transport models parameterized for larval and early juvenile stages of polar cod and saffron cod. These models were used to simulate the growth and dispersal of their ELS in the northern Bering, Chukchi, and Beaufort seas to identify possible spawning locations, which are currently largely unknown, as well as examine connectivity between these regions. Several behavior scenarios were tested and modeled distributions were compared to known summer distributions of larvae and early juveniles from acoustic-trawl surveys conducted in 2012 and 2013 in the northern Bering and Chukchi seas. Selected behavior scenarios were then used to model their growth and dispersal from 2004 – 2015 to assess interannual variability relative to oceanographic and atmospheric conditions. In addition to providing important information about potential spawning areas and nursery habitats of polar cod and saffron cod, this research helps establish whether observed aggregations of larvae and early juveniles are likely to be retained in the Chukchi Sea, contributing primarily to local populations, or if they are likely to be

transported from the northern Chukchi Sea into the Beaufort Sea, thereby serving as a source population for gadids in the Beaufort Sea. This research also provides valuable information about the growth and dispersal of Arctic gadids under variable climate conditions, which is important for understanding how these species respond to environmental perturbations and how their connectivity between the Chukchi and Beaufort seas may be impacted.

Methods

Circulation model

To realistically simulate the three-dimensional (3-D) circulation field and force the Lagrangian particle-tracking model, we used an implementation of the state-of-the-art, free-surface Regional Ocean Modeling System (ROMS; Shchepetkin and McWilliams, 2005) set up in a Pan-Arctic (PAROMS) configuration (Curchitser et al., 2013, Danielson et al., 2016, 2020b; Lovvorn et al., 2020). The domain of this coupled ocean/sea-ice numerical model spans the Arctic from the Bering Sea in the North Pacific to the North Atlantic. The horizontal resolution varies from ~5 km south of the Aleutian Islands to ~9 km in the North Atlantic and is approximately 5.5 – 6.0 km in the Chukchi Sea. The 50-layer vertical coordinate system is based on terrain-following sigma-layers with finer resolution within the surface and bottom boundary layers. PAROMS is forced by NASA's Modern-Era Retrospective-Analysis for Research and Applications atmospheric reanalysis (Rienecker et al., 2011), with boundary conditions coming from the Simple Ocean Data Assimilation (SODA, Carton and Giese, 2008) for 2008 and prior, and from the Hybrid Coordinate Ocean Model (HYCOM; Chassignet et al., 2009) for more recent years. Tidal forcing is provided by the Oregon State TOPEX/Poseidon Global Inverse Solution (Egbert and Erofeeva, 2002) and the sea ice field is based on the single-category Budgell ice model (Budgell, 2005). For surface fresh water flux, the model uses the method of Dai et al. (2009) south of the Yukon River and that of Whitefield et al. (2015) for the Arctic. A careful model-to-observation comparison of hindcast velocity, temperature, and salinity in the Chukchi and Beaufort seas found that the model exhibited appreciable skill in reproducing the mean velocity directions and magnitudes and the velocity variances at time scales from tidal to annual (Curchitser et al., 2013). The model also captured synoptic and seasonal temperature, salinity, and stratification variations. Offshore ice thicknesses in mid-winter were found by Curchitser et al. (2013) to generally be within 1 m of those estimated from the IceSat satellite missions (Kwok et al., 2009). Without restoring sea ice concentrations to observational data or data assimilation, the model reproduced approximately 50% of both the observed monthly and annual ice concentration anomalies (Curchitser et al., 2013). Additional model-data comparisons that demonstrate model fidelity in reproducing wind-driven SSH anomalies are provided in Danielson et al. (2020b).

Output from the PAROMS 2004 – 2015 hindcast was saved as daily averages to force the offline particle-tracking model, as described below. Specifically, the particle-tracking model used PAROMS-generated velocities, temperature, and salinity.

Particle tracking

To simulate advective transport and growth of larvae, we developed individual-based models (IBMs) for polar cod and saffron cod using the particle tracking tool TRACMASS, which calculates Lagrangian trajectories from Eulerian velocity fields (Döös, 1995). The TRACMASS model is run offline using stored daily output from PAROMS integrations, thus it is less computationally expensive and allows for more calculations of trajectories in comparison to those made online within the circulation model. TRACMASS runs on the 3-D PAROMS grid and solves the trajectory path through each grid cell with an analytical solution of a differential equation, which depends on the horizontal and vertical velocities at the grid cell walls (Döös, 1995). TRACMASS has been used in atmospheric and oceanic studies (Drijfhout et al., 2003; Döös and Engqvist, 2007), as well as for modeling the dispersal of fish and invertebrate larvae (Jacobi and Jonsson, 2011; Berglund et al., 2012; Petrik et al., 2015, 2016).

The particle-tracking time step used in TRACMASS was 1 hour and sub-grid scale turbulence was incorporated by adding a random horizontal turbulent velocity to the horizontal velocity from PAROMS to each trajectory and each horizontal grid wall at every time step (Döös and Engqvist, 2007). A horizontal diffusion value of 4 m2 s-1 was used, based on the relationship between diffusion and model resolution defined in Okubo (1971). Model output of position (latitude and longitude), temperature, salinity, and larval length (see Section 2.3 below) was saved at daily intervals. In addition to particle trajectories, TRACMASS calculated surface light as a function of latitude, longitude, date, and time of day for behavior scenarios that included diel vertical migrations (DVM). While TRACMASS had impermeable boundary conditions at the coast, the incorporation of diffusion into the model allowed for beaching of simulated particles. Trajectories of particles that beached were no longer tracked in the model. Particles rebounded from ice.

We based the number of particles released for each dispersal simulation on the method described in Petrik et al. (2015). In that study, the number of particles released at each time and location (number of simulation repetitions) was determined by calculating the fraction of particles at four random locations downstream of the initial start locations. The minimum number of particles for which those fractions did not change appreciably was determined, with 10 particles per 10 m depth increment per spawning location deemed appropriate for producing stable results (Petrik et al., 2015). For our study, we doubled the number of particles, given that the Chukchi Sea is shallower than the Bering Sea, releasing 10 particles per 5 m depth increment at each PAROMS grid point within each release location (Table 1). Due to the lack of information available about the vertical distributions of post-hatch polar cod and saffron cod larvae in the water column at the time of this study, simulated larvae were released every 5 m from the surface to the bottom. Since saffron cod spawn in close proximity to the bottom (Chen et al., 2008) and their eggs are demersal and adhesive (Berg, 1949; Wolotira, 1985), spawning and hatching locations were assumed to be identical, with dispersal simulations reflecting dispersal from their spawning grounds. For the initial simulations, the minimum and maximum number of particles released were 15,480 and 289,220, respectively, for a total of 623,510 particles released across all locations on each simulation date (Table 1).

Table 1. Hypothesized spawning and/or hatching areas of polar cod (Boreogadus saida) and saffron cod (Eleginus gracilis), region, number of PAROMS grid points, and number of particles released for each dispersal simulation.

Hatch area	Region	# of grid points	# of particles
Gulf of Anadyr	Bering Sea	3,347	289,220
St. Lawrence Island	Bering Sea	235	15,480
Norton Sound	Bering Sea	735	19,370
Bering Strait	Bering Sea	663	48,530
Chukotka Peninsula	Chukchi Sea	888	57,550
Kotzebue Sound	Chukchi Sea	534	20,790
Cape Lisburne	Chukchi Sea	700	45,690
Hanna Shoal	Chukchi Sea	759	68,750
Barrow Canyon	Chukchi Sea	616	58,130
Total:		8,477	623,510

Biological model

Growth

Temperature-dependent growth rates have recently been estimated for larval polar cod and saffron cod in the laboratory (Koenker et al., 2018; Laurel et al., 2018; B. Laurel, National Oceanic and Atmospheric Administration (NOAA), unpublished results). These data provide the information necessary for parameterizing models such as the one presented in this study and provide temperature-dependent growth and developmental rates from the newly hatched larvae to ~25 mm for polar cod and 10 mm for saffron cod. All growth models were based on food 'unlimited' scenarios.

Polar cod

Egg stage: Despite the availability of a temperature-dependent equation for egg development, simulations were initialized at the time of hatching due to uncertainties about where in the water column polar cod eggs occur (e.g., whether they are frozen into the sea ice (Yudanov, 1976) or float at the ice-water interface) and uncertainties about the ability of the PAROMS model to accurately capture small-scale under-ice flow dynamics. Currently, sea ice in PAROMS is modeled as a flat-bottomed surface; however, sea ice is a complex surface that can vary dramatically across even short distances, with ice keels in the Chukchi Sea regularly exceeding 20 m in depth (Hauri et al., 2018). Thus, in an attempt to minimize uncertainties in drift trajectories and ensure more realistic growth and transport of ELS, simulations were restricted to the post-hatch period.

Yolksac larvae: Yolksac larvae were initialized at a random hatch length selected from a normal distribution with a mean standard length (SL) of 5.70 mm and standard deviation (SD) of 0.48 mm. These values were obtained from temperature incubation experiments of polar cod eggs from Beaufort Sea broodstock (Laurel et al., 2018).

Preflexion larvae: Growth from hatch to 10 mm (Fig. 2 a) was modeled as a function of temperature (T) as:

Growth (mm day-1) = 0.0735 + 0.0149*T - 0.0013*T2,

with coefficients determined from a polynomial regression (Koenker et al., 2018).

Post-flexion larvae: Due to the lack of temperature-dependent growth data available for larger sizes, growth from 10 – 25 mm (Fig. 2 a) was modeled using a temperature-dependent growth equation derived for polar cod larvae 10 – 15 mm in length (Koenker et al., 2018):

Growth (mm day-1) = 0.0369 + 0.0583*T - 0.0044*T2

Late-larvae/early juveniles: Growth from 25 – 45 mm (Fig. 2 a) was modeled using a temperature-dependent growth equation for early juveniles between 45 – 70 mm in length (> 10 weeks old, Laurel et al., 2017), as temperature-dependent growth data were not available for these sizes:

Growth (mm day-1) = 0.1377 + 0.0311*T + 0.0041*T2 - 0.0004*T3

Larval length was only updated for nonnegative growth rates, thereby preventing larvae from shrinking at lower temperatures.

Saffron cod

Egg stage: Similar to polar cod, the egg stage of saffron cod was not included in our simulations, despite the availability of information about temperature-dependent egg development. Simulations were initialized at the time of hatching due to uncertainties about the ability of the PAROMS model to accurately capture small-scale under-ice flow dynamics (see Section 2.3.2.1 above). Thus, in an attempt

to minimize uncertainties in drift trajectories and ensure more realistic growth and transport of ELS, simulations were restricted to the post-hatch period.

Yolksac larvae: Yolksac larvae were initialized at a random hatch length selected from a normal distribution with a mean SL of 5.44 mm and SD of 0.30 mm based on values obtained from temperature incubation experiments of saffron cod eggs from Gulf of Alaska broodstock (B. Laurel, NOAA, unpublished results). Size at hatch was not related to incubation temperature.

Preflexion larvae: Growth from hatch to 10 mm (Fig. 2 b) was modeled as:

Growth (mm day-1) = 0.0016 + 0.0088*T

Flexion larvae – early juveniles: At present, temperature-dependent growth models for larval saffron cod > 10 mm in length are not available. Growth of saffron cod at these small sizes is linear and resembles that of walleye pollock (B. Laurel, NOAA, unpublished results). Assuming that growth of larger saffron cod remains similar to that of larger walleye pollock, we used the walleye pollock growth model described in Porter and Bailey (2007) and Petrik et al. (2015) to model saffron cod growth from 10 mm to 45 mm (Fig. 2 b).

Growth (mm day-1) = 0.0902 * log(T) - 0.0147

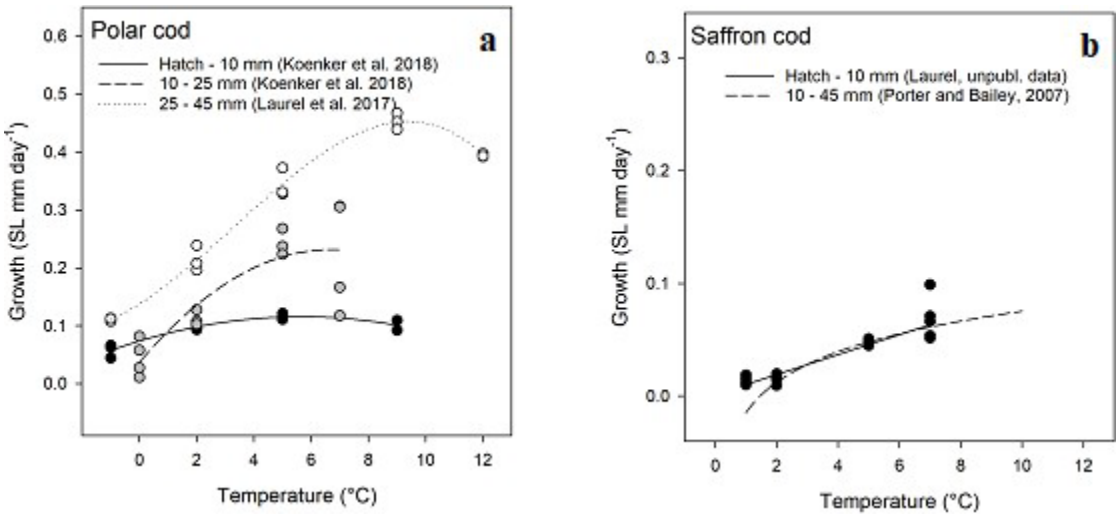

Fig. 2. Temperature-dependent growth rates (in mm day-1) used to model growth of (a) polar cod (*Boreogadus saida*) and (b) saffron cod (*Eleginus gracilis*) early life stages in the individual-based models (IBMs). Growth rates for polar cod yolksac (hatch – 10 mm) and feeding (10 – 25 mm) larvae in the model were based on those derived in Koenker et al. (2018), while early juvenile growth (25 – 45 mm) was based on Laurel et al. (2017). The growth rate for saffron cod yolksac larvae (hatch to 10 mm) was based on unpublished data (B. Laurel, NOAA). For growth of saffron cod preflexion larvae to early juveniles (10 – 45 mm), the walleye pollock (*Gadus chalcogrammus*) growth model described in Porter and Bailey (2007) was used, as a saffron cod- specific growth model for larger sizes is not available and walleye pollock exhibit similar growth (B. Laurel, NOAA, personal communication).

Vertical behavior

Vertical behaviors selected for polar cod were based on values obtained from the literature (Borkin et al., 1986; Bouchard et al., 2016) and from laboratory observations (B. Laurel, NOAA, unpublished results). Similar behaviors were used for the saffron cod simulations, as no information on the vertical distribution of saffron cod larvae is currently available. Five different vertical behavior scenarios were developed and tested: (1) passive (neutrally buoyant) individuals at all stages; (2) surface-oriented individuals such that all stages move to the middle of the 10-m surface layer at 5 m; (3) passive yolksac larvae where older stages move progressively deeper in the water column: preflexion/flexion larvae (5 – 10 m), transformation (10 – 15 m) and early juveniles (20 m); (4) surface-oriented yolksac larvae and older individuals that move progressively deeper in the water column; and (5) surface-oriented yolksac larvae and transformation and early juvenile stages that make diel vertical migrations (DVMs) to the middle of the surface layer (5 m) at night (Table 2). For DVM, day was defined as times when surface light was greater than zero.

Table 2. Model parameters for different behaviors tested for polar cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*). Passive = passive (neutrally buoyant) individuals of all stages; Surface = surface-oriented individuals of all stages; Passive & ontogeny = passive yolksac and preflexion larvae with late larvae and early juveniles moving deeper with ontogeny; Surface & ontogeny = surface-oriented yolksac and preflexion larvae with late larvae and juveniles moving deeper with ontogeny; DVM = surface-oriented yolksac and preflexion larvae with late larvae and early juveniles making diel vertical migrations (DVMs) between specified depths during the day, and 5 m during the night. wmax = maximum vertical swimming speed, nb =neutrally buoyant, trans = transformation, early juv. = early juvenile.

Polar cod

Behavior	Length (mm)	Stage	W_{max} (m s^{-1})	Daytime depth (m)	Nighttime depth (m)	Temperature-dependent growth
Passive	Hatch – 10	Yolksac, preflexion	0.002 – 0.003	Nb	Nb	Koenker et al., (2018)

Vertical swimming speed (w) was parameterized for both polar cod and saffron cod as:

w = wmax * (-tanh(0.2 * (z – zpref)))

where z is depth (m), zpref (m) is the preferred depth (middle of depth range or day-time/night-time preferred depths), and the maximum vertical swimming speed, wmax (m s-1), is

wmax = 0.3 * Llarva *10-3

where Llarva is larval length (mm).

The swimming speed of fish larvae is often overestimated in IBMs (Peck et al., 2006); therefore, we chose a maximum speed of 0.3 body-lengths s−1 as a conservative estimate for sustained swimming. This value aligns well with that used to model polar cod growth in the Greenland Sea and Baffin Bay (Thanassekos and Fortier, 2012) and is comparable to swimming speeds used in studies of Atlantic cod (Gadus morhua) larvae (Sundby and Fossum, 1990; Björnsson, 1993; Vikebø et al., 2007).

Simulations

Release locations and hatch dates

Larvae were released from several hypothesized hatching locations based on information from a review of the literature, anecdotal evidence, and known areas of retention in the region (Craig et al., 1982; Wolotira, 1985; Sunnanå and Christiansen, 1997; A. Whiting, Native Village of Kotzebue, personal communication). In total, nine locations were selected from which to initialize the dispersal simulations: the Gulf of Anadyr, St. Lawrence Island, Norton Sound, Bering Strait, Chukotka Peninsula, Kotzebue Sound, Cape Lisburne, Hanna Shoal, and Barrow Canyon (Table 1). Ellipses were created around the hypothesized hatching locations (Fig. 3) using ArcGIS 10.4 (ESRI, 2017) and simulations were initialized from all PAROMS grid points falling within each ellipse. Points on land were excluded.

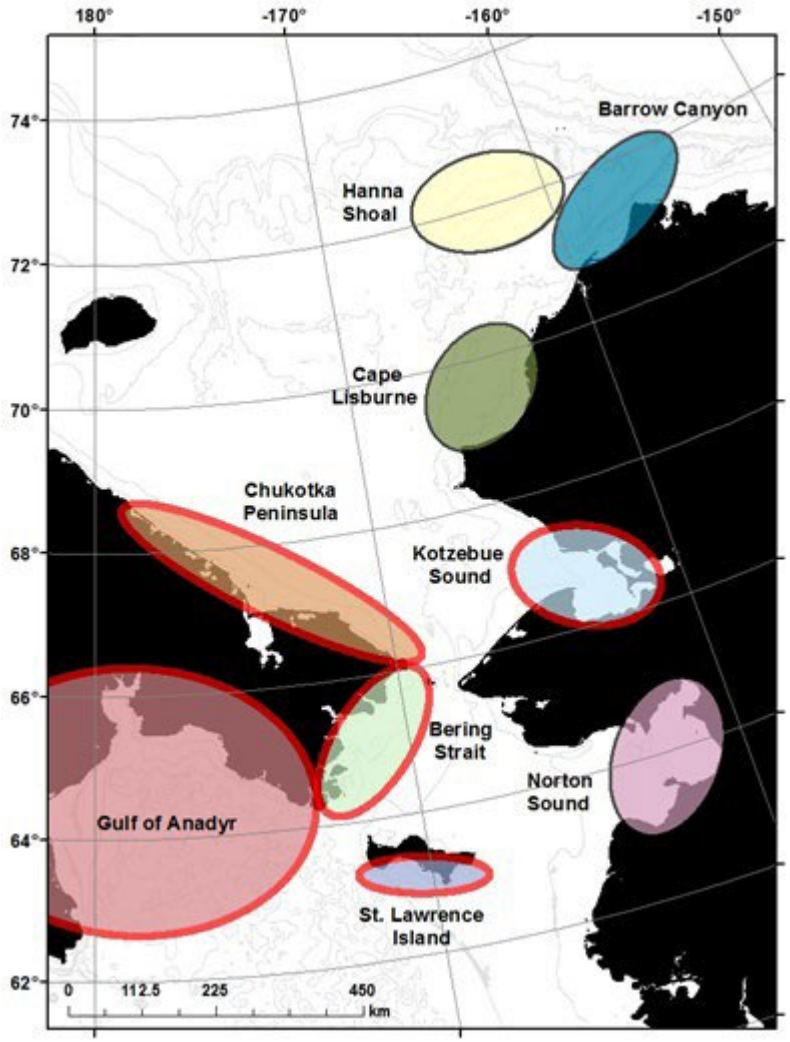

Fig. 3. Map of polar cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*) hypothesized spawning and/or hatching locations used to develop the biophysical transport models. All 9 locations were used for the initial dispersal simulations to select plausible release locations. Areas highlighted in red were used to test 5 different behavior scenarios against 2012 and 2013 Arctic Ecosystem Integrated Survey acoustic-trawl survey observations. Simulations for 2004 through 2015 were initiated from the Bering Strait and Chukotka Peninsula locations for polar cod, and the Bering Strait and Kotzebue Sound locations for saffron cod.

In other Arctic seas, peak hatching of polar cod eggs occurs in May and June (Yudanov, 1976; Bouchard and Fortier, 2008), though it can occur as early as December and January in regions warmed by large inputs of fresh water and as late as August in colder regions (Bouchard and Fortier, 2011). In the Chukchi Sea, hatching can occur as late as July (Wyllie-Echeverria et al., 1997). Initial particle releases were based on a hatch date calculated from the midpoint of when polar cod were encountered in the Chukchi Sea portion of the Arctic EIS survey in 2013. The approximate hatch date was estimated by back-calculating

from the average length of age-0 polar cod observed in the survey (~35.2 mm) using the regression of length on hatch date in Bouchard and Fortier (2011). This method resulted in an estimated hatch date of Julian day 72.5 (± 31.5 days SD), with most larvae hatching around early to mid-March (Marsh et al., 2019). Initially, simulated larvae hatched every two weeks from 15 February through 15 May, for a total of 7 hatching events in each year. Simulations were conducted separately for each release location and each hatch date. Results from the initial simulations suggested that larvae did not have sufficient time to achieve the lengths observed in the field, therefore, hatch dates were expanded to include the 1st and 15th day of each month from 1 January through 15 May for a total of 10 polar cod hatching events in each year. This range of hatch dates was also supported by otolith-derived ages of polar cod collected during the Arctic EIS survey (Z. Chapman, University of Alaska Fairbanks, personal communication) and allowed simulated fish lengths to better match field observations. The same range of hatch dates was used for the saffron cod simulations.

Particle tracking

Particle trajectories were tracked forward in time. While tracking particles backward in time can be used to identify potential source locations (e.g., Christensen et al., 2007; Calò et al., 2018), processes such as physical diffusion are not reversible in time (Batchelder, 2006). Backtracking can be complicated by ontogenetic development and the active behavior of larvae due to the stochastic and nonlinear nature of these processes (Christensen et al., 2007). Backtracking may be more suitable for short-duration simulations, but is less effective in shallow, nearshore regions with strong flow–bathymetry interactions (Batchelder, 2006, Bauer et al., 2013). Although inefficient and computationally expensive (Batchelder, 2006; Christensen et al., 2007), tracking particles forward in time can be used to evaluate retention in suitable areas, transport to nursery grounds, or loss to unfavorable habitats (Christensen et al., 2007). Given the shallow Chukchi shelf (~50 m deep), the long drift duration (see Section 2.4.3. below), and the incorporation of diffusion and behavior in our simulations, backtracking was not implemented. The feasibility of tracking fish larvae backwards from observed distributions for several months was unclear, and may have resulted in overly broad distributions. Furthermore, backtracking in TRACMASS at the time did not allow for active behavior of the particles.

Duration of simulated drift

Growth and dispersal of larvae were simulated until 1 September, the midpoint of the Arctic EIS survey, so that the simulated distribution and size composition during summer could be compared to the observed distributions and size compositions in the 2012 and 2013 Arctic EIS acoustic-trawl surveys. Polar cod and saffron cod transition from pelagic juveniles to more demersally-oriented juveniles at approximately 35 – 45 mm (ICES CM, 1988) and between 39 – 60 mm (Wolotira, 1985), respectively, with enhanced swimming abilities that are difficult to capture in an IBM, thus fish larger than 45 mm in length were excluded from further analysis.

Data-model comparison with acoustic-trawl surveys

We used data on the abundance and length composition of larval (preflexion and flexion) and early juvenile polar cod and saffron cod (to 45 mm in length) from acoustic-trawl surveys conducted in the Chukchi Sea as part of the Arctic EIS program (Mueter et al., 2017) to compare with results from the IBMs developed in this study. In late summer 2012 and 2013, the Arctic EIS program conducted comprehensive ecosystem surveys of the U.S. northern Bering Sea and Chukchi Sea shelves (Mueter et al., 2017). Surveys began on 7 August in both years and progressed northward from Bering Strait along designated transects until reaching the Chukchi shelf break by the first week of September, after which sampling recommenced in Bering Strait and progressed southward to 60°N until the last week of September. Acoustic-trawl methods were used to estimate the abundance and distribution of pelagic

organisms in the northern Bering and Chukchi seas (see De Robertis et al., 2017a, b for further details), and provide the best available information about the late summer distributions of age-0 polar cod and saffron cod in the region. The size and species composition of acoustic scatterers were estimated from a combination of surface trawls conducted at pre-determined stations and midwater trawls conducted in areas of high backscatter to convert the measurements of acoustic backscatter into animal abundances. A large Cantrawl rope trawl was used for all surface trawls and for midwater trawls in 2012, while a smaller modified-Marinovich trawl was used for midwater sampling in 2013. In 2013, a series of paired midwater trawls were conducted with the Cantrawl and modified-Marinovich trawls to determine the relative selectivity of the two gear types (De Robertis et al., 2017a). Selectivity-adjusted estimates of abundance (fish m-2) for 10-mm size classes of polar cod and saffron cod ranging from 5 – 305 mm in length were calculated along the acoustic track.

Field distributions of polar cod and saffron cod were compared to simulated distributions by overlaying a 30- x 30-km grid over the 2012 and 2013 Arctic EIS acoustic-trawl survey areas (Fig. S1) in ArcGIS (ESRI, 2017). Survey abundance estimates of fish ≤ 45 mm in length (all size classes ≤ 45 mm in length) were aggregated to each grid cell that overlapped with the survey area in each year. The aggregated abundance estimate for each cell was divided by the total survey abundance to get the proportion of the survey observations of fish ≤ 45 mm in length occurring in each grid cell. A similar process was used to determine the proportion of the simulated larvae falling within each survey grid cell for each release location and each hatch date. The locations of simulated polar cod and saffron cod ≤ 45 mm in length at the end of the simulation (1 September) were plotted and only those that overlapped with the survey grid cells were included in the analysis. The proportion of the simulated distribution that fell within each survey grid cell was calculated by dividing the number of simulated fish ≤ 45 mm in length occurring in each grid cell by the total number of simulated fish falling within the survey area. Note that we chose to analyze release locations and hatch dates separately, as aggregating larval releases over space and time assumes that each release location and time contributes equally, which is almost certainly not the case as the numbers of eggs released and the survival of larvae (which was not modeled) can be expected to vary widely across time and space. While the correlations between observed and simulated particles from a particular release location and time are not expected to be high when multiple hatching events contribute to larvae observed in a given region, significant correlations - even if weak - would strongly suggest that a given release location and time may have contributed to the observed concentrations of larvae.

Initial passive particle trajectory simulations from the northern release locations (Cape Lisburne, Hanna Shoal, and Barrow Canyon) showed poor overlap with the Arctic Ecosystem Integrated Survey (Arctic EIS) acoustic-trawl survey grids (see De Robertis et al., 2017b) used to ground truth the model (see Section 2.5 below), with most particles being advected into the Beaufort Sea and Arctic Basin (Fig. S2). Similarly, particles from the Norton Sound release location had minimal overlap with the acoustic-trawl survey grid and were largely retained in the Bering Sea (Fig. S2). Therefore, subsequent simulations were initialized from the five remaining locations with greater overlap with the acoustic-trawl surveys in 2012 and 2013 (i.e., transport into or retention within the Chukchi Sea), allowing for comparisons between simulated distributions and field observations.

Correlations between simulated distributions and survey observations were calculated for each behavior scenario, spawning location, release date, and release depth using Pearson's Product Moment Correlation, for a total of 525 comparisons per species per year. Correlations were consistent across release depths and are therefore reported for the total, depth-integrated values only.

Interannual variability of simulated distributions

To examine how polar cod and saffron cod dispersal were influenced by variability in climate and oceanographic conditions, the IBMs were run for multiple years (2004 – 2015) over the full range of hatch dates from the release areas that produced the strongest correlations between observed and simulated distributions in 2012 and/or 2013. As simulations with surface-oriented behavior showed the

strongest correlations between observed and simulated distributions for both species, this behavior scenario was used to model polar cod and saffron cod dispersal between 2004 and 2015.

Simulated distributions on 1 September from 2004 – 2015 were compared using a center of gravity (COG) analysis in the R package SDMTools (R Core Team, 2018). Inertia, or the dispersion of simulated particles around the COG (Woillez et al., 2009), was calculated for each year, along with the standard deviations around the major and minor axes. This was done to test for trends in spatial dispersion, which may reflect changes in oceanographic and atmospheric circulation. For example, volume flow through Bering Strait has shown a strong, increasing trend over recent years (Woodgate et al., 2015; Woodgate, 2018). Geographic coordinates (latitude, longitude) were converted to projected coordinates using the North Pole Lambert Azimuthal Equal Area (LAEA) Alaska projection (EPSG: 3572, https://epsg.io/3572, accessed 16 September, 2019) prior to the inertia calculation to minimize the distortion in lengths, areas, and angles at the poles (Skopeliti and Tsoulos, 2013).

Correlations with Climate Indices

To examine how larval growth and connectivity may change under variable climate forcing, we developed COG indices from the simulation output. Anomalies were calculated as deviations from the mean latitude and longitude values for the 2004 – 2015 period normalized by the standard deviation. Larval indices were then compared to several climate indices thought to influence circulation in the Bering and Chukchi seas (Fig. S3). The large-scale climatic indices selected were the winter (December – February) Arctic Oscillation (AO) index, which represents the first empirical orthogonal function (EOF) pattern of sea level pressure (SLP) from 20 – 90°N regressed to the SLP anomaly time series (Thompson and Wallace, 1998); the Arctic Dipole (AD) index, which is the first EOF pattern of 70 – 90°N regressed to the SLP anomaly time series (Wu et al., 2006); and the Siberian-Alaskan (SA) index, which provides a measure of atmospheric circulation based on a correlation between sea ice cover and the 700 hPa geopotential height gradient between Siberia and Alaska, that can be used to estimate thermal conditions in the Bering Sea and ice cover extent (Overland et al., 2002). All indices were obtained from NOAA's Bering Climate website (https://www.beringclimate.noaa.gov/data/index.php, accessed 6 June, 2019).

An index representing ice extent and timing of retreat (IER) was developed for 2005 – 2015 based on the findings of Okkonen et al. (2019), where sea ice areal extent and concentration from April 1 through the third week of August were compared to late August water masses encountered during surveys in Barrow Canyon. Okkonen et al. (2019) found that greater daily sea ice extents and slower/later sea ice retreats occurred in years when the August late season meltwater (LMW) volumes in Barrow Canyon were greater than the 2005–2015 mean (2006, 2008, 2009, and 2012–2014; IER index = 1 in this study), while smaller daily sea ice extents and faster/earlier sea ice retreats occurred in years when August LMW volumes were less than the 2005–2015 mean (2005, 2007, 2010, 2011, and 2015; IER index = 0 in this study).

Correlations between the annual climate indices and the annual COG anomalies between 2004 and 2015 from the selected spawning/hatching areas were calculated for all hatch dates using Pearson's Product Moment Correlation. Correlations with the SA index were calculated for 2004 – 2013, as data beyond 2013 were not available. Similarly, correlations with the IER index were only calculated for 2005 – 2015, as 2004 data were not available. All statistical analyses were carried out in R (R Core Team, 2018).

Results

We found variations in simulated lengths-at-age between hatching areas and hatch dates for both polar cod and saffron cod. Overall, polar cod larvae that hatched from more southerly locations (Gulf of Anadyr, St. Lawrence Island), attained a greater length at the end of the simulation than those originating from the more northerly hatching locations (Fig. 4 a, b). This difference was more apparent in larvae hatched earlier in the year compared to those that hatched at later dates. Differences in length were also

evident between years, with more variability in both simulated and observed polar cod lengths in 2013 compared to 2012 (Fig. 4 a, b). Saffron cod were much smaller in size at the end of the simulation than polar cod (Fig. 4) due to faster growth of polar cod at low temperatures (Fig. 2). While saffron cod lengths differed between southerly and northerly hatching locations, the difference was not as great as that found for polar cod, again, likely due to slower growth of saffron cod at low temperatures. The difference in length remained fairly consistent across hatch dates in 2012, but was less apparent in 2013 (Fig. 4 c, d). Despite some overlap, simulated sizes based on lab-derived growth were smaller than the sizes observed in the Arctic EIS acoustic-trawl survey (Fig. 4). This overlap was much greater for polar cod and nearly absent for saffron cod (Fig. 4).

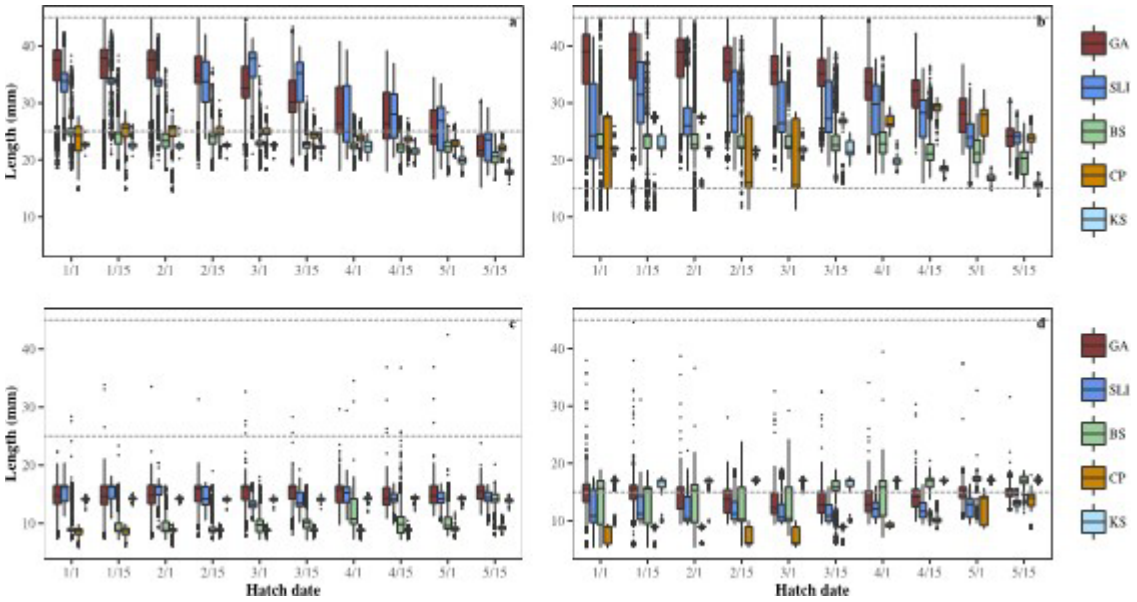

Fig. 4. Simulated lengths of (a, b) polar cod (*Boreogadus saida*) and (c, d) saffron cod (*Eleginus gracilis*) larvae and early juveniles ≤ 45 mm in length located within the Arctic Ecosystem Integrated Survey acoustic-trawl survey area on 1 September (a, c) 2012 and (b, d) 2013. Simulations were initiated from five hypothesized areas on 10 hatch dates. Data presented are from simulations with surface-oriented behavior, which had the strongest correlations with the acoustic-trawl survey data. The dashed grey lines represent the minimum and maximum lengths estimated by the survey (to 45 mm). GA: Gulf of Anadyr; SLI: St. Lawrence Island; BS: Bering Strait; CP: Chukotka Peninsula; KS: Kotzebue Sound. The minimum, first quartile (Q1), median, third quartile (Q3), maximum, and outliers are represented.

Data-model comparison with acoustic-trawl surveys

We found distinct differences in larval distributions between the different behavior scenarios, particularly for those simulations with a passive component (Fig. S4). Behavior scenarios that included a surface component produced relatively similar distributions, especially for the simulations with and without DVM for surface-oriented early larvae that moved deeper with ontogeny, which had almost identical distributions (Fig. S4, Tables 3 and 4). Simulated and observed polar cod larval distributions were not significantly correlated for any of the hatching locations in 2012, except for larvae with surface-oriented behavior that were released around Bering Strait and the Chukotka Peninsula (Table 3). Significant positive correlations were also found for simulations from the Chukotka Peninsula with all other behavioral scenarios except that with DVM (Table 3). Earlier hatching larvae resulted in significant

overlap with observed distributions from the Bering Strait release location, while the correlations for the Chukotka Peninsula simulations were significant across all release dates (Table 3). No significant correlations were found between observed and simulated distributions of polar cod in 2013 (not shown).

Table 3. Correlations between observed distributions of polar cod (Boreogadus saida, larvae and early juveniles ≤ 45 mm in length) in the 2012 Arctic Ecosystem Integrated Survey acoustic-trawl survey and simulated distributions on 1 September from 5 different behavior scenarios. Particles were released at 5 locations (Gulf of Anadyr, St. Lawrence Island, Bering Strait, Chukotka Peninsula, and Kotzebue Sound) on the 1st and 15th of each month from 1 January – 15 May. **p-value < 0.05 (darker shading), *0.05 ≤ p-value < 0.10 (lighter shading). p = p-value, n = number of simulated larvae found within the survey grid.

For saffron cod, the simulations that produced results most similar to observed field distributions in 2012 were those initiated from Bering Strait and Kotzebue Sound. Simulations initiated from Bering Strait were significantly correlated for all simulation behaviors across most simulation dates, while those initiated from Kotzebue Sound were significant across all behaviors and dates (Table 4). Early passive particle simulations from the Chukotka Peninsula (15 January – 1 March) were also marginally or significantly correlated with observations (Table 4). No significant correlations were found for other release locations. Similar to the 2012 results, most simulations in 2013 from Bering Strait and Kotzebue Sound produced distributions that were significantly correlated to observed distributions of saffron cod in the acoustic-trawl survey (not shown). For both 2012 and 2013 simulations, the majority of correlations were strongest for later release dates (Table 4 for 2012, not shown for 2013). Correlations with release depth did not reveal any patterns for either species, except for saffron cod simulations initiated in Kotzebue Sound, where correlations were significant for all release depths across all behaviors (not shown). Note that most release dates occurred in winter and spring months, when the shallow Chukchi

and Bering shelf water columns exhibit relatively weak stratification. Hence, current-induced turbulent motions can readily redistribute passively floating plankton through the water column at this time of year.

Table 4. Correlations between observed distributions of saffron cod (Eleginus gracilis, larvae and early juveniles ≤ 45 mm in length) in the 2012 Arctic Ecosystem Integrated Survey acoustic-trawl survey and simulated distributions on 1 September from 5 behavior scenarios. Particles were released at 5 locations (Gulf of Anadyr, St. Lawrence Island, Bering Strait, Chukotka Peninsula, and Kotzebue Sound) at bi-weekly intervals from 1 January – 15 May. **p-value < 0.05 (darker shading), *0.05 ≤ p-value < 0.10 (lighter shading). p = p-value, n = number of simulated larvae found within the survey grid.

Interannual variability in simulated distributions

Large interannual variability in the COGs of simulated particles was found for polar cod, particularly for the Chukotka Peninsula release locations. The COG across simulation years (2004 – 2015) was located in the western portion of the Chukchi Sea, southwest of Herald Shoal (Fig. 5 a), similar to the centers of gravity in 2008, 2013, and 2015. For 2004 – 2006, the COGs shifted to the southwest, while that in 2012 was to the southeast (Fig. 5 a). In 2007, 2011, and 2014, particles were located further north compared to the 2004 – 2015 COG. In 2009, the COG was in the eastern portion of the Chukchi Sea, east of Herald Shoal, while in 2010, it was in the western Chukchi Sea, just south of Wrangel Island (Fig. 5 a). Most of the COGs for the Bering Strait release location were found in close proximity to Cape Lisburne, located north and south of the cape for the majority of the time series. The only exceptions were in 2005, when the COG was located near Herald Shoal, and in 2007, when it was farther north of Cape Lisburne compared to in other years (Fig. 4 a). The COGs of saffron cod released from the Bering Strait region were similar to those of polar cod and were mainly centered around Cape Lisburne (Fig. 5 b). In 2005, the COG was over Herald Shoal, while in 2007 it was located to the north of Cape Lisburne (Fig. 5 b). The COGs for particles released in Kotzebue Sound were found on the north side of the sound, located around Cape Krusenstern (Fig. 5 b), suggesting retention within Kotzebue Sound.

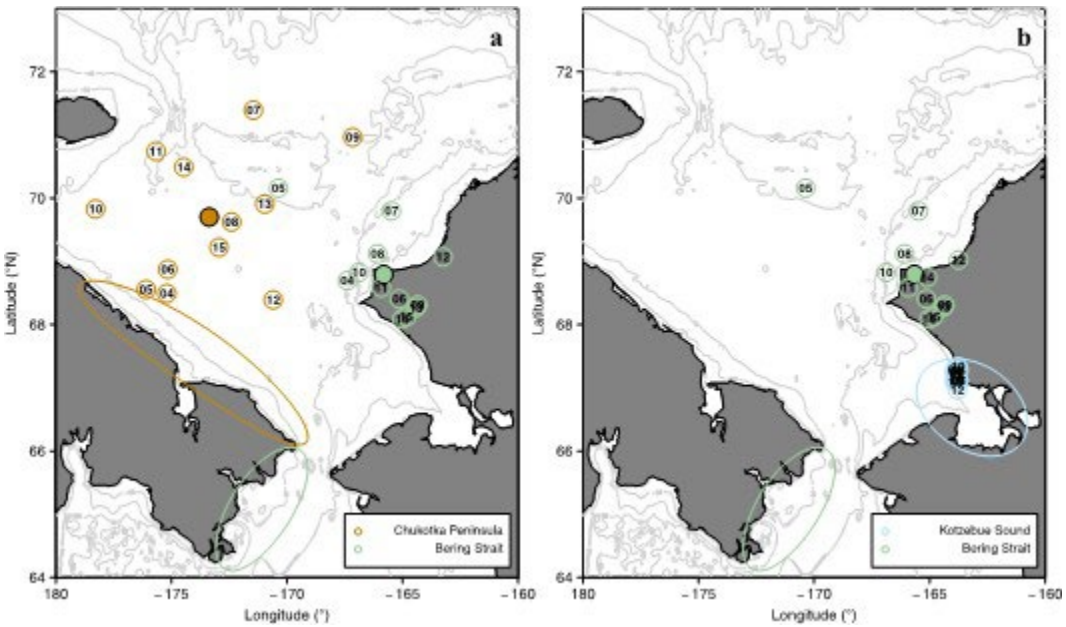

Fig. 5. Mean latitude and longitude of (a) polar cod (Boreogadus saida) and (b) saffron cod (Eleginus gracilis) larvae and early juveniles ≤ 45 mm in length on 1 September from 2004 – 2015. Simulations for polar cod were initiated from Bering Strait (green) and the Chukotka Peninsula (orange). Simulations for saffron cod were initiated from Bering Strait (green) and Kotzebue Sound (blue). Data from simulations with surface-oriented behavior are presented. Solid circles represent overall centers of gravity for 2004 – 2015, color coded to release location. Numbers in circles represent the last two digits of the simulation year. Ellipses represent particle release locations.

Polar cod inertia between 2004 and 2015 was highly variable for both the Bering Strait and Chukotka Peninsula simulations (Fig. 6). Bering Strait had a mean inertia of 97,755 km2 and a SD of the major and minor axes of ± 260,074 km2 and ± 173,542 km2, respectively. The Chukotka Peninsula had a mean inertia of 123,034 km2 and a SD of the major and minor axes of ± 283,059 km2 and ± 207,150 km2, respectively. For Bering Strait releases, inertia declined significantly over time (linear regression, LR: β = -5894, t10 = -3.129, p = 0.011), while it increased over time for simulations originating from the Chukotka Peninsula, although not significantly (LR: β = 4914, t10 = 1.568, p = 0.148). Similar to polar cod, saffron cod inertia for the Bering Strait release location was highly variable (95,729 ± 261,437 and 165,469 km2) and declined significantly over time (LR: β = -5044, t10 = -2.611, p =0.026). Inertia for simulations originating in Kotzebue Sound was very low (15,475 ± 115,195 and 46,956 km2) and remained relatively constant over time (LR: β = -106.2, t10 = -0.384, p = 0.709).

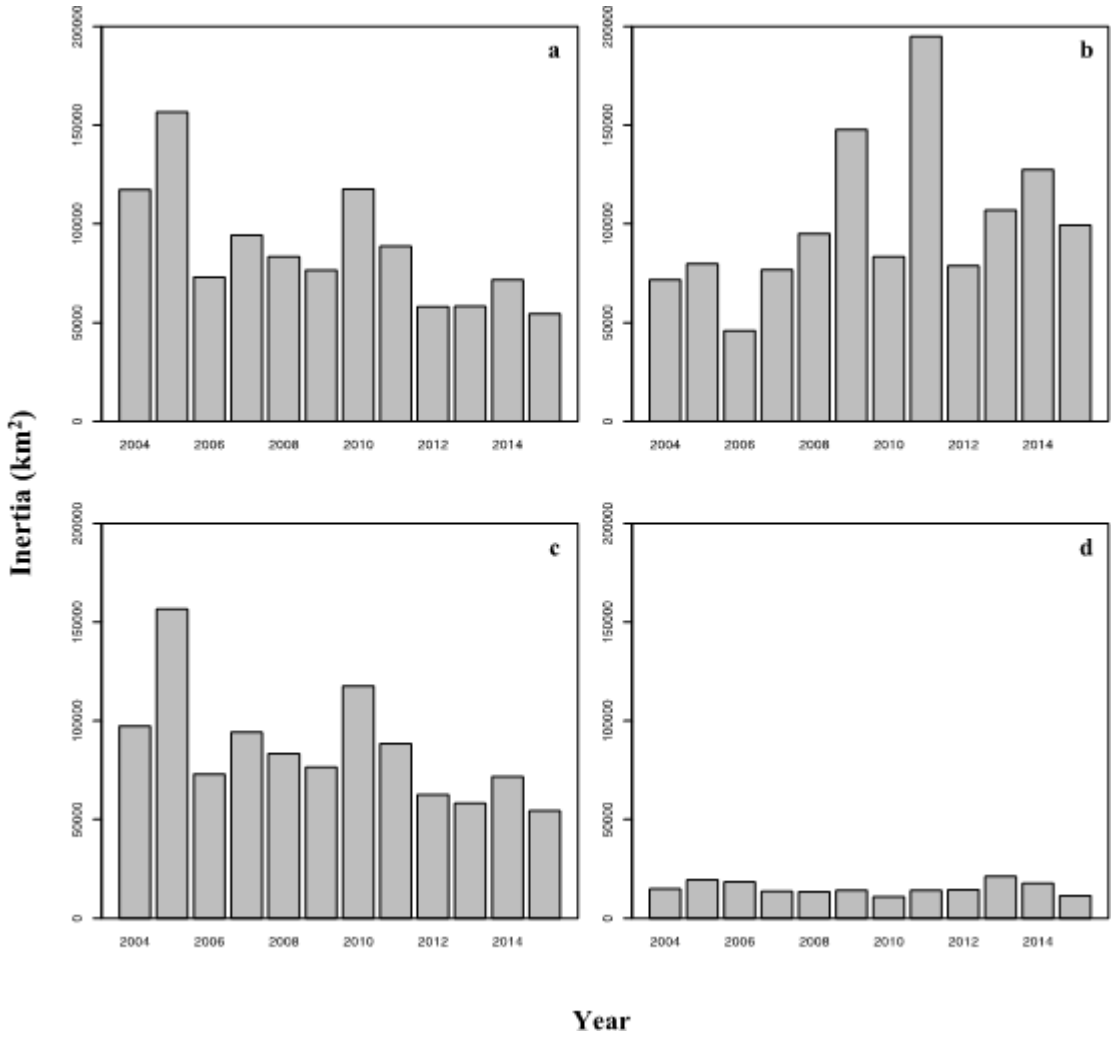

Fig. 6. Inertia (in km2), which measures the dispersion of simulated particles around the center of gravity, for polar cod (Boreogadus saida) simulations from (a) Bering Strait and the (b) Chukotka Peninsula and saffron cod (Eleginus gracilis) simulations from (c) Bering Strait and (d) Kotzebue Sound from 2004 – 2015. Data from simulations with surface-oriented behavior are presented.

Correlations with Climate Indices

Significant correlations were found between latitudinal and longitudinal COG indices for both polar cod and saffron cod at the end of the simulation and several of the climate indices, although correlations were not consistent across release areas or dates (Tables 5, 6). Simulated particles from the Bering Strait region for both species tended to have a more southern and eastern COG during years with a strong summer AD index, a weaker SA index, and more extensive ice (IER index = 1). In most cases, these correlations were stronger for later release dates (March – May). Similarly, the COG of simulated polar cod released at the Chukotka Peninsula were further south and east when the summer AD and AO indices were high and ice was extensive and retreated later (IER index = 1). In contrast to Bering Strait releases, the COG of simulated particles from the Chukotka Peninsula, in particular early releases, occurred further south during years with a stronger SA index, as evidenced by negative correlations with latitude (Table 5). For saffron cod from the Kotzebue Sound release locations, environmental variability appeared to primarily affect the longitudinal COG of early releases but the latitudinal COG from later releases. Simulated

particles from earlier release dates were displaced to the east during years with stronger AO and SA indices and a weaker winter AD index, all indicative of cold winters with heavy ice. Correlations with the latitudinal COG were variable and inconsistent (Table 6).

Table 5. Correlations between latitude and longitude center of gravity (COG) anomalies of simulated polar cod (Boreogadus saida, larvae and early juveniles ≤ 45 mm in length) on 1 September (2004 – 2015) and selected climate indices. AD: Arctic Dipole index, MAM: March, April, May, JJA: June, July, August; AO: Arctic Oscillation index; SA: Siberian/Alaskan index (2004 – 2013); IER: Ice extent/retreat index (2005 – 2015). Simulations were initiated from Bering Strait and Chukotka Peninsula release locations using surface-oriented behavior. **p-value < 0.05 (darker shading), *0.05 ≤ p-value < 0.10 (lighter shading). Red (blue) represents a positive (negative) correlation.

When the five climate indices were compared over the 2004 – 2015 period, no obvious trends were noted (Fig. S3), though the summer AD index was negative from 2004 – 2012 (Fig. S3 b) and the SA index was positive between 2004 – 2008 (Fig. S3 d). Correlations between the climate indices were not significant (Table S1).

Discussion

Results of our biophysical transport modeling study suggest that the source of aggregations of polar cod and saffron cod larvae and early juveniles observed in the Chukchi Sea during the 2012 and 2013 Arctic EIS surveys were most likely from the northern Bering Sea or the southern Chukchi Sea. In particular, Bering Strait and the Chukotka Peninsula were identified as potential spawning and/or hatching locations of polar cod. Our findings support other research that has suggested the existence of a number of nearshore, shallow spawning grounds in the North American and Siberian Arctic (Craig et al., 1982; Thanassekos and Fortier, 2012; Logerwell et al., 2015). In addition, our results align well with those of Ponomarenko (1968) and Sunnanå and Christiansen (1997), which suggested that polar cod spawn in the northern Bering and southern Chukchi seas. For saffron cod, simulations that produced results most similar to observed field distributions were those initiated from Bering Strait and Kotzebue Sound. Saffron cod are believed to spawn demersally under ice in shallow, nearshore areas (Morrow, 1980; Fechhelm et al., 1985; Wolotira, 1985; Johnson, 1995; Mecklenburg et al., 2002) and our results are supported by observations of saffron cod in spawning condition in nearshore areas along the coast, such as Kotzebue Sound (A. Whiting, Native Village of Kotzebue, personal communication). Strong and consistent correlations between field observations and modeled distributions across several behaviors and over a wide range of dates lends further support to the hypothesis that Kotzebue Sound is an important spawning habitat for saffron cod. Furthermore, correlations between simulated and observed saffron cod distributions were strongest from early April to mid-May. These results match well with the timing of

peak hatching for saffron cod, which occurs in April and May, prior to the warming of coastal waters in the Arctic and northern Pacific (Wolotira, 1985).

Simulated distributions and sizes of polar cod overlapped with those estimated by the Arctic EIS program's acoustic-trawl survey in 2012, yet there was poor overlap in 2013, as evidenced by the lack of significant correlations with any of the release locations or dates in that year. A comparison of particle locations on 1 September showed strong variability in dispersal patterns between the two years, with reduced overlap of particles with the Arctic EIS survey grid in 2013 (18.72%) compared to 2012 (22.05%)(Fig. S1). In 2012, simulated particles on the Chukchi Shelf were concentrated along the Central Channel or the Western Pathway towards Herald Canyon. Additional concentrations were found along the Alaskan coastline and formed a thick band between Herald and Hanna shoals, which extended eastward towards the coast between Icy Cape and Wainwright, and towards the head of Barrow Canyon (Fig. S1). High concentrations of simulated larvae in this region are in agreement with other studies that have noted high abundances of polar cod ELS in the northern Chukchi Sea offshore of Wainwright (De Robertis et al., 2017b; Vestfals et al., 2019; Deary et al., in review). In contrast, simulated polar cod in 2013 were mainly distributed outside of the Arctic EIS survey grid (Fig. S1) and found mostly outside of the areas of the shelf that were occupied in 2012. There were some similarities between the two years, mainly along the Alaskan coastline and in the region between Herald and Hanna shoals, towards Icy Cape and Wainwright, although the band in 2013 was narrower (Fig. S5 – S6). Higher concentrations of simulated larvae and early juveniles were found in the western portion of the Chukchi Sea in 2013, along the Chukotka Peninsula and in Long Strait, with additional particles taking a more westward route towards Herald Canyon, over the northern Chukchi shelf, and across the shelf break compared to 2012. While the majority of particles (81.27%) were outside of the Arctic EIS survey area in 2013, limited ichthyoplankton sampling in the western and northern Chukchi Sea in 2004, 2009, and 2012 during the Russian-American Long-Term Census of the Arctic (RUSALCA) program encountered high abundances of polar cod larvae and early juveniles in these areas, and as far west as the East Siberian Sea (Norcross et al., 2006; Vestfals et al., 2019; M. Busby, NOAA, unpublished results).

Simulated distributions of saffron cod from the Bering Strait release location were similar to those of polar cod (Fig. S7). Given that the starting locations and behavior scenarios were identical between species, the distributional differences can be attributed to the different temperature-dependent growth rates used for each species in the IBMs. As fish grow, changes in body length affect their swimming speed. This, in turn, affects their vertical position in the water column, and ultimately, the horizontal transport of their ELS through exposure to different flow schemes (Vikebø et al., 2005; Fiksen et al., 2007; Leis, 2007). Here, the slower growth rates of saffron cod would result in individuals being located in the surface layer for longer in comparison to polar cod. Particles from simulations initiated in Kotzebue Sound were consistently retained within the Sound or were advected northward along the Alaskan coastline (Fig. S8). Age-0 saffron cod are known to occupy shallow, nearshore habitats (Wolotira, 1985; Logerwell et al., 2015; De Robertis et al., 2017b) and have been found in high abundances from Kotzebue Sound to north of Cape Lisburne in late summer (De Robertis et al., 2017b; Vestfals et al., 2019). Recent surveys in the eastern Chukchi Sea in 2017 encountered high abundances of saffron cod larvae around Kotzebue Sound in late spring, though by late summer they were found in nearshore areas from northern Kotzebue Sound to around Cape Lisburne (Deary et al., in review). These findings, combined with our modeling results, suggest that saffron cod spawned in Kotzebue Sound are retained there or are transported northwards by currents to juvenile nursery habitats along the coast. Over time, fish have evolved to spawn in areas where bathymetric features and prevailing currents transport their larvae to or retain them within suitable nursery habitats (Iles and Sinclair, 1982; Bailey and Picquelle, 2002; Bailey et al., 2008; Duffy-Anderson et al., 2013). Satellite tracked drifters with near-surface drogues (Danielson and Whiting, 2016) and numerical modeling (Panteleev et al., 2013) show that a gyre forms in Kotzebue Sound, which was also evident in the PAROMS model output. Hence, the circulation in and around Kotzebue Sound may be especially conducive to larval retention and/or delivery to juvenile nursery

habitats. The retentive nature of Kotzebue Sound is also supported by the results of our analyses, which showed COGs that were consistently located in northern Kotzebue Sound (Fig. 5 b), along with low inertia over the time series (Fig. 6 d).

The strong year-to-year variability in simulated distributions of polar cod and saffron cod suggests that transport of their early life stages is highly sensitive to variations in flow across the Chukchi shelf. Only simulations from Kotzebue Sound showed relatively consistent dispersal patterns between years. Observed differences in simulated particle distributions across the broader Chukchi Shelf in 2012 and 2013 can be linked to differences in oceanographic and atmospheric conditions between the two years. In 2013, persistent northeasterly winds in late summer led to flow reversals over much of the northeast Chukchi Sea, which limited the northward extent of the ACC and advected Arctic waters onto the Chukchi Shelf via Barrow Canyon (Danielson et al., 2017). This is consistent with simulated particles following a more westward pathway along the shelf in 2013, compared to 2012 (Fig. S1). The inflow of Pacific waters through Bering Strait is bathymetrically steered along either Herald Canyon, the Central Channel, or along the Alaskan coast; however, this inflow can be driven towards the western portion of the shelf during periods with easterly winds (Windsor and Chapman, 2004). Similarly, Bond et al. (2018) described a stronger than normal flow pattern through Bering Strait, where a disproportionate portion of the flow travels northwest toward and beyond Wrangel Island rather than joining the ACC, which they linked to anomalous winds from the east-northeast. Indeed, winds were more persistent from the northeast and annual transport through Bering Strait was higher in 2013 (~1.1 Sv) compared to 2012 (~0.7 Sv) (Woodgate et al., 2015).

One curious aspect of the modeled larval aggregations was that they appeared to aggregate in long banded arrangements stretching from the Barrow Canyon region in the NE Chukchi Sea across the shelf toward the west. Examination of the model hydrographic fields in 2012 (Fig. S9) revealed that the larvae were accumulating in the vicinity of the ice-edge frontal zone (Fig. S9 a), which is delineated by a change of density (salinity (Fig. S9 e) and temperature (Fig. S9 c)) from the open water zone south of the marginal ice zone to under the pack ice. Recent investigations into the hydrographic structure associated with ice edge fronts and the melting of ice on the Chukchi shelf has revealed convergent zones associated with the ice and thermohaline fields (Lu et al., 2020a; 2020b). These frontal zones can extend several meters (up to 15 m) below the surface and likely provide enhanced feeding opportunities for surface-oriented larvae and early juveniles by maintaining them in close proximity to the ice edge, where they can take advantage of copepod production fueled by ice-edge phytoplankton blooms (Søreide et al., 2010; Perrette et al., 2011), as well as the higher concentrations of food particles that tend to accumulate in convergent frontal zones (Bakun, 2006). For surface-oriented larvae, these frontal zones may act as a barrier to northward advection, however, this may not be the case for species that live at or migrate to depths below the vertical extent of the frontal zone. Much work remains to be done to determine to what extent polar cod larvae in the field are actually subject to the influences of the convergent ice-edge fronts, but the combination of our work and the ice edge modeling study raises many interesting questions, provides new testable hypotheses, and provides new ways to think about the early life stages of polar cod and other Arctic species.

Correlations between location indices derived from the simulation output and several climate indices provide evidence that dispersal of polar cod and saffron cod ELS are likely sensitive to environmental forcing. During periods that were characterized by colder conditions in the Pacific Arctic (i.e., a positive AO index, with a strong jet stream that retains cold air over the polar region (Thompson and Wallace, 2000); a negative AD index, where more sea-ice remains in the western Arctic (Watanabe et al., 2006; Wu et al., 2006); a positive SA index, with anomalously strong northwesterly winds and heavy ice cover (Fang and Wallace 1994; Overland et al., 2002); and a greater ice extent and later ice retreat (Okkonen et al., 2019)), cod ELS were found farther south and east compared to periods that represented warmer conditions in the region. The findings of our study have important implications for polar cod and saffron cod connectivity between the Chukchi and Beaufort seas. Our results suggest that in warmer years with

greater Pacific inflow and an earlier sea-ice retreat (e.g., 2005, 2010, and 2011 in Figs. S5 – S8), a higher proportion of larvae spawned in the northern Bering or southern Chukchi seas would be transported northwestward towards Herald Canyon and across the northern Chukchi shelf (see Okkonen et al., 2019, their Fig. 6B), which would result in a greater contribution to populations in the northern Chukchi and western Beaufort seas. In contrast, during colder years with reduced Pacific inflow and a later ice retreat (e.g., 2006, 2009, and 2012 in Figs. S5 – S8), larvae would be advected along the ice edge towards the Alaskan coast, with a greater proportion of the population retained in the eastern Chukchi Sea (see Okkonen et al., 2019, their Fig. 6A). The timing and pattern of sea-ice retreat across the Chukchi shelf has been linked to the strength of the Pacific-Arctic pressure head, which is influenced by the strength and location of the Beaufort Sea High pressure cell and its associated winds (Danielson et al., 2014; Okkonen et al., 2019). A stronger Pacific-Arctic pressure head (i.e., 2005, 2007, 2009, 2011, and 2015) was associated with greater northward volume and property fluxes along the Alaskan coast (i.e. a stronger Alaska Coastal Current), which promoted earlier ice retreat across the eastern Chukchi shelf (Okkonen et al., 2019). In contrast, a weaker pressure head (i.e., 2006, 2008, 2010, 2012 – 2014) was associated with lower volume and property fluxes along the Alaskan coast and slower, less directionally-biased ice retreat across the Chukchi shelf (Okkonen et al., 2019). Similarly, Luchin and Panteleev (2014) found that during warm years, the inflow of Pacific water through Bering Strait spread widely along the Siberian coast, with extensive transport through Herald Channel. In cold years, however, the inflow of warm Pacific water was reduced and mostly flowed along the Alaskan coast before exiting the shelf through Barrow Canyon. Thus, as continued Arctic warming further impacts sea-ice extent and timing of sea ice retreat in the Chukchi Sea, we anticipate that polar cod and saffron cod ELS will be affected by concomitant changes in flow across the shelf, which will likely affect population connectivity between the northern Bering, Chukchi and Beaufort seas.

Simulations that produced saffron cod distributions most similar to Arctic EIS field observations were those initiated from Bering Strait and Kotzebue Sound, particularly those with a passive component. This result was not surprising, as saffron cod larvae grow slowly at low temperatures and as such, their dispersal is more likely to be affected by currents than by their behavior. However, larvae are not passive particles that drift along with currents and even first-feeding larvae have the ability to control temperature, salinity, light, turbulence and food concentrations by migrating vertically, which in turn contributes to their horizontal movement (Norcross and Shaw, 1984; Boehlert and Mundy, 1988; Hare and Govoni, 2005; Hurst et al., 2009). Late-stage larvae and pelagic juveniles have also been shown to have considerable control over their speed, direction, and position in the water column (Olla et al., 1996; Leis and Carson-Ewart, 1997, 1999). Even slight differences in behavior can have long-term and large-scale consequences, since vertical positioning influences the drift trajectory of the larva, and thereby the physical environment it experiences along the way (Vikebø et al., 2007). Our simulation results showed that behavior did indeed have a strong effect on larval dispersal (Fig. S4, Tables 3 and 4). While detailed information about the vertical distribution of saffron cod larvae is not currently available, newly hatched larvae spend between 2–3 months as plankton before descending to the bottom in mid-summer, between 39 and 56 mm in length in the Pacific and 55 and 60 mm in the Arctic (Wolotira, 1985); larger age-0 fish can still be found in surface waters in late summer (Eisner et al., 2012). Similarly, polar cod larvae have been shown to be surface-oriented in the first few months of life (Spencer et al., 2020; B. Laurel, unpublished results), moving deeper as they develop (Borkin et al., 1986), with pelagic juveniles descending deeper in the water column in late summer, between 30 and 55 mm in length (Matarese et al., 1989; Ponomarenko, 2000; Bouchard and Fortier, 2011). Recent repeat acoustic surveys in the eastern Chukchi Sea from mid- to late-summer in 2019 indicated that age-0 polar cod moved deeper in the water column and underwent DVM as the season progressed (Levine et al., 2020). While these data were not available at the time of our study, this behavior was considered in our preliminary simulations, as previous research has shown that polar cod undergo DVM in other areas of the Arctic (Borkin et al., 1986; Bouchard et al., 2016). However, the sizes at which fish begin their DVM and the depths to which they migrate had to be estimated for the Chukchi Sea, which is shallower (< 40 m) than the other regions

where DVM behavior has been observed. We ultimately chose the surface-oriented behavior to model growth and dispersal from 2004 – 2005, as this behavior was most strongly correlated with observed distributions in the field, though the overall results and conclusions were similar when based on the more complex surface-oriented behavior for early larval stages that moved deeper with ontogeny (C. Vestfals, unpublished results). The new information provided by the repeat acoustic surveys on the depth distribution of polar cod ELS, the sizes at which they begin to vertically migrate, and the depths to which they migrate (Levine et al., 2020) will be invaluable to future modeling efforts in the Chukchi Sea.

While climate-driven changes in advective transport and mixing will affect the dispersal and ultimately the distribution of larvae, the temperatures they experience during the drift period will, in turn affect their growth rates and their survival (Vikebø et al., 2005, 2007). We found differences in simulated lengths on 1 September between release locations, hatch dates, and species. The greater lengths attained by larvae hatching in southern locations can be attributed to warmer temperatures in the Bering Sea, in general, which results in faster growth of larvae hatching there compared to the Chukchi Sea. In spring, solar heating and the inflow of warmer water from the Bering Sea leads to rapid warming in the Chukchi Sea. Thus, the temperature conditions experienced by larvae hatching at later dates are more similar between regions compared to those hatching during the winter months. While polar cod simulated lengths aligned fairly well with fish ≤ 45 mm in length observed in the Arctic EIS acoustic-trawl survey, those for saffron cod did not, with much smaller simulated sizes than field estimates. The differences in simulated sizes between species result from assuming higher growth rates at lower temperatures for polar cod compared to saffron cod based on laboratory studies (Laurel et al., 2016; B. Laurel, unpublished results). The difference between observed and simulated lengths for saffron cod could have resulted from incorrectly specified growth in the IBM, incorrect temperatures in the model, strong size-selective mortality, incorrect assumptions about hatch dates, or other factors. It should be emphasized that the final estimates of acoustic-trawl survey abundance at length were sensitive to the selectivity parameters used in the calculations, particularly for the smallest size classes, which are poorly retained by the trawls (De Robertis et al., 2017a, b). In particular, 2012 abundance estimates for fish < 25 mm in length were effectively zero for both species across the entire survey region, which was most certainly due to the ineffectiveness of the Cantrawl gear at catching these smaller-sized fish, rather than a lack of presence of these sizes over the eastern Chukchi shelf. While use of the modified Marinovich trawl in 2013 improved the abundance estimates of fish in the 15 – 25 mm range, estimated abundances of fish < 15 mm remained at zero across the entire survey region, which clearly does not reflect their true abundance and distribution. Recent studies of polar cod and saffron cod ELS in the Chukchi Sea have found the presence of larvae < 25 mm in length in the Arctic EIS survey area during late summer (Vestfals et al., 2019; Deary et al., in review). In other regions of the Arctic, polar cod lengths in late summer can vary in size from 10 mm for fish hatched late in July, to 50 mm for young-of-the-year fish hatched early in January (Bouchard and Fortier, 2011). Thus, our simulation results for polar cod from the northern hatching locations (Bering Strait, Chukotka Peninsula, Kotzebue Sound) and saffron cod, in general, may reflect sizes in the field not captured in the acoustic-trawl survey estimates. However, our models clearly underestimated growth in both species. Field-based estimates of polar cod growth range from 0.27 – 0.51 mm day-1 (Bouchard and Fortier, 2011; Vestfals et al., 2019; Deary et al., in review), which are higher than the laboratory estimates used in this study (0.04 – 0.46 mm day−1, Koenker et al., 2018; Laurel et al., 2017), particularly for smaller polar cod larvae and those growing at lower temperatures (Fig. 2). As only the survivors of size-based predation are encountered in field samples, which selects for faster growing individuals (Bailey and Houde, 1989; Litvak and Leggett, 1992), field-based growth estimates are often higher than those derived in the laboratory because fish larvae are known to grow and survive better on natural prey (Sargent et al., 1999; Evjemo et al., 2003).

The laboratory-derived growth rates used in our model likely underestimated saffron cod growth in the field, which contributed to the smaller simulated lengths compared to the lengths estimated by the Arctic EIS acoustic-trawl surveys. Unfortunately, a growth equation for larger stages of saffron cod is not

currently available and we used growth of a related gadid, walleye pollock, to model growth in the IBM. While walleye pollock ELS exhibit linear growth similar to that of saffron cod (Porter and Bailey, 2007; B. Laurel, NOAA, personal communication), some component of saffron growth was not fully captured in our model. Saffron cod may have a specific size or thermal range at which growth increases exponentially, or a particular habitat factor may influence their growth. Growth of saffron cod might be slow and constant during early development, but this could be followed by a period of rapid acceleration in growth. For example, Pacific hake (Merluccius productus), another North Pacific gadiform with a similar trophic role to saffron cod, grow slowly in the first 3 months of life (< 30 mm SL), after which their growth accelerates (Bailey, 1982; Bailey et al., 1982; Woodbury et al., 1995). Saffron cod may also experience faster growth in nearshore regions, with under-ice river plumes in coastal areas providing a thermal refuge for developing eggs and larvae during winter and early spring via relatively warmer freshwater runoff (Bouchard and Fortier, 2011). The solar-heated waters in Kotzebue Sound, Norton Sound, and coastal areas to the south provide a major source of the heat to the Alaska Coastal Current (Coachman et al., 1975; Ahlnäs and Garrison, 1984) and may also provide a thermal habitat conducive for optimal growth in saffron cod. Indeed, temperatures in Kotzebue Sound in July can exceed 12°C (Ahlnäs and Garrison, 1984), which exceeds thermal optima for some gadids, but is near the temperature of maximum growth for age-0 saffron cod (Tmax = 14.8°C) found in the lab (Laurel et al., 2016).

There are some limitations to using observations from the 2012 and 2013 Arctic EIS acoustic-trawl survey to validate our simulation results. The acoustic-trawl surveys were limited in their spatial extent and did not cover the inshore region or more northern areas of the Chukchi and Beaufort seas, or the Arctic Basin. Polar cod and saffron cod larvae may be present in these locations, so without further sampling, it is important not to rule out the northern locations as potential spawning or hatching areas. Results from the initial passive particle simulations showed that polar cod larvae hatching from more northern locations (Cape Lisburne, Hanna Shoal, and Barrow Canyon) were transported into nearshore regions in the northern Chukchi and Beaufort seas, as well as into the Arctic Basin. Due to the lack of overlap between simulated larval distributions and the Arctic EIS survey grids, which prevented model validation with field observations, further simulations from these hatching locations were not explored. However, these northern spawning/hatching locations in the Chukchi Sea may be a source of larvae for the Beaufort Sea and Arctic Basin. Indeed, small polar cod and saffron cod larvae corresponding to the sizes observed in our preliminary simulations from northern hatch locations (see Fig. S2) were collected in August 2008 around Barrow Canyon (Logerwell et al., 2015) and in 2017, small polar cod larvae were collected beyond the Chukchi shelf break in late summer/early fall (M. Busby, NOAA, personal communication.). High abundances of age-0 polar cod may also be present in the western portion of the Chukchi Sea outside the Arctic EIS survey area, as suggested by our simulations. This is consistent with large aggregations of age-0 polar cod along the western edge of the survey area in 2017, and to a lesser extent in 2019 (A. De Robertis, NOAA, R. Levine, UW, personal communication).

The PAROMS model used to drive the polar cod and saffron cod IBMs has been shown to resolve important oceanographic processes [e.g. mean flows and flow variances, wind-driven currents, continental shelf waves, seasonality of ice, and annual volume, heat, freshwater, and ice transport (Curchitser et al., 2013, 2018; Danielson et al., 2016; Danielson et al., 2020) and biological covariates (Rand et al., 2018; Lovvorn et al., 2020). Although PAROMS has relatively fine resolution (e.g. front-resolving and eddy-permitting) for basin-scale models covering a region as broad as the whole Arctic, it undoubtedly fails to accurately reproduce some submesoscale dynamics that could be important in the transport of polar cod and saffron cod larvae to nursery areas. Nonetheless, we believe that our polar cod and saffron cod IBMs can improve our understanding about the growth, transport, and connectivity of these species in the Pacific Arctic and provides an important framework for examining transport in other key arctic species.

Conclusions

We developed the first individual-based, biophysical transport models for polar cod and saffron cod in the Pacific Arctic, which we used to reproduce observed late summer distributions of their ELS in the Chukchi Sea. The results of this study provide important information about these key forage fishes. In particular, we have identified potential spawning locations and nursery habitats for larvae and early juveniles, and have shown how the growth and dispersal of their ELS change in response to variable climate forcing. The source of observed aggregations of polar cod on the Chukchi shelf appear to be from the northern Bering and southern Chukchi seas, while spawning locations in the northern Chukchi Sea may be a source population for the western Beaufort Sea. Kotzebue Sound appears to be both an important spawning and nursery area for saffron cod, as well as a source of larvae and juveniles to nearshore nursery areas. We found strong variability in dispersal patterns among years, which were linked to changes in oceanographic and atmospheric forcing. Observed variability in the dispersal of polar cod and saffron cod ELS is likely related to changes in the strength of the Pacific-Arctic pressure head, which influences the inflow of Pacific waters into the Chukchi Sea and the timing and pattern of sea ice retreat. Understanding how connectivity between the Chukchi and Beaufort seas may change in response to Arctic warming is important if we are to understand the stock structure and population dynamics of polar cod and saffron cod in the region. Such information is essential to spatial management of Alaska's Arctic marine ecosystems.

Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Acknowledgements

This study was supported by a grant from the North Pacific Research Board (NPRB; Project #1508) and was also funded in part by the Bureau of Ocean and Energy Management (BOEM) Award #M12AC00009 and in part with qualified outer continental shelf oil and gas revenues by the Coastal Impact Assistance Program, U.S. Fish and Wildlife Service, U.S. Department of the Interior (Contract #s: 10-CIAP-010; F12AF00188). This paper is EcoFOCI Contribution

No. EcoFOCI-N950. The authors wish to thank the scientists and volunteers that collected data on the Arctic EIS acoustic-trawl surveys, Elizabeth Drenkard, and Joakim Kjellsson for their initial assistance with TRACMASS, Alicia Billings for assistance with data processing, and Alison Deary, Esther Goldstein, and two independent reviewers for their helpful comments on this manuscript. The findings and conclusions in this paper are those of the authors and do not necessarily represent the views of the National Marine Fisheries Service. Reference to trade names does not imply endorsement by the National Marine Fisheries Service, NOAA or any of its subagencies. SLD acknowledges support from NPRB grants A91-99a and A91-00a. This manuscript is a product of the North Pacific Research Board Arctic Integrated Ecosystem Research Program, NPRB publication number ArcticIERP-XX.

Supplemental Material

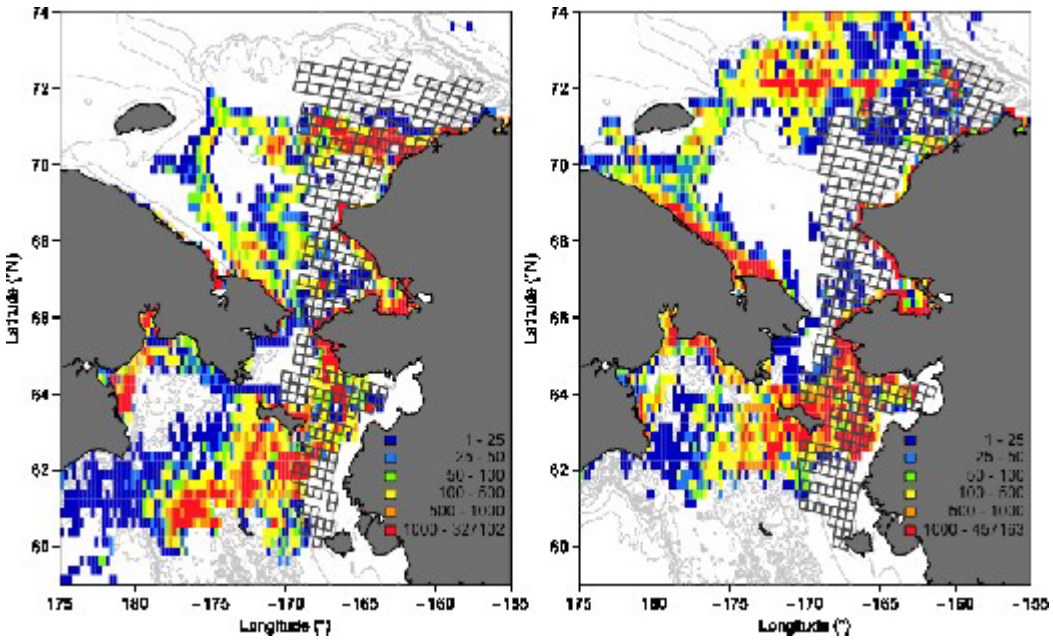

Fig. S1. Simulated particle distributions of polar cod (Boreogadus saida) on 1 September (a) 2012 and (b) 2013 from selected release areas (Gulf of Anadyr, St. Lawrence Island, Bering Strait, Chukotka Peninsula, and Kotzebue Sound) and all release dates (every 2 weeks from 1 January – 15 May) compared to the 30-km x 30-km grid overlaid on the Arctic Ecosystem Integrated Survey (Arctic EIS) acoustic-trawl survey area. These 5 areas were chosen from a total of 9 hypothesized spawning/hatching locations due to the overlap of particles from these locations with the Arctic EIS survey grid. Cell colors represent the total number of particles in each 0.25° x 0.25° grid cell. Dark blue = 1 – 25, light blue = 25 – 50, green = 50 – 100, yellow = 100 – 500, orange = 500 – 1000, red > 1000. Data from simulations with surface-oriented behavior are presented.

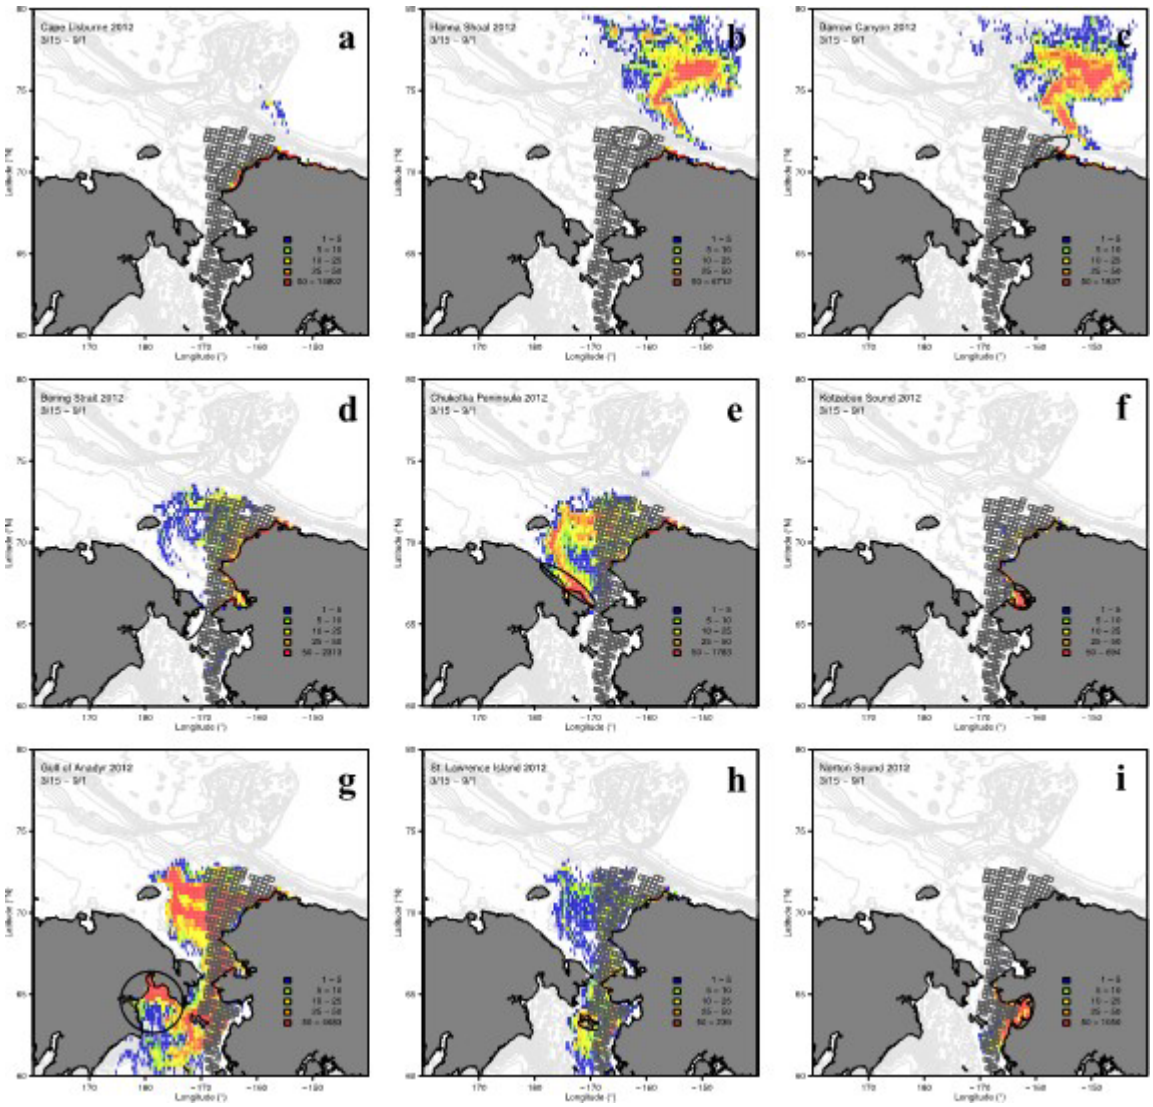

Fig. S2. Distributions of polar cod (Boreogadus saida) on 1 September 2012 from passive particle simulations initiated on 15 March from (a) Cape Lisburne, (b) Hanna Shoal, (c) Barrow Canyon, (d) Bering Strait, (e) Chukotka Peninsula, (f) Kotzebue Sound, (g) Gulf of Anadyr, (h) St. Lawrence Island, and (i) Norton Sound hatching areas. Cell colors represent the total number of particles in each 0.25° x 0.25° grid cell. Blue = 1 – 5, green = 5 – 10, yellow = 10 – 25, orange = 25 – 50, red > 50. Black ellipses represent hatching areas. The 30-km x 30-km grid overlaid on the Arctic Ecosystem Integrated Survey acoustic-trawl survey area for the analysis is shown.

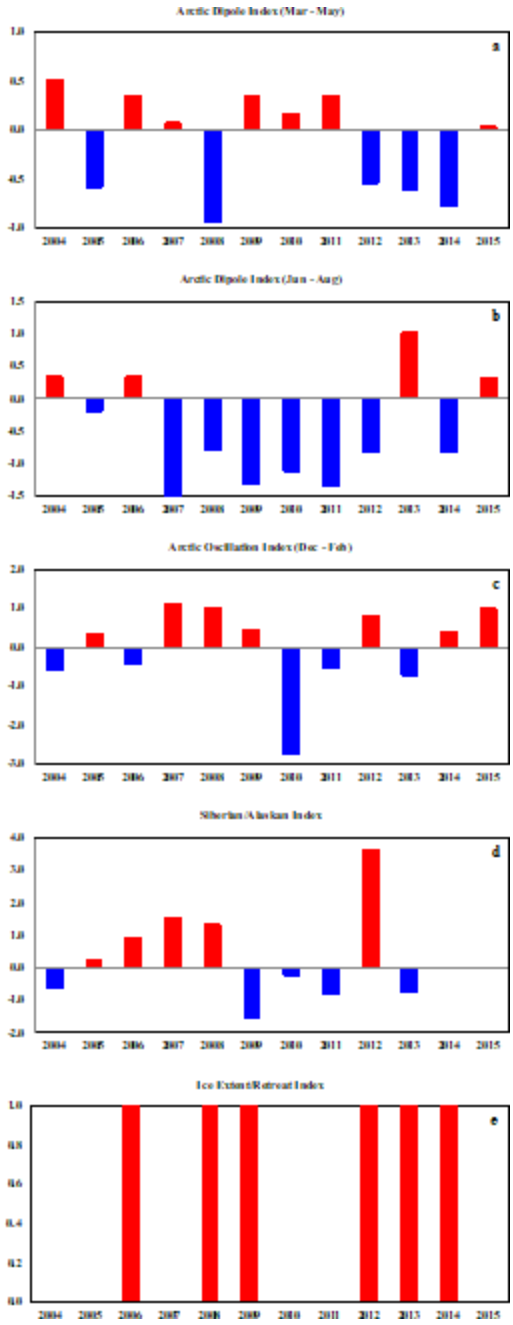

Fig. S3. Index values used in the correlation analyses between latitudinal and longitudinal center of gravities of simulated particles on 1 September and the (a) March – May and (b) June – July Arctic Dipole index, (c) the December – February Arctic Oscillation index, (d) the Siberian/Alaskan index (2004 – 2013), and (d) the Ice extent/retreat (IER) index (2005 – 2015). For the IER, an index value = 0 represents years with smaller daily sea ice extents and faster/earlier sea ice retreats, while an index value = 1 represents years with greater daily sea ice extents and slower/later sea ice retreats. Note that the y-axis scale differs between plots.

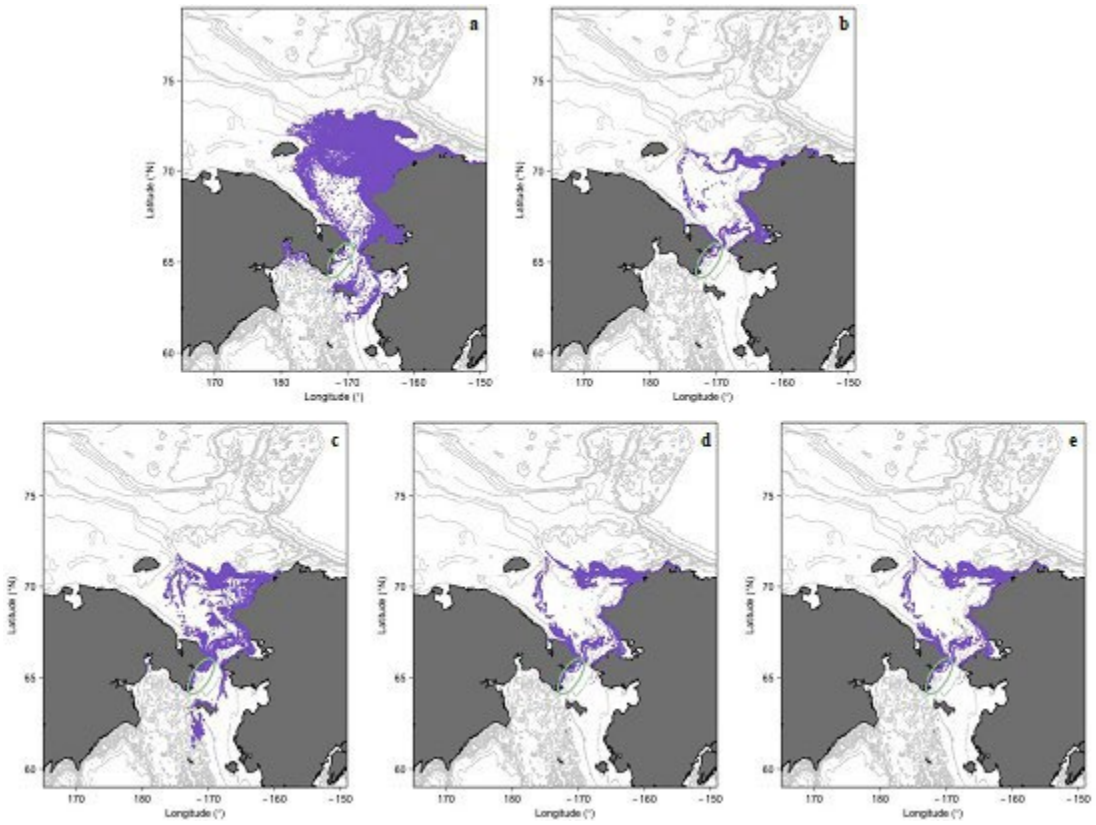

Fig. S4. Distributions of polar cod (Boreogadus saida) on 1 September 2012 from the 5 different behaviors tested; (a) passive (neutrally buoyant) individuals of all stages, (b) surface-oriented individuals of all stages, (c) passive yolksac and preflexion larvae with late larvae and early juveniles moving deeper with ontogeny, (d) surface-oriented yolksac and preflexion larvae with late larvae and juveniles moving deeper with ontogeny, and (d) surface-oriented yolksac and preflexion larvae with late larvae and early juveniles making diel vertical migrations (DVMs) between specified depths during the day, and 5 m during the night.

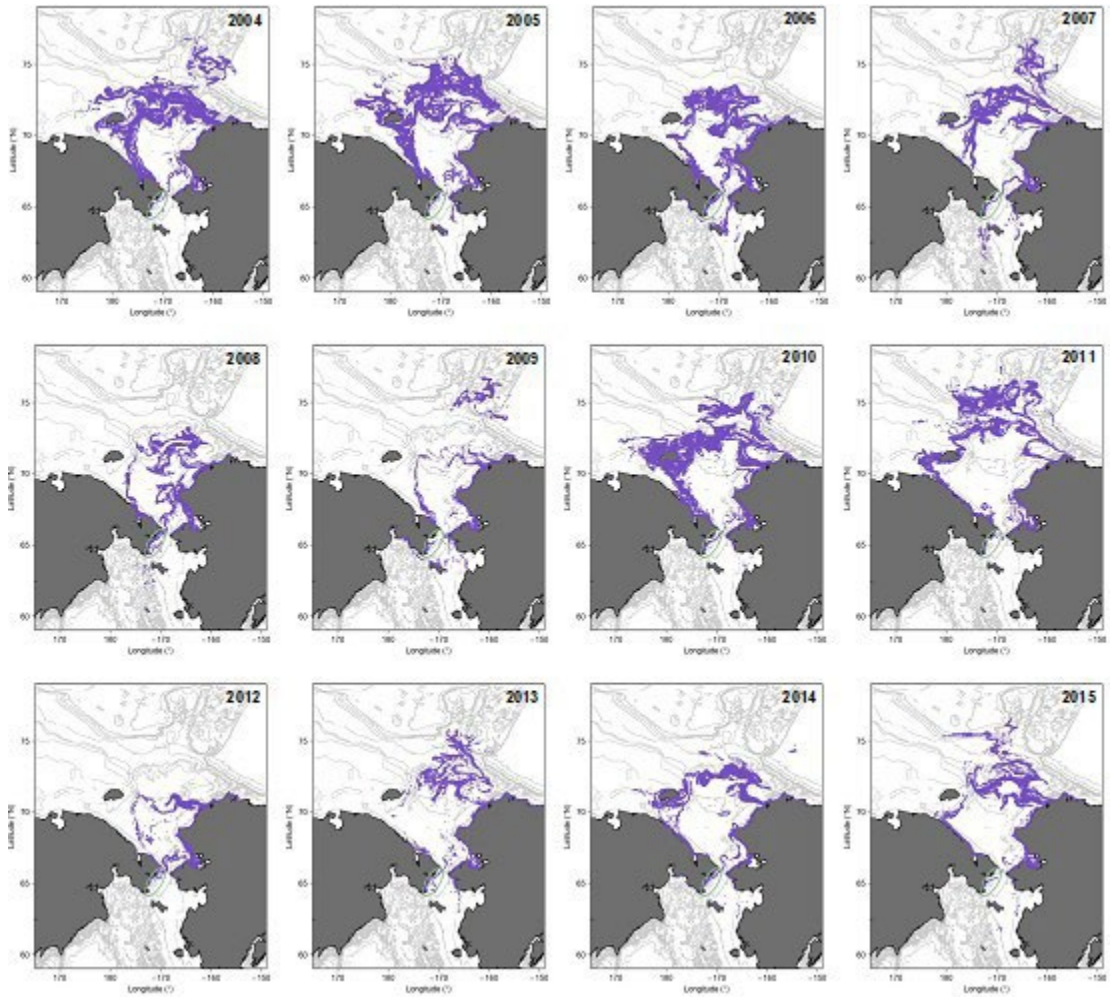

Fig. S5. Simulated particle distributions of polar cod (Boreogadus saida) on 1 September 2004 – 2015 from the Bering Strait release area (green ellipse) for all release dates (every 2 weeks from 1 January – 15 May). Data from simulations with surface-oriented behavior are presented.

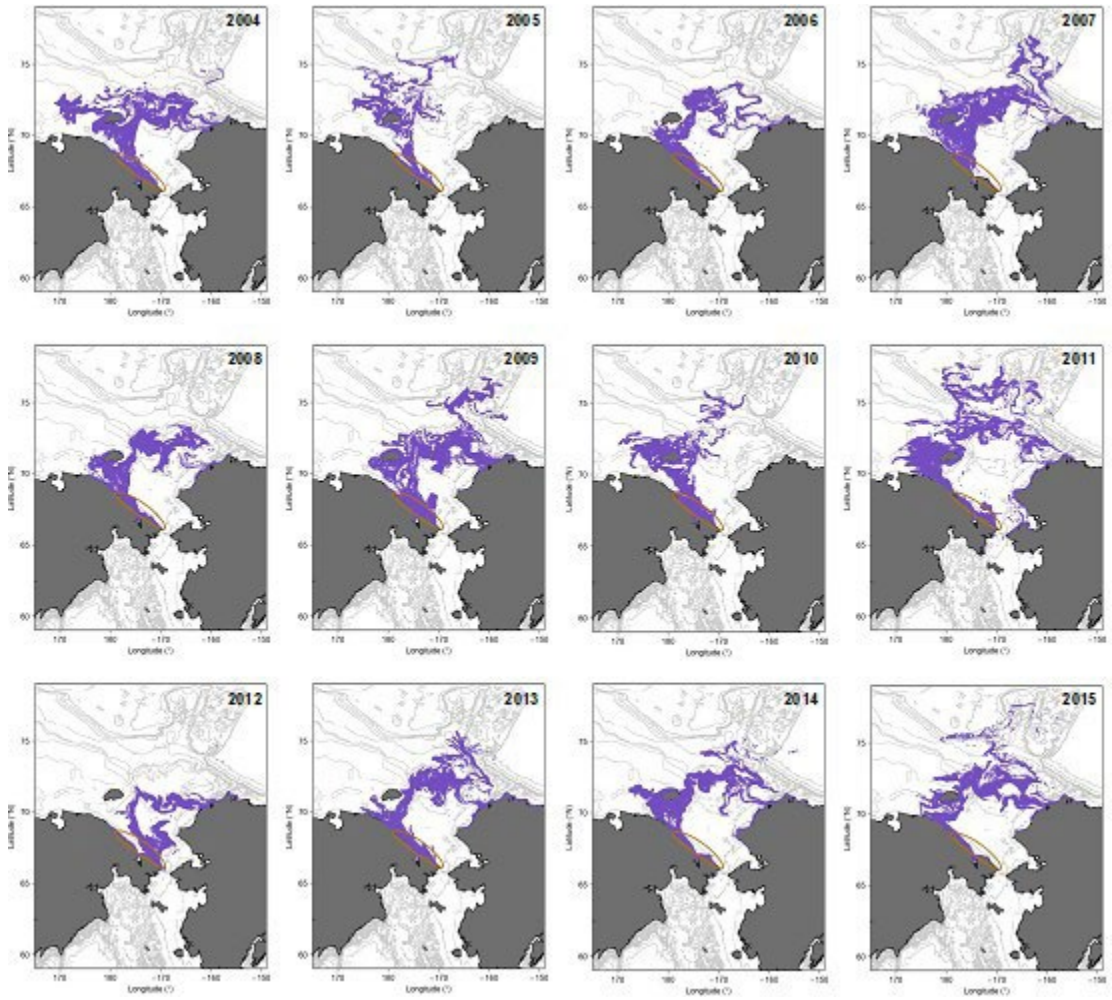

Fig. S6. Simulated particle distributions of polar cod (Boreogadus saida) on 1 September 2004 – 2015 from the Chukotka Peninsula release area (orange ellipse) for all release dates (every 2 weeks from 1 January – 15 May). Data from simulations with surface-oriented behavior are presented.

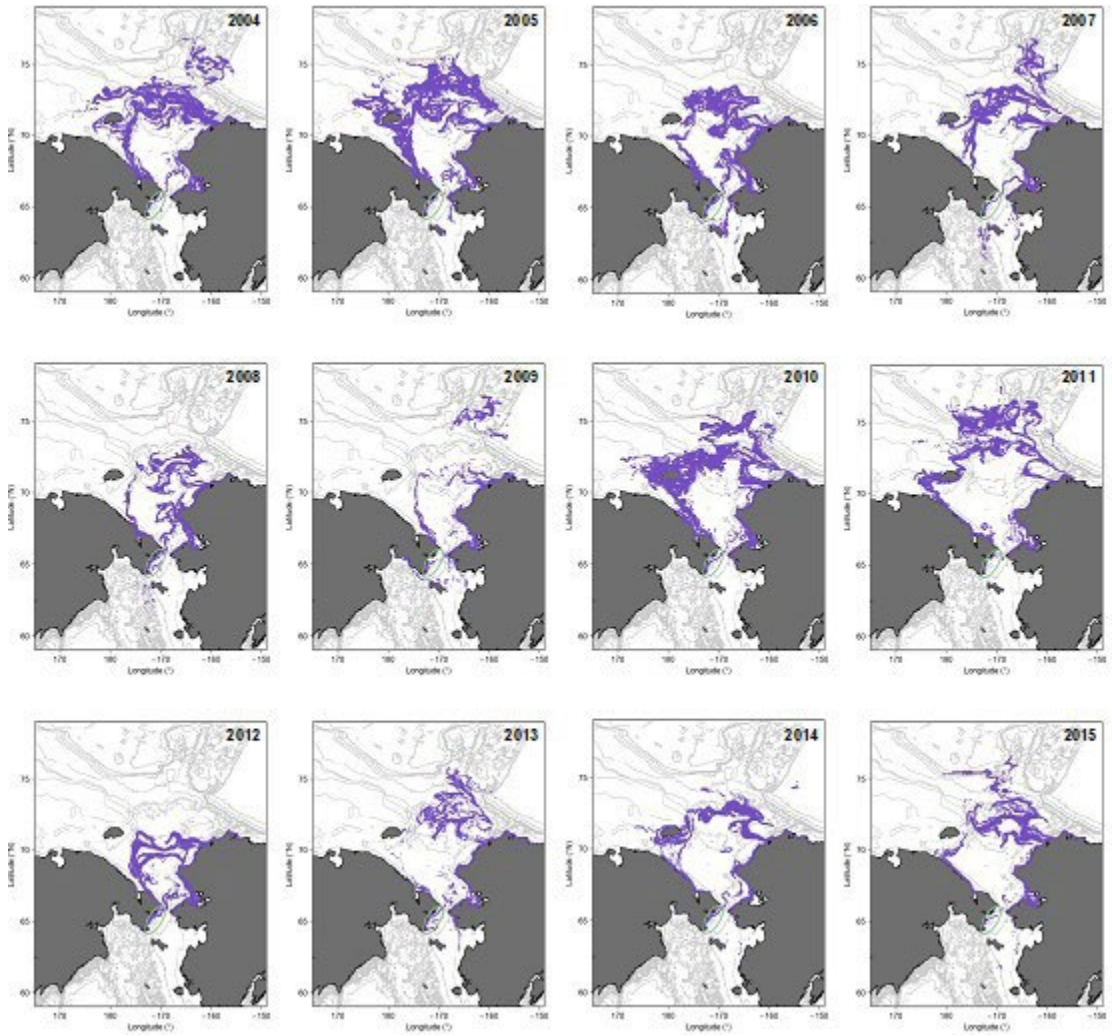

Fig. S7. Simulated particle distributions of saffron cod (Eleginus gracilis) on 1 September 2004 – 2015 from the Bering Strait release area (green ellipse) for all release dates (every 2 weeks from 1 January – 15 May). Data from simulations with surface-oriented behavior are presented.

Fig. S8. Simulated particle distributions of saffron cod (Eleginus gracilis) on 1 September 2004 – 2015 from the Kotzebue Sound release area (blue ellipse) for all release dates (every 2 weeks from 1 January – 15 May). Data from simulations with surface-oriented behavior are presented.

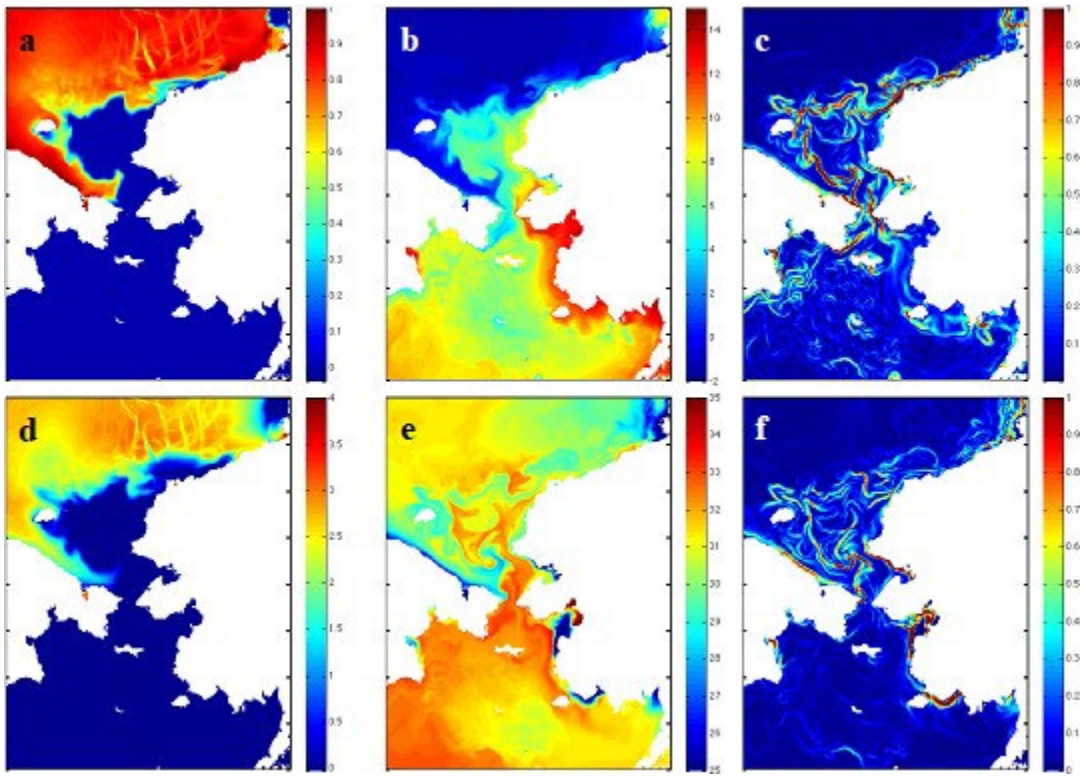

Fig. S9. Pan-Arctic Regional Ocean Modeling System (PAROMS) model (a) ice concentration, (b) sea surface temperature (°C), (c) sea surface temperature gradient (°C 5 km-1), (d) ice thickness (m), (e) sea surface salinity (PSU), and (f) sea surface salinity gradient (PSU 5 km-1) on 30 August, 2012.

CHAPTER 19: Otolith-derived hatch dates and growth rates of Arctic Cod (Boreogadus saida) support existence of several spawning populations in Alaskan waters

Objective 5: Further resolve early life history characteristics of Arctic cod and saffron cod and their behavior and connectivity between the Chukchi Sea and western Beaufort Sea.

Prepared for submission to Deep-Sea Research Part II

Abstract

Arctic cod are an important prey species in Arctic marine ecosystems as they provide efficient energy transfer up the food web. They are found throughout the Arctic and have locally high abundances. Little is known about the early life of Arctic Cod in the Pacific Arctic, such as when and where they spawn and hatch, but they have a close relationship with sea ice during incubation and may associate with sea ice through much of their early life history. The goal of this study was to estimate hatch dates and growth rates of first year Arctic Cod, which was accomplished through analysis of otolith growth increments. First-year Arctic Cod were captured in the northern Bering, Chukchi, and Beaufort seas during the spring or summer between 2012 and 2017. Estimated hatch dates ranged widely from November to July with peak hatching occurring from February through May depending on the region of capture. Combined with large individual and regional variability in growth rates, this suggests a bet-hedging strategy to ensure some larvae encounter favorable growth conditions. In addition to regional differences, we identified a clear separation of hatch dates between spring- and summer-caught Arctic Cod, suggesting different origins or strong size-dependent mortality. Finally, differences in hatch dates between pelagic and demersal juveniles support the settlement of older, larger juveniles to the seafloor on deeper portions of the shelf in late summer. Differences in hatch timing and growth in the context of variability in sea ice retreat, river discharge and other environmental conditions can provide new insights into the future of Arctic Cod as the Arctic climate continues to change.

Introduction

Arctic Cod (*Boreogadus saida*) were identified as a keystone species within Alaska's Arctic waters by the Fisheries Management Plan for Marine Resources in the Arctic (NPFMC, 2009). Arctic Cod provide an important pathway for energy transfer from planktonic prey to larger animals. With large abundances, high energy content, and an assimilation efficiency around 80%, Arctic Cod are ideal prey for many Arctic predators (Hop et al., 1997; Bluhm and Gradinger, 2008, Crawford et al., 2016). Many larger predators such as seals, whales, and seabirds depend on Arctic Cod as a source of energy; in turn, polar bears and Alaska Native communities rely on some of these marine mammals for their caloric intake (Welch et al., 1992). Arctic Cod are also targeted by commercial and subsistence fisheries in the Barents Sea (Gjosaeter 1995; Magdanz et al., 2010).

Previous research on Arctic Cod has identified characteristics of their life history as adults; however, less is known about their early life history due to the difficulties associated with sampling early stages. Arctic Cod males reach sexual maturity between 1 and 3 years of age while females reach sexual maturity at 2 or 3 years of age. They have a life span of 7-8 years (Hop and Gjosaeter, 2013), and reportedly spawn mostly between January and March in large groups underneath the ice (Craig et al., 1982; Bouchard and

Fortier, 2011; Gallaway et al., 2017). Based on laboratory studies, Arctic Cod eggs remain suspended at the surface of the water just under the sea ice and can tolerate sub-zero temperatures without affecting survival (Laurel et al., 2015). Artic cod spawning locations and dates, as well as hatch times, are currently unknown, although such information is needed to protect these vulnerable life stages. Early larval stages have been found throughout the spring (Deary et al. in review) and summer sampling seasons (Vestfals et al. 2019), suggesting a broad distribution of spawning and hatching in space and time. However, the bongo nets used in these studies under-sample larger larvae and juveniles in the summer. High abundances of larvae and juveniles have been observed over multiple years on the northeast Chukchi Sea shelf (de Robertis et al 2017; Levine et al. 2021), but their origins remain poorly known. High abundances of larval and juvenile Arctic Cod have also been documented in the western Beaufort Sea (Parker-Stetter et al., 2011; Forster et al., 2020; Vestfals et al., 2019), but it is unclear if this population is connected to Arctic Cod found in the northern Chukchi Sea. In spite of these recent observations of Arctic Cod during their first summer, large gaps remain in the understanding of the reproductive biology and early life history of Arctic Cod in the Pacific Arctic (Mueter et al., 2016; 2020).

The Arctic marine environment is changing rapidly; how this may affect the distribution, abundance, condition, and phenology of Arctic Cod is of great interest to researchers and resource-dependent communities. The Arctic has seen a significant reduction in sea ice, an increase in water temperatures, and a rate of air temperature change that is double the global average (Thoman et al., 2020). These changes are reshaping the ecosystem, allowing southern, warmer-water species such as Capelin (*Mallotus villosus*), Saffron Cod (*Eleginus gracilis*), and other gadids to move north and compete with Arctic Cod for habitat and food resources (Hop and Gjøsæter 2013, Marsh and Mueter, 2020). Arctic Cod have a much lower thermal tolerance than these southern gadid species with high mortalities occurring above 16°C and a peak growth rate at 7.3°C as juveniles (Laurel et al., 2015). The eggs of Arctic Cod have a much narrower temperature tolerance and will not survive in temperatures exceeding 3.8°C (Drost et al., 2016). As the Arctic environment continues to change, the impact of these changes on Arctic Cod will have ripple effects across the Arctic ecosystem.

Arctic Cod growth and hatch timing have been examined in Canadian and European Arctic waters using daily otolith increment deposits. These analyses indicate two hatching patterns: a short hatch event that occurs concurrently with ice break-up and the beginning of increased biological production (May-June) and a protracted hatching pattern that can occur under the sea ice and extend into the summer (January-July) (Bouchard et al., 2017). Hatching patterns, and in particular hatch timing, may be an important determinant of subsequent growth and survival. Early hatching Arctic Cod are able to attain a greater pre-winter size but experience increased mortality during the long larval phase. Later hatching Arctic Cod have reduced pre-winter size, but experience less larval morality. Therefore, there is greater potential for a higher abundance of later hatching fish at the end of the summer season, but these fish are on average smaller than the early hatching Arctic Cod (Fortier et al., 2006; Bouchard and Fortier, 2008) and may experience higher overwinter mortality as a result. If hatch timing is linked to sea-ice retreat, reductions in sea ice and early ice melt may contribute to observed changes in the abundance and distribution of Arctic Cod at the southern end of their range such as the Bering Sea (Marsh and Mueter, 2020). However, the links between changing ice conditions, hatching, and the survival of larval Arctic Cod in the Pacific Arctic are not understood at present.

Understanding the timing and location of spawning and hatching in Alaskan waters, as well as the subsequent growth, movements and survival of eggs and larvae, is critical to identifying habitat requirements for early life history stages of Arctic Cod. This is especially true in areas of potential oil exploration, as Arctic Cod are highly vulnerable to crude oil during their early life history (Gallaway et al., 2017; Laurel et al., 2019). Limited information is available on the distribution of eggs and early larval stages due to the challenges of sampling these life stages. However, field-based information derived from the otoliths of later larval and juvenile stages can be used to inform our understanding of earlier life stages

in several ways. First, information on hatch timing is needed to parameterize biophysical transport models for Arctic Cod (Deary et al., In Review; Vestfals et al., 2021). Such models, in turn, can help identify and protect potential spawning aggregations and can be used to simulate how sea ice reduction and changes in water temperature may affect early life survival. Second, inferred hatch dates can be compared to the known hatch dates for other Arctic Cod stocks to help identify environmental drivers that control hatch timing and to compare the time of hatching across different stocks (Bouchard and Fortier, 2011). Finally, age-length relationships based on otolith-derived ages can be used to estimate growth rates of larval and juvenile Arctic Cod in the field during their first few months and to compare growth rates among regions. A better understanding of the life history and hatching habitats will help inform the conservation and management of Arctic Cod under the NPFMC to ensure that these resources are adequately protected.
To address the gaps in our understanding of Arctic Cod early life history, the goal of this study was to estimate the hatch date distribution of larval and early juvenile Arctic Cod sampled during the spring and summer in the Chukchi and Beaufort seas and to compare inferred hatch dates among regions. Specifically, we estimated age in days of Arctic Cod larvae based on daily otolith growth increments and used age-at-length relationships to infer the distribution of hatch dates from observed length-frequencies. A second objective was to derive field-based estimates of average daily growth rates and to compare realized growth among stocks from different regions and to laboratory-derived and other field-based estimates from the literature. These results will improve the current understanding of early life history dynamics of Arctic Cod and inform ongoing modeling efforts to help better understand ecosystem changes.

Methods

Study Region

Arctic Cod samples were obtained from the Bering, Chukchi and Beaufort seas and were assigned to five distinct regions based on differences in bathymetric and oceanographic characteristics within each of the seas (Fig. 1). From south to north, these regions are northern Bering Sea (NBS), southern Chukchi Sea (SCS), northern Chukchi Sea (NCS), western Beaufort Sea (WBS), and eastern Beaufort Sea (EBS). The NBS is a broad shelf that encompasses Norton Sound and the Chirikov Basin between St. Lawrence Island and Bering Strait, with depths generally less than 50 m. It connects to the Chukchi Sea via the Bering Strait at 56.9°N, which has a depth of less than 50 m. The majority of the Chukchi Sea is a shallow (40-60 m) continental shelf, which was split into a southern and northern region for our analyses due to differences in water masses. Alaska coastal water, Bering shelf water and Anadyr water from the Bering Sea converge in Bering Strait before entering the Chukchi Sea (Danielson et al., 2017; Eisner et al., 2012) and continuing to flow north. These water masses of recent Pacific origin cover a variable portion of the Chukchi Sea shelf, but are typically separated from distinct water masses in the NCS, referred to as Winter Water and recent Melt Water, by a semi-permanent front that extends from the surface to the sea floor (Weingartner 1997). The colder and more saline Winter Water extends as far south as 70°N, therefore 70°N was used as the dividing line between the NCS and SCS for our analyses (Pickart et al., 2010). In contrast to the Chukchi Sea, the Beaufort Sea has a narrow shelf that quickly drops into the Arctic Basin to depths exceeding 2,000m. The Beaufort Sea shelf receives relatively nutrient-poor water via the Alaska Coastal Current entering from the West and is influenced by fresher waters from the Mackenzie Rivers, as well as by deeper Atlantic waters from the East (Carmack and Macdonald 2002, Pickart 2004). For this analysis, the Beaufort Sea was separated into an eastern (samples east of 147°W; EBS) and western region (153 °W to 147 °W; WBS) (Fig. 1), with the EBS experiencing a stronger influence from the Mackenzie River than the WBS (MacDonald et al., 1987). Because of the strong connectivity between the NCS and the westernmost portion of the Beaufort Sea (west of 153° W), we pooled samples from these regions and refer to them collectively as the NCS.
Sample Collection and Processing

Larval and juvenile Arctic Cod used for this analysis were collected during five Arctic surveys that covered the spring (June) and summer (August/September) seasons: the Arctic Shelf Growth, Advection, Respiration and Deposition (ASGARD) rate measurement survey in the NBS and SCS in the spring of 2017 (Danielson et al., 2017), the Arctic Marine Biodiversity Observation Network (AMBON) survey in the Chukchi Sea in the summer of 2017 (Iken et al., 2018), the Arctic Integrated Ecosystem Survey (Arctic IES II) in the Chukchi Sea and WBS in the summer of 2017 (Farley et al., 2017), and the Transboundary Surveys which sampled the summer seasons in the WBS in 2012 (TB12) and in the EBS in 2013 (TB13) and 2014 (TB14) (Norcross et al., 2017; Table 1). Four types of sampling methods were used to collect Arctic Cod: (1) an Isaacs-Kidd Midwater Trawl (IKMT, Methot 1986) with a 3 mm mesh body and 1 mm mesh codend liner was deployed obliquely to collect larval and juvenile pelagic fish from near bottom to the surface during the AMBON, TB12, and TB13 surveys; (2) a modified Marinovich trawl with a 64 mm mesh body which tapered to a 3 mm mesh codend was used to target aggregations identified by acoustic backscatter as part of an acoustic-trawl survey during Arctic IES II (de Robertis et al., 2017); (3) two types of bottom trawls were used to sample demersal fish, including a 3 m modified Plumb Staff Beam Trawl (PSBTA, Abookire and Rose, 2005) with a 7 mm mesh body and a 4 mm liner in US waters during the AMBON, Arctic IES II and transboundary surveys and a Canadian Beam Trawl (CBT, Majewski et al., 2017) with a 10 mm mesh body and a 6 mm liner during the U.S. and Canadian transboundary surveys; and (4) a 60 cm diameter Bongo net with a 505µm mesh was used to sample zooplankton and ichthyoplankton during ASGARD and Arctic IES II surveys.

Two sets of Arctic Cod samples were used for analyses. First, standard lengths of all larval and juvenile Arctic Cod sampled in a given region, season and vertical location (demersal or pelagic) were measured in the field or laboratory to the nearest mm (Table 1). Second, length-stratified sub-samples for otolith aging were obtained from each region and season, except the WBS and 2012 EBS, to estimate region-specific relationships between length and age (Table 2) and to convert observed length-frequencies to estimated hatch date distributions using the approach described below. For summarizing length-frequencies and hatch date distributions and for comparisons, samples from different seasons, regions, and vertical locations were organized in and will be referred to as 'groups'. We defined a total of 10 groups consisting of pelagic spring samples from the NBS (1 group), pelagic spring and pelagic and demersal summer samples from the SCS (3 groups), and pelagic and demersal summer samples from the NCS, WBS, and EBS (2 groups each).

To obtain representative length-frequency distributions for larval and juvenile Arctic Cod for each group, lengths samples from different gear types and cruises were used (Fig. 3, Table 1). Length-frequency distributions during spring were quantified using Bongo samples because larval fish are generally small (< 20 mm) at that time. Although the Bongo may select against some of the larger larvae in the water column because of its small mesh size, Bongo samples were considered to be most representative of the size distribution of larval Arctic Cod in the sampling area during spring. This was supported by opportunistic IKMT samples that indicated larvae were generally less than 20 mm in June. During the summer sampling period, age-0 fish were generally larger than 20 mm and were distributed throughout the water column or had settled to the bottom. We used fish collected by either the Marinovich trawl or the IKMT (when Marinovich was unavailable) to quantify length-frequencies of pelagic juveniles, whereas samples from the bottom trawls (PSBTA or CBT) were used to characterize lengths of demersal fish. The Marinovich has very little size selectivity over the size range of interest (de Robertis et al., 2017; A. de Robertis, NOAA, Seattle, pers. comm.). Similarly, the PSBTA has been estimated to retain all or most age-0 Arctic Cod (Marsh et al., 2020). We focused primarily on the pelagic fish for comparisons among regions because they are assumed to be age-0 fish, whereas the bottom trawl catches may include some small Arctic Cod (< 75 mm) that could be age-1 or older as there is considerable overlap in sizes among ages (Helser et al., 2017). Length data for the Transboundary surveys from both the PSBTA and CBT were combined to characterize the length-frequency distribution of Arctic Cod in the eastern Beaufort Sea because there was no evidence that the size composition of the catches differed significantly

between these gear types (Norcross et al., 2017). The combined gear type will be referred to hereafter as bottom trawl. In summary, pelagic fish in spring were represented by Bongo samples, while in the summer Marinovich and IKMT samples were used to represent pelagic samples, and bottom trawls were used to represent demersal fish.

To assess length frequency distributions of age-0 fish, as well as for aging age-0 fish, we included only fish up to a maximum size of 75 mm in the Bering Sea, Chukchi Sea and WBS and up to 60 mm in the EBS. The upper limits were estimated to be the maximum size of age-0 Arctic Cod in late summer based on the length-frequency distribution of all Arctic Cod sampled in a given region (Fig. A1.1). The estimated cutoff of 75 mm for the southern regions was consistent with that used for age-0 fish sampled in the Chukchi Sea in late summer 2012 and 2013 (Marsh et al., 2020). In the EBS, a cutoff of 60 mm was used as larger fish were clearly separated from a dominant mode of smaller, age-0 fish and were continuous with a mode of larger, presumably age-1 or older fish (Fig. A1.1). This cutoff is consistent with previous studies in the Beaufort Sea (Norcross et al. 2017).

To sample fish for otolith aging, age-0 Arctic Cod were sampled randomly over the full size range of approximately 6 mm to 75 mm. Our sampling goals were to obtain samples for aging that were representative of the full range of sizes of larval Arctic Cod in the spring and of young-of-year Arctic Cod in late summer within each sampling region. We collected size-stratified random subsamples of specimens collected across much of the study region (Fig. 1), subject to other sampling priorities. Lengths were stratified into a small, medium, and large group for each region to ensure that a broad range of lengths was represented for aging. Subsamples of larval and juvenile gadids for otolith analyses were frozen or stored in 95% ethanol and shipped to the University of Alaska Fairbanks in Juneau, Alaska, where they were identified and processed for further analysis. Samples of archived otoliths from the Transboundary surveys in the Beaufort Sea and the corresponding standard lengths were obtained from the Fisheries Oceanography Lab at the University of Alaska Fairbanks (UAF). Of the smaller specimens (< 15 mm) shipped to Juneau, ~ 60% were cross-checked by a larval taxonomist to minimize misidentification. Larger fish are difficult to identify in the field and fish greater than 20 mm captured during the Arctic IES II survey were verified by sequencing the mitochondrial cytochrome oxidase c, subunit 1, and aligning them with known gadid sequences at the National Oceanic and Atmosphere Administration (NOAA) Ted Stevens Marine Research Institute in Juneau, Alaska (Sharon Wildes, NOAA, Seattle, pers. comm.). All samples were processed and analyzed at UAF's Lena Point Fisheries Facility and at the Alaska Department of Fish and Game Mark, Age and Tagging laboratory in Juneau.
Otolith Aging

To estimate ages of juvenile Arctic Cod, sagittal otoliths were examined for daily growth increments. After measuring standard lengths, the sagittal otoliths were removed under a dissecting microscope with fine-tipped forceps. The left otolith was extracted, rinsed with 95% ethanol to remove any organic matter, and mounted to a glass slide using clear, thermal plastic cement. The right otolith was removed, cleaned, and stored dry to be used if the left otolith was damaged or unusable. The mounted otoliths were polished with various grades of lapping film to expose the daily growth increments within the otolith. Due to their uneven shape, some otoliths required polishing on both sides.

To estimate hatch dates, daily growth increments were counted on the otoliths. The deposition of daily growth increments in Arctic Cod was previously confirmed using a tetracycline marking experiment and visual examination under light and scanning electron microscopy (Bouchard and Fortier, 2011). In this study, growth increments were identified under a light microscope at 40x and 100x magnification to confirm adequacy of the otolith preparation for identifying potential daily rings. The otoliths were imaged using Image Pro Plus© (Media Cybernetic), where each visible ring was assumed to represent one day of growth (Fig. 2 A). Using Image Pro Plus© (Media Cybernetic), daily growth increments were counted from the hatch mark to the edge of the otoliths (Fig. 2 B). Hatch marks were identified and validated

using otoliths of lab-reared, known-age Arctic Cod from the Hatfield Marine Science Center in Newport, Oregon (Benjamin Laurel, NOAA Alaska Fisheries Science Center, pers. comm.; Fig. 2 C). The otoliths of lab-reared Arctic Cod were aged to confirm the presence of daily growth increments and test the reader's aging ability. Using the known age of the fish, the location of the hatch mark was then identified and confirmed to further improve age determinations. This method of hatch mark identification is similar to other studies that determined the hatch mark by examining otoliths shortly after the fish hatched (Eckmann and Rey 1987).

To ensure accuracy of otolith aging, all sampled otoliths were aged at least twice and a third time if the first two ages were not within a 5% coefficient of variation (CV). The second and third ages were done at a separate time from the first to avoid any aging bias. If the first two ages fall within a 5% CV of each other the second age was used. In the event the first two ages had a greater than 5% CV then the otoliths was aged a third time and the final age was used if it was within 5% of either the first or second age. Although there are other methods for validating age determinations, the CV is statistically more rigorous and flexible (Chang, 1982; Campana 2001). A subsample of the aged otoliths (n = 15) was examined by a second otolith aging expert to confirm that the images, measurements and ages had no errors.

Growth increments in the center of some otoliths were unreadable because too much material had been removed during polishing. Therefore, the saved otolith was used for aging, but for some of the larger fish (20 - 54mm), the center again became washed out. In these cases, daily ages were counted using the otolith with the most amount of visible increments starting at the first readable growth increment. The number of increments that were unreadable was estimated based on a regression approach using completely aged otoliths from the same region (Appendix 2).

Length-frequency distributions

Length-frequency distributions that best represent the total population of larval or juvenile Arctic Cod were visually examined by season and region, and separately for pelagic and demersal sampling gear. In addition, the mean lengths of demersal and pelagic larvae and juveniles were plotted for each station to visualize spatial patterns in mean size. These representative length-frequency distributions, combined with age-at-length regressions for a given region, provide the basis for determining the hatch date distribution.

Hatch Date Determination

To estimate the distribution of hatch dates for Arctic Cod in each group we first estimated age-at-length relationships and their uncertainty for a subsample of fish using linear regressions. The resulting relationships were then used to convert all observed lengths in a group to estimated ages. Finally, the estimated ages were subtracted from the dates of capture to obtain an estimated hatch-date distribution. We assumed a linear relationship between age and length based on a previous study of Arctic Cod (Bouchard and Fortier, 2011) and visual examinations of age-at-length. Therefore, counts of daily growth increments (hereafter 'age') within each season were modeled as a linear function of length and region with an interaction term to allow for possible differences in age-at-length by region(r):

$$age_{r,i} = a_r + \beta_r \cdot length_{r,i} + \varepsilon_{r,i} \qquad \varepsilon_{r,i} \sim N(0, \sigma_\varepsilon^2)$$

Eq. 1

where and are the estimated age and length of the i^{th} specimen in region r, a_r and b_r are the intercept and slope for region r, and the $\varepsilon_{r,i}$ are residuals that are assumed to be normally distributed with mean 0 and variance . Region-specific coefficients ( ) were only estimated if the interaction term was significant ($p < 0.05$), otherwise a single regression line was estimated across the sampled regions (a, b). Preliminary analyses indicated that the standard deviation in estimated ages increased linearly with the predicted mean

ages, therefore a variance structure accounting for this mean-variance relationship was incorporated into the models. All models were fit using a generalized least squares approach as implemented in the 'nlme' package in R (Pinheiro et al., 2020). Residual diagnostics did not suggest any violations on the linearity or normality assumptions.

To estimate age distributions within each region, we used the best age-at-length model for each region to predict ages from observed lengths. Age data were not available for the WBS and the age-at-length model for the NCS was applied to this region because it is contiguous with and immediately downstream of the NCS. Juveniles from the NCS are likely advected into the western Beaufort Sea (Levine et al. 2021). To appropriately reflect variability in age-at-length arising from individual variations in growth, we randomly simulated up to 10 ages for each observed length based on the estimated mean age and its standard deviation at a given length. Occasionally, the age of a simulated fish exceeded one year due to the large estimated variance in the age of larger fish; those fish were removed from the simulated age distribution. The number of simulated ages per measured individual was arbitrarily chosen to generate at least 10,000 ages for obtaining a smooth age distribution for plotting and this choice did not affect results. The simulated ages were subtracted from the corresponding capture dates to obtain estimated hatch dates for further analyses of hatch date distributions. Regression models to predict ages from lengths for the SCS were fit separately to data from spring and summer surveys due to large differences in the observed length ranges of fish between spring and summer. The SCS was the only region where data from both seasons were available.

Hatch date comparisons

Simulated hatch dates were compared among the groups using graphical and statistical analyses. The full simulated hatch date distributions were visually compared among groups using density plots. To statistically compare these distributions among groups, we calculated the mean hatch dates for each group of Arctic Cod and used a bootstrap approach to construct confidence intervals for the means. Bootstrap samples were generated for each group by randomly re-sampling with replacement both the observed length-frequencies for a given group and the age-length samples used for estimating age-at-length for that group. For each set of bootstrap samples, a hatch date distribution was simulated following the same series of steps used in estimating the hatch date distribution from the original samples and the mean hatch date of the simulated distribution was calculated. This was repeated for each of 10,000 sets of bootstrap samples to construct percentile-based 95% confidence intervals for the mean hatch date of each group, as well as for pairwise differences between groups. If the confidence interval for a pairwise difference did not include zero, mean hatch dates between groups were considered statistically different. In addition, p-values for all pairwise comparisons were computed based on the proportion of simulated differences that were less than or larger than zero, whichever was smaller. The proportion was multiplied by two for a two-sided test because we did not specify *a priori* hypotheses about which groups had earlier or later hatch dates. Mean hatch dates and 95% confidence intervals were visually and statistically compared among groups.

Initial comparisons among regions showed no difference in mean hatch dates between Arctic Cod captured in the most western portion of the Beaufort Sea and the Northern Chukchi Sea from the 2017 Arctic IES survey. This was true for both the pelagic and demersal captured fish with p-values of 0.647 and 0.952 respectively. Due to this lack of significant differences and because of the small sample size (n = 68 pelagic and 77 demersal fish) for length measurements from the Beaufort Sea portion of the Arctic IES survey the two regions were pooled and will be referred to as NCS hereafter. The similarity between the two regions was not surprising given their close proximity and oceanographic connectivity, and the hypothesis that most northern Chukchi and western Beaufort Sea Arctic Cod are advected into those regions from southern hatching locations (Levine et al., 2021).

In the Chukchi Sea during summer, data for both pelagic and demersal Arctic Cod were available from two overlapping surveys and were analyzed separately. Mean hatch dates for pelagic Arctic Cod collected during the transect-based AMBON survey (IKMT) and those collected during the grid-based Arctic IES II survey (Marinovich) (Table 1) were quantified separately as the surveys covered different areas. For comparing hatch dates of fish among regions, we present results for Arctic IES II samples collected in the SCS and NCS using the Marinovich trawl (pelagic fish) or bottom trawl (demersal fish) because the Arctic IES II survey sampled a systematic grid and covered a larger geographical area within each region, providing more representative length-frequency distributions (Fig. 3).

Growth Rates

To obtain field-based estimates of age-0 growth rates for Arctic Cod we fit linear regressions of length on age by region and season. A simple linear regression of length as a function of age was used, where the slope (mm d^{-1}) represents the estimated average growth rate of the sampled population in a given region and season. Growth rates were estimated separately by region to account for differences in temperature, prey availability among regions, and genetic differences among stocks, all of which can affect the rate of growth (Laurel et al., 2015; Helser et al., 2017; Laurel et al., 2018). Growth rates were also estimated by season to account for potential differences between the growth of early larval and juvenile stages and the apparent growth of the surviving age-0 fish sampled later in the summer, whose average growth may differ due to size selective mortality or seasonal changes in temperature.

Results

Otolith-based ages

A total of 181 Arctic Cod otoliths were aged, with ages ranging from 10 to 161 days for Arctic Cod sampled in the spring, and from 55 to 308 days for those collected during summer (Table 2). The age range was greater for samples from the Chukchi Sea (55-308 days) than the Beaufort Sea (76 - 241 days), which may in part be due to smaller sample sizes in the Beaufort Sea (Table 2). The mean CV between first and second age assessments was 0.02 (range: 0.00 to 0.05), indicating acceptable accuracy.

Length-frequency distributions

Length-frequency distributions of age-0 Arctic Cod differed by region, season, and depth of capture. Arctic Cod captured in the spring were much smaller than those captured in the summer (Table 1). In the SCS, where Arctic Cod were sampled in both seasons, pelagic spring caught fish had a mean length of 8 mm (range: 5 - 17 mm) and the pelagic summer captured fish had a mean length of 52 mm (range: 28 - 74 mm). Within seasons, differences in length frequency distribution were observed among regions (Fig. 5). The WBS had the largest mean length of age-0 Arctic Cod followed closely by the SCS (Table 1). Within regions, demersal caught fish were on average larger than fish caught in pelagic nets (Table 1). We also observed differences in mean length among surveys within the same regions sampled during the summer of 2017. Specifically, pelagic captured fish were larger in the Arctic IES II survey (mean length of 52 and 42 mm in SCS and NCS, respectively) than the AMBON survey (mean length of 37 and 29 mm in SCS and NCS respectively). The surveys overlapped spatially, but the Arctic IES II survey took place about one month later (Table 1), which likely accounts for the larger mean sizes. Spatial patterns in mean length across the study region suggest a gradient from larger fish in the south to smaller fish in the north during both spring and summer in the Chukchi Sea (Fig. 3). During summer, the smallest fish were observed in the EBS, while WBS fish were slightly larger on average. These spatial differences are confounded with differences in the timing of sampling as the SCS and WBS were sampled later in the year than the NCS and EBS (Table 1). The number of Arctic Cod captured varied across regions and seasons from 19 cod captured in the NBS during spring to >4,000 captured in the NCS during summer, reflecting differences in average catch-per-unit-effort and differences in the number of stations sampled (Table 1).

Age-at-length regressions

The best age-at-length model included a significant interaction between length and region for spring-caught samples ($F = 12.76$, $p = 0.001$), indicating that slopes differed between the NBS ($\beta_{NBS} = 8.210$, se = 0.561, $R^2 = 0.943$) and SCS ($\beta_{SCS} = 5.485$, se = 0.763, $R^2 = 0.688$; Table 3, Fig. 4A). In contrast, there was no significant interaction between length and region in the summer ($F=0.45$, $p = 0.715$), indicating that age increased at the same rate with length across sampling regions ($\beta = 4.09$, se = 0.24, $R^2 = 0.696$; Table 4, Fig. 4B). However, intercepts differed significantly among regions ($F = 4837$, $p = 0.009$) and fish at a given length were on average 17.5 days older in the NCS compared to the EBS, 22 days older in the SCS compared to the NCS, and 39 days older in the SCS than in the EBS (Table 3). Coefficients from the best model for each season and region were used to predict ages and hatch date distributions from the observed length-frequencies.

Hatch timing

The estimated distribution of hatch dates differed between Arctic Cod sampled in the spring and in the summer, between Arctic Cod from different regions and between pelagic and demersal age-0 Arctic Cod. Within the SCS, spring captured pelagic fish had a mean hatch date that was 131 days later than summer captured pelagic fish (Table 4; Fig. 7). Arctic Cod hatch dates of summer-caught fish differed significantly among regions ($p>0.05$) except for pelagic fish caught in the NCS and WBS ($p=0.957$, ~1-day difference) and demersal fish from the NCS and EBS ($p=0.059$, 12-day difference; Table 5; Fig. 7). Demersal SCS fish sampled during the summer had the earliest mean hatch date (December 27) and pelagic EBS fish had the latest mean hatch date (March 10, Table 4). Summer-caught pelagic fish in the SCS hatched on average 14 days earlier than those in the NCS, 26 days earlier than those in the WBS, and 51 days earlier than EBS pelagic fish (Table 5). Within each region, pelagic Arctic Cod had mean hatch dates significantly later ($p<0.05$) in the year than demersal Arctic Cod, except in the Chukchi Sea where SCS and NCS demersal and pelagic fish did not differ significantly in mean hatch dates. The NCS was the only region where demersal fish hatched later than pelagic fish with a mean hatch date of nine days later (Fig. 7).

Growth rates

Estimated growth rates differed among regions as evident from significant differences in the slopes of the length-age regressions (Table 2). Apparent growth rates of spring-caught Arctic Cod larvae were 37% slower in the NBS (0.115 mm d^{-1}) than in the SCS (0.183 mm d^{-1}) (Table 2; Fig. 8A). Growth rates of Arctic Cod captured in the summer season similarly differed significantly among regions ($F=3.14$, $p=0.047$), ranging from 0.097 mm d^{-1} in the EBS to 0.200 mm d^{-1} in the SCS (Table 2; Fig. 8B).

Discussion

The use of otoliths for age estimation has proven beneficial in furthering the understanding of the early life history of Arctic Cod (Bouchard et al., 2015), and was used in this study to estimate hatch dates within several regions in the Pacific Arctic. We assessed age-at-length relationships for several regions and used those relationships to convert observed length-frequency distributions to hatch date distributions. Arctic Cod from all regions hatched over a protracted period from as early as November through June, with peak hatch dates ranging widely from February through May, depending on the season, region, and vertical location. The observed differences in hatch dates among groups likely reflect gradients in the timing of sea ice retreat, stock-specific differences, and different transport pathways from hatching to sampling due to ocean currents.

Estimated hatch dates ranged from as early as September through August of the following year. This protracted hatching pattern is consistent with previous studies (Bouchard and Fortier, 2011) and maximizes the chances that at least some offspring will hatch during favorable conditions. This bet-hedging strategy helps mitigate against annual variability in environmental conditions (Shama, 2015),

which at high latitudes can impact the timing and magnitude of the spring algal bloom and thereby the timing and abundance of prey for Arctic Cod (LeBlanc et al., 2020). Because of these highly variable conditions, a bet-hedging strategy can impart some resilience to Arctic Cod in a changing environment, as long as some portion of a given year class encounters conditions within an acceptable range. The protracted hatching period can be a result of differences in incubation time or a difference in spawn timing among the regions. The large sizes (>50 mm) of some fish in our samples produced hatch dates that indicate spawning occurred outside of published literature dates (November-March) and prior to ice formation. At least two factors may have contributed to these results. First, early hatch dates could be an artefact of simulating ages based on lengths that exceeded the maximum length in our aging samples. The age-at-length model estimated a strong increase in the variance of age at a given length and could have resulted in unrealistically large simulated ages when extrapolating beyond the maximum length of the estimated age-at-length relationship. The length range we were able to sue to estimate the age-at-length relationship was limited due to the challenges associated with aging larger larvae. Second, some of the Arctic Cod in our length samples may have been age-1 fish. The oldest estimated ages and earliest mean hatch dates were associated with fish sampled in the SCS for both demersal and pelagic samples. Within this region there was a wide range of observed lengths and in particular the demersal samples may have included some age-1 Arctic Cod. Previous studies have reported age-1 Arctic Cod below the cutoff lengths used for this study (Norcross et al., 2017). Both the presence of age-1 fish and unrealistically large variances for the age of larger juveniles are likely causes of the seemingly unrealistic early hatch dates that we estimated.

Seasonal differences in hatch dates

Arctic Cod captured during the spring and summer had different mean hatch dates, with the spring-caught fish hatching later in the year. This result was unexpected and suggests that spring-caught and summer-caught fish in the same region originated from two separate hatch events. Two separate hatch patterns among regions have been previously document, specifically a short hatching event associated with ice break up and a protracted hatching event extending from January to July (Bouchard and Fortier, 2006; Leblanc et al., 2020). The protracted hatch dates were associated with regions that do not experience significant freshwater influence (Bouchard and Fortier, 2006). Larval fish captured in the SCS in June had a mean hatch date in mid-May, suggesting that they originated relatively close to their sampling locations. Within the SCS, Kotzebue Sound has been hypothesized to be a hatching location for Arctic Cod due to the large number of larval fish captured in the outer Sound during the 2017 Arctic IES survey (Deary et al., in Review). In contrast, the summer captured pelagic fish in the SCS had a mean hatch date of mid-February, ranging from January to June. The age of the summer SCS fish indicates that they were likely advected from southern regions as suggested by biophysical transport models (Deary et al., in Review, Vestfals et al., 2021).

Spawning locations of Arctic Cod in the Pacific Arctic are largely unknown, but several areas in the Bering Strait region are believed to serve as spawning grounds, including the waters south of St. Lawrence Island, the Gulf of Anadyr, Kotzebue Sound, and areas along the Russian coast both south and north of the Bering Strait (A. Whiting, Native Village of Kotzebue, personal communication; Craig et al., 1982; Christiansen and Fevolden, 2000; Kono et al., 2016). In 2017, sea ice melt in the NBS occurred in late April and was complete by late May and 99% of estimated hatch dates occurred prior to May 25 with the mean hatch date occurring on April 6th. This indicates that Arctic cod captured in the NBS hatched prior to and during sea ice retreat. Spring-captured fish in the SCS had the latest mean hatch dates of all the regions in this study, possibly reflecting later ice melt in their hatching region. Two spawning sites have been proposed within the SCS, Kotzebue Sound in Alaska and the region along the Chukotka Peninsula in Russia (Deary et al., in Review). Both of these locations had later sea ice recession than the proposed hatching locations in the NBS. The delayed sea ice recession could explain why the spring SCS fish had a later mean hatch date than those caught in the NBS.

The observed length distribution of Arctic Cod sampled in spring 2017 was similar to those of samples collected in 2008 and 2013 from the NBS and SCS regions (Kono et al., 2016). In all three years, lower numbers of larger Arctic Cod were observed in the NBS compared to high abundances of smaller fish in the SCS. For example, the mean catch per unit effort in 2017 was 73 times higher in the SCS than in the NBS (this study). Although Kono et al. (2016) did not determine hatch dates, the observed differences in size and relative abundance of Arctic Cod between the two regions suggest that earlier ice retreat, coupled with warmer waters in the NBS, is associated with earlier hatching (Kono et al., 2016). The earlier hatching larvae experienced a longer period of natural mortality, which can explain their lower abundances in the NBS. Alternatively, larvae may have been advected out of the region prior to sampling.

In contrast to spring-captured fish, the mean simulated hatch date for all summer-captured fish occurred much earlier; with the earliest mean hatch date observed for juveniles caught in the SCS. The summer-caught fish had a mean hatch date 87 days earlier than the spring-caught fish in the SCS which suggests that they originated from a different spawning population than those caught in the spring. Summer-caught fish in the SCS displayed a wide range of hatch dates from January to May (Fig. 6). The protracted range of hatch dates in the SCS may be an indication of multiple spawning events occurring at different times in different areas of the Bering and Chukchi sea. By the time of summer sampling, fish from multiple hatching events may have been advected into the Chukchi Sea, explaining the wide range of hatch dates observed. The earlier hatch dates of summer-captured fish indicate that they likely hatched south of Bering Strait when sea ice was still present in the region, before being advected with the prevailing northward currents through the Bering Strait into the Chukchi Sea (Berline et al., 2008; Vestfals et al., 2021). This is supported by the prevailing currents in the region and by simulations with an individual based particle tracking model, which suggests that age-0 Arctic Cod sampled in the northeast Chukchi Sea during 2012 and 2013 likely originated south of Bering Strait (Vestfals et al., 2021). This model also suggests that age-0 Arctic Cod in the Chukchi Sea must have originated in more southern, warmer waters to grow to the sizes observed during the summer surveys.

Alternatively, spawning could have occurred at similar times in the same region, but differences in development rates driven by environmental influences could have contributed to differences in hatch dates. For example, earlier hatching has been hypothesized to be associated with areas that receive an influx of fresh water such as the Mackenzie River (Bouchard and Fortier, 2008). This could warm the area enough to accelerate egg development and larval growth under the ice, giving juvenile Arctic Cod a physiological advantage over juveniles in colder waters because their increased size likely leads to increased feeding success and predator avoidance (Bouchard and Fortier, 2011; Laurel et al., 2015; Kent et al., 2016).

Another possibility for Chukchi Sea Arctic Cod is that spawning and hatching occurs in association with northern polynyas, such as the recurring polynyas in the eastern Chukchi Sea between Cape Lisburne and Icy Cape. However, this polynya is characterized by high salinity and low but stable temperatures, despite reduced sea ice (Ladd et al., 2016). Thus, temperature conditions do not support the accelerated growth that would be necessary to achieve the observed sizes of summer caught larvae in the NCS. This contrasts with polynyas in the Beaufort Sea, which provide more favorable conditions for EBS Arctic Cod (Bouchard and Fortier, 2011). Moreover, simulations suggest that larvae hatched in the northeast Chukchi Sea would be advected out of the region (Vesfals et al., 2021). Therefore, we conclude that the observed hatch date distributions in the NBS and Chukchi Sea are most consistent with spawning and hatching occurring in the Bering Strait region or south of Bering Strait, with perhaps some contributions from Kotzebue Sound or other coastal areas in the Chukchi Sea. After hatching, larvae are advected northward and may be retained for extended periods over the northeast Chukchi Sea shelf due to wind and flow patterns that favor retention in the summer, before being advected northward off the shelf (Levine et al., 2021).

Seasonal differences in estimated hatch dates could also be impacted by the gear types used for sampling as most sampling gears have some size selectivity. Specifically, the bongo net may not have adequately sampled larger larvae in the spring (Shima and Bailey, 1994) and the Marinovich and IKMT may have excluded small larvae in the summer (de Robertis et al., 2017). This could result in biases towards later hatch dates in the spring because the bongo retains larvae that are smaller and younger on average than those in the water column. In contrast, summer samples could have been biased towards earlier hatch dates because the midwater trawls preferentially select larger and older larvae. Although these differences may partially explain the estimated difference in hatch dates between the spring-and summer-caught Arctic Cod, they are unlikely to account for the large difference in mean hatch dates. While the Bongo may have selected against larger larvae, larvae over 20 mm were not present in IKMT hauls during ASGARD. The similar size composition between the IKMT and bongo tows supports our assumption that the bongo tows provided an adequate representation of the larval Arctic Cod present in the region during the spring.

In addition to gear selectivity, natural mortality can also be size selective as smaller fish are typically more likely to be preyed upon then larger ones (Houde, 1987). Natural mortality of larval Arctic Cod is likely to be very high (Marsh et al., 2020) and may be size dependent. Feeding success and survival typically increase with size, thus faster growing larvae tend to have greater survival rates and may be overrepresented in the summer samples (Pepin et al., 2015). The selection against smaller Arctic Cod due to both natural mortality and gear selectivity may have caused our hatch date estimates to be biased towards earlier hatching, as well as lead to higher growth rate estimates for summer-captured fish.

Seasonal differences in hatch dates may have been further impacted by biased length measurements of preserved larvae. The surveys used two different methods for storing samples: all summer-caught samples were frozen, while most spring-caught samples were preserved in 95% ethanol. Larval fish stored in ethanol have been shown to decrease in length over time. To our knowledge, the effect of ethanol on Arctic Cod has not been studied, but such studies have been conducted on a similar gadid, Walleye Pollock. Larval Walleye Pollock have been observed to shrink between 1.8 and 5.7% in 95% ethanol (Buchheister and Wilson, 2005). To examine the potential bias associated with using preserved fish for aging, we applied the upper shrinkage value estimated for Walleye Pollock (5.7%) to correct the lengths of the spring-caught SCS samples and re-estimated the corresponding age-at-length relationship. Using the corrected relationship to convert field-measured lengths to estimated ages resulted in younger ages at length and in mean hatch dates that were four days later than those based on uncorrected lengths. Because of the uncertain magnitude of the shrinkage and because overall conclusions were not affected, we presented the uncorrected results.

Regional differences in hatch dates

Differences in hatch dates among regions may be partially explained by the timing of sea ice recession, as well as other oceanographic differences among regions. While sea ice formation may affect spawn timing of Arctic Cod (Craig et al., 1982), we focus on the timing of hatch, which is influenced by ice coverage, water temperature (Kent et al., 2016), and potentially genetic differences. Sea ice retreat generally moves in a northerly direction, consistent with fish caught in the southern regions hatching earlier in the season compared to their counterparts in the North. Both pelagic and demersal age-0 Arctic Cod captured during summer had significantly earlier mean hatch dates in the SCS than in the NCS, possibly indicating that they originated from different spawning populations, although there was considerable overlap in hatch date distributions between the two regions. Similarly, pelagic and demersal age-0 fish sampled in the WBS on average hatched earlier compared to those sampled in the EBS. It is important to note that while the differences are significant, each region in the Beaufort Sea was sampled during different years, hence inter-annual variability could contribute to the observed differences.

Similar hatch dates for pelagic captured fish in the NCS and WBS are consistent with oceanographic connections between the two regions. The NCS and WBS are connected via the Alaska Coastal Current, which flows along the coastline of Alaska from the Gulf of Alaska to the Beaufort Sea (Pickart et al., 2005) and has been hypothesized to transport larval and juvenile Arctic Cod from southern hatching locations in the Bering Sea or Chukchi Sea into the WBS (Forster et al., 2020; Levine et al., 2021). Arctic Cod in the NCS and WBS appeared to be distinct from those in the EBS based on a gap in the spatial distribution of age-0 fish (Forster et al., 2020), genetic differences (Wilson et al., 2017a, 2019b; Nelson et al., 2020), and different chemical compositions of age-0 otoliths (Chapter 2). The observed differences in hatch dates provide further evidence that juvenile Arctic Cod in the WBS and EBS originate from two separate spawning populations.

Differences in hatch dates between demersal and pelagic juveniles

Hatch date distributions were different between demersal and pelagic age-0 Arctic Cod in most regions (Fig. 7). Demersal fish were generally older than pelagic fish, supporting previous observations that juveniles descend to the bottom in late summer and throughout the fall as they grow (Geoffroy et al., 2016). Differences in size and inferred hatch date distributions between pelagic and demersal fish are consistent with the general ontogenetic movements of age-0 fish from the surface ocean into deeper waters and settlement to the bottom (Houde et al., 2002; Geoffroy et al., 2016). For example, Arctic Cod in the Chukchi Sea start moving out of the epipelagic layer and descend into the water column when they reach lengths of > 30mm (Levine et al., 2021). In the Beaufort Sea age-0 Arctic Cod have been observed to descend to depths >100 m and are completely out of the epipelagic zone by October (Geoffroy et al., 2011; Bouchard et al., 2015). The observed differences in hatch dates between demersal and pelagic fish were more pronounced in the Beaufort Sea, where the average station depth was 283 m deeper than in the Chukchi Sea with maximum sampling depths of 200 m for the IKMT and 1,000 m for bottom trawls. Deeper stations in the Beaufort Sea allowed for greater stratification of size classes between demersal and mid-water habitats. By contrast, in the NCS region mean hatch dates between pelagic and demersal fish were much smaller and demersal captured fish had a mean hatch date slightly later than the pelagic captured fish. This is likely due to the shallow depth (< 50 m) of the Chukchi Sea shelf, which is less than the depth ranges over which age-0 Arctic Cod are distributed in late summer in the Beaufort Sea (Geoffroy et al., 2016). Thus, daily vertical migrations of juvenile Arctic Cod on the Chukchi shelf are likely to extend to the bottom, limiting the vertical separation by size class.

Interannual variability in hatch dates

Samples in the EBS were collected over two years in 2013 and 2014, providing an opportunity for comparing Arctic Cod hatch dates and growth rates between these two years and between this study and previous estimates. Earlier estimates are available from Bouchard and Fortier (2011), who sampled pelagic age-0 Arctic Cod from 2005 and 2006 approximately 285 km east of our EBS sampling region and from Gallaway et al. (2017) who sampled the WBS and the U.S. side of the EBS in 2011. These comparisons suggest some notable differences that may be due to annual differences in sea ice conditions, sea surface temperatures (SST), or salinity, all of which have been hypothesized to play a large role in Arctic Cod early life history (Doroshev and Arnovich, 1974; Graham and Hop, 1995; Geoffroy et al., 2011). Sea ice thickness and the timing of ice retreat in the EBS varied considerably among years based on satellite-derived estimates for the EBS study region and may explain some of the observed differences.

Pelagic age-0 Arctic Cod from 2013 had the same mean hatch date as samples from 2006 (11 April) but hatched 9 days earlier on average than fish sampled in 2005 (20 April) (Bouchard and Fortier, 2011). Peak hatching in 2011 occurred in late April (Gallaway et al., 2017), similar to 2005. The range of hatch dates was also similar among the four years, beginning in mid to late December and extending through mid-July. There were, however, some differences among years in the peak hatch dates. Specifically, the

hatch date distributions in 2005 and 2006 were bimodal with one peak occurring in early April and the other in mid-May (Fig. 6 in Bouchard and Fortier, 2011). These peaks were more pronounced in 2005, while the 2006 hatch dates were more broadly distributed around these peak dates. In contrast, the hatch date distribution in 2013 showed a single, broad peak in late April (Fig. 6), similar to 2011 (Gallaway et al., 2017). Differences in hatch timing could be due to interannual differences in environmental conditions such as sea ice coverage and freshwater influences. The samples collected in 2006 and 2013 had the same mean hatch date and similar timing of ice retreat compared to an earlier sea ice retreat (Fig. 9) but a later mean hatch date in 2005. Thus, the observed patterns in the EBS are not consistent with a positive association between hatch timing and the timing of sea ice retreat. Alternatively, hatch timing in the EBS may be explained by differences in freshwater discharge. The January-March Mackenzie River discharge, approximately corresponding to the egg incubation period, was 1,266 $m^3 s^{-1}$ higher in 2006 than in 2005 (extracted from https://wateroffice.ec.gc.ca/mainmenu/historical_data_index_e.html on 10/1/2020), and was associated with earlier hatching in 2006. This is consistent with the hypothesis that increased freshwater discharge is associated with earlier hatching due to accelerated egg development in a freshwater lens that has slightly elevated temperatures compared to the surrounding seawater (Bouchard and Fortier, 2011). Thus, differences in freshwater discharge may be more important than the timing of sea ice retreat for determining the timing of hatching of Arctic Cod in the EBS, as previously hypothesized (Bouchard and Fortier, 2011), whereas the timing of sea ice retreat may determine hatch timing in areas without strong freshwater influences such as the Chukchi Sea.

No pelagic samples were collected in the EBS in 2014, but demersal fish captured in 2013 and 2014 had different mean hatch dates with an earlier mean hatch date in 2014 (18 Feb) compared to 2013 (16 March). These differences are consistent with the freshwater discharge hypothesis as the Mackenzie River discharge was considerably higher in 2014 (4655 $m^3 s^{-1}$) compared to 2013 (4022 $m^3 s^{-1}$). The differences were also consistent with the hypothesis that hatch timing is determined by the timing of sea ice retreat. In 2013, sea ice began to decrease in early June and some ice was still present in mid-August in the EBS, whereas ice began to recede in early May and was completely gone by the end of June in 2014 (Fig. 9). Therefore, the observed differences in hatch timing between 2013 and 2014 could be explained by either differences in freshwater discharge, differences in the timing of ice retreat or both.

Arctic Cod growth rates

The growth rates reported here, derived from linear regressions of length on age for each of our study regions, suggest significant regional differences in growth rates that may reflect differences in temperatures, food availability, or genetic differences. Arctic Cod growth rates range from 0.18 - 0.54 mm d^{-1} for field-based estimates (Bouchard and Fortier, 2011; Deary et al., in Review; Levine et al., 2021; Vestfals et al., 2019), whereas laboratory estimates are generally lower, ranging from 0.11 - 0.19 mm d^{-1} (Laurel et al., 201; Koenker et al., 2018). The growth rates from our study fall within the range estimated by Bouchard and Fortier (2011) for the Beaufort Sea, with the exception of the spring NBS and summer EBS samples, which were lower (Table 2). Our low estimate for the EBS could reflect interannual differences but may also be due to the higher uncertainty in our length-age regression for the EBS ($R^2 = 0.397$) relative to other regions (Table 2) and to those reported by Bouchard and Fortier (2011).

Growth rates have been shown to be positively correlated with SST across multiple Arctic seas (Bouchard and Fortier, 2011). That pattern was true for our summer samples as well, with fish in the more southern, warmer regions having higher estimated growth rates. However, spring-caught fish in the NBS had lower growth rates than those in the SCS, despite being caught in warmer waters. The mean temperature across stations sampled for aging in the NBS was 5.57°C whereas the SCS had a mean temperature of 4.35°C across sampling stations. Slower growth in the NBS could be due to the temperature differences at capture not being representative of the average temperatures experienced by larvae since hatching. The

differences in growth could also be an artifact of genetic differences between the stocks as well as differences in food availability (Koenker et al., 2018). Growth rate estimates for Arctic Cod in this and other studies could be affected by methodological differences and the biases associated with them. Among other factors, growth rate estimates are affected by size-selective mortality, gear selectivity and sampling design. Size-selective mortality favors faster growing individuals; thus field-based growth rates based on the survivors, such as in this study, may overestimate the average growth rate for a sampled population (Bailey and Houde, 1989; Litvak and Leggett, 1992). This could have contributed to the lower estimated growth rates for spring-captured larvae in the SCS compared to those captured in the summer, assuming that slower growing Arctic Cod experienced higher predation mortality than larger cod.

Gear selectivity may also bias estimated growth rates. For example, spring-caught Arctic Cod in this study were sampled using a bongo trawl that may have selected against larger, faster-growing larvae, resulting in growth rates that are biased low. In contrast, pelagic Arctic cod in the summer were sampled with a Marinovich trawl that may have selected against smaller larvae due to its large mesh size. These gear-related biases could have contributed to the estimated differences in apparent growth rates between the spring and summer-caught Arctic Cod in this study.

Finally, the sampling design can strongly impact growth rate estimates. Our approach requires age and length samples that are representative of the population of interest. Length samples from two different surveys in the SCS and NCS in 2017 (AMBON and Arctic IES II) were very similar and did not result in a significant different in hatch date distributions (SCS: $p = 0.423$; NCS: $p = 0.107$), despite differences in sampling locations and gear type (Marinovich vs. IKMT). Age samples were collected over a wide range of stations to minimize geographical biases but the extent to which they are representative of the broader populations in the study region is unclear as the population structure and the spatial distribution of different populations is largely unknown. Many studies (e.g. Deary *et al*., in review; Levine *et al*., 2021 for Arctic Cod) have estimated growth rates based on increases in mean length between successive surveys, making the strong assumption that the same population was sampled across surveys. For example, Levine *et al*. (2021) estimated a growth rate for Arctic Cod of 0.54 mm day^{-1} over a relatively short time period and within a region of the NCS where larvae were largely retained over the duration of the study. Their estimate was more than three times the growth rate estimated for the NCS in this study (0.149 mm/day) and higher than most growth rate estimates for Arctic Cod (Bouchard and Fortier, 2011; Koenker *et al*., 2018; Vestfals *et al*., 2021). While their growth rate is sensitive to the assumed relationship between acoustic target strength and length (range: 0.24 – 0.89 mm day^{-1}), higher growth rates could potentially result from favorable growth conditions during the relatively short period of observation during the summer, when temperatures and food availability are high.

Arctic Cod early life history dynamics in a changing climate

Water temperatures in the Arctic are expected to increase by an additional 1.5 ° C by 2100 under current carbon emissions scenarios (Collins et al., 2013). The effects of rising temperatures on Arctic Cod will impact the broader Arctic ecosystem. Warming conditions are expected to initially result in increased growth rates for juvenile Arctic Cod; however, once temperatures exceed 7.3°C, growth rates will begin to decrease (Laurel et al., 2015). Arctic Cod have a growth rate advantage over other gadid species at colder temperatures (< 5°C), but other gadid species grow faster and thus gain a competitive advantage for food resources at higher temperatures. Arctic cod eggs will similarly be disadvantaged in a warming climate as they presumably depend on sea ice cover and experience high mortality and other developmental issues at temperatures above 3.5°C (Kent et al., 2016). If the abundance of Arctic Cod declines in a warming ocean, many predators will have to feed on other species that are not as lipid-rich as Arctic Cod.

In addition to changes in growth rates, continued warming will affect other aspects of Arctic Cod early life history, such as the timing of hatching. Water temperature impacts the egg incubation period of

Arctic Cod, which decreases from an average of 79 days at -1.5°C to as short as 29 days at 3.5°C (Aronovich et al., 1975; Kent et al., 2016; Laurel et al., 2018). Changes in incubation time can result in a potential mismatch with important prey species if larvae emerge early and deplete their yolk sac prior to prey emergence. Decreased incubation time at warmer temperatures also results in decreased length at the time of hatch (Laurel et al., 2018), which limits the size of prey they can ingest and their ability to avoid predation (Cowan et al., 1996). The impact of climate change on Arctic Cod is likely to be more severe at the southern limit of their range in the Bering Sea than in the Chukchi Sea as the former is warmer on average and has experienced more pronounced temperature anomalies in the fall (1.2°C) compared to the Chukchi Sea (0.7°C) (Danielson et al., 2020). Our results, combined with laboratory studies on size at hatch, indicate that, as the Arctic continues to warm, Arctic Cod will hatch earlier in the year and at a smaller size. Our results on Arctic Cod hatch dates provide a benchmark for Arctic Cod emergence and can be compared to future studies to understand how warming ocean conditions impact hatch dates and how changes in hatch dates impact their survival and recruitment to the spawning population.

Management considerations

Arctic Cod are recognized as a critically important forage species in the Arctic and in the US are managed and protected under the Arctic Fishery Management Plan (FMP) (NPFMC, 2009). The FMP requires mapping and periodically updating essential fish habitat, including the distribution of early life history stages and potential spawning areas that were largely unknown at the time the Arctic FMP was written (NPFMC, 2009). After more than a decade of additional research on Arctic Cod in the Pacific Arctic, much has been learned (Mueter et al., 2020), but direct observations of spawning or eggs are still lacking. Our hatch date estimates can provide much needed information for biophysical transport models (Deary et al., in Review; Vestfals et al., 2021) to refine estimates of likely hatching locations. More broadly, this study increases our understanding of the early life history dynamics of Arctic Cod to help predict how their life history and abundance will change under changing Arctic conditions. Important subsistence resources such as ringed seals and beluga whales rely on Arctic Cod as a lipid dense food source and changes in Arctic Cod distribution and abundance will impact the Indigenous people that depend on them (Magdanz et al., 2010; Crawford et al., 2015).

As Arctic waters become more accessible, oil exploration is likely to increase and a better understanding of when and where spawning occurs can inform measures to protect Arctic Cod and mitigate potential impacts from oil development. Larval Arctic Cod exposed to oil for only one hour have a greatly reduced chance of survival to age 1 and mortality would increase if physical or chemical dispersal methods were used to clean up an oil spill (Gallaway et al., 2017; Word et al., 2011). Artic cod eggs may be even more susceptible to oil contamination because their buoyancy increases the chance of interaction with oil spills (Laurel et al., 2019). When exposed to low concentrations of crude oil during the critical period of Arctic Cod it can disrupt the normal development of the jaw and heart, as well as causes changes lipid metabolism and growth (Laurel et al., 2019, Bender et al., 2021). This can lead to degradation of the health of Arctic Cod which would ultimately impact predators that rely on them. If water temperatures are increased by 2.3°C the rate of deformities and mortality during this early stage are significantly increased illustrating the potential an oil spill can have as waters continue to warm (Bender et al., 2021). Bioaccumulation after oil exposure is also a concern as Arctic Cod are a key component of the food web in the Arctic. Indirect exposure to oil thru the consumption of contaminated prey such as *Calanus* spp. can lead to large scale bioaccumulation within Arctic Cod (Agersted et al., 2018). This, in turn, can lead to bioaccumulation in larger animals such as seals, whales, and sea birds that are important subsistence resources. Thus, a spill in an area with high concentrations of Arctic Cod can cause large scale food web impacts for many predatory species in the Arctic, which already face challenges in a changing environment. Modeling efforts to predict the impact of oil spills on the Arctic ecosystem focus on how larval and juvenile Arctic Cod are affected (Word et al., 2014). By estimating how oil spills will impact the recruitment of adult females to the spawning population they can predict the total ecological impact

by extrapolating the loss of critical prey to the Arctic food web. Thus, Arctic Cod can serve as a key indicator for the potential ecological impacts from anthropogenic disturbances.

Transport ships are also known to disrupt and negatively impact survival of Arctic Cod. The sound pollution created by vessel traffic can cause Arctic Cod to move away from vessels and can alter Arctic Cod behavior (Ivanova et al., 2020). The presence of vessels, both moored and when traveling, caused Arctic Cod to spend more time moving away from the source of the noise and less time searching for food. During the summer, when food is most abundant, the trade off in energetics from feeding to fleeing can have a negative impact on Arctic Cod achieving optimal size prior to the winter season (Ivanova et al., 2020). It is important that management strategies account for potential anthropogenic impacts on Arctic Cod, as well as to their essential habitat, to preserve Arctic ecosystem functions.

Conclusions

We used otolith-derived ages to estimate hatch timing and growth rates of Arctic Cod, greatly improving our understanding of the early life history of Arctic Cod in the Pacific Arctic. The wide range of estimated hatch dates provides strong evidence that Arctic Cod use a bet-hedging strategy that distributes offspring over a wide range of environmental conditions by spawning over a protracted time period across multiple locations in the Pacific Arctic. Our results align with previous findings and indicate that regional and interannual variations in hatch dates and growth rates are associated with the timing of sea ice retreat and freshwater discharge, highlighting the sensitivity of Arctic Cod to changing conditions in the Pacific Arctic. Earlier sea ice retreat and increased freshwater discharge under climate warming suggest that Arctic Cod will hatch earlier in the future, with unknown consequences for their early growth and survival. Any impacts of climate change on Arctic Cod have the potential to negatively affect upper trophic level species that rely on Arctic Cod or their consumers as a critical food source, including humans in many local communities that depend on subsistence resources. The regional and seasonal differences in Arctic Cod hatch dates documented here provide evidence for the existence of multiple spawning populations in the Pacific Arctic. However, while our results are suggestive, additional genetic and biological information is required to help differentiate putative populations or sub-populations. Finally, the improved understanding of hatch timing and spawning dynamics can inform the development of measures to protect Arctic Cod during their early life history. Continued monitoring and additional research on Arctic Cod will be required to fully understand how climate change will impact their distribution and abundance and the consequences of these changes for the Arctic ecosystem.

Acknowledgements

The authors thank the boat and field crews of the R/V *Norseman II*, M/V *Ocean Starr*, and R/V *Sikuliaq* for their effort in data collection. We thank Morgan Busby and Alison Deary for their assistance in identifying larval Arctic Cod, and Kristin Cieciel and Sharon Wildes for confirming Arctic Cod identifications through genetic analysis. We also thank Kevin McNeel and Chris Hinds from the Alaska Department of Fish and Game Mark, Age and Tagging laboratory for their resources and knowledge of otolith extraction, preparation and age determination. Thank you to Benjamin Laurel at the Hatfield Marine Science Center for providing lab raised Arctic Cod to test our ageing ability and help determine where the hatch mark is located for Arctic Cod otoliths. Study collaboration and funding were provided by the US Department of the Interior, Bureau of Ocean Energy Management Environmental Studies Program, Washington, DC, under Agreement Numbers M17PG00007, M17AC00016, and M19AC00018. Additional support was provided by the University of Alaska Coastal Marine Institute through a Graduate Student Research Award.

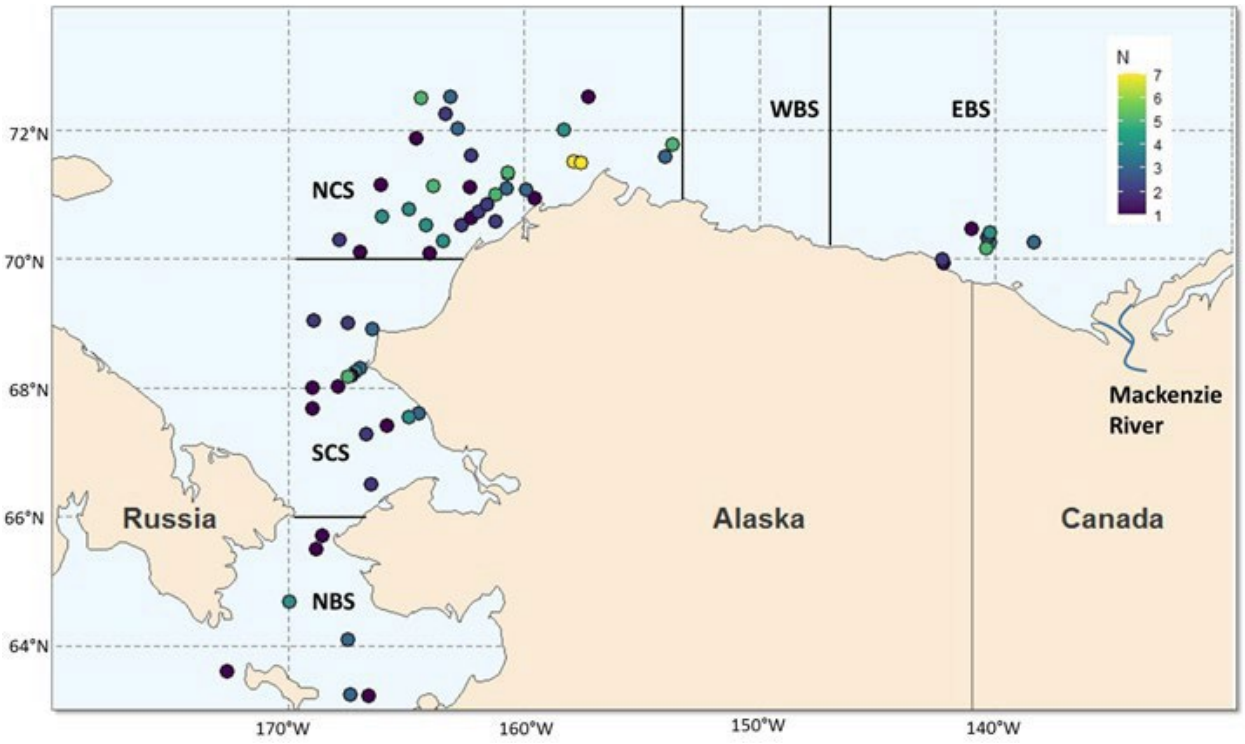

Figure 1: Locations where Arctic Cod for aging were captured. Color change from cool (blue) to warm (yellow) represents the number of specimens captured at a station, where N=7 denotes 7 or more specimens. Study regions are the northern Bering Sea (NBS), southern (SCS) and northern Chukchi Sea (NCS) and western (WBS) and eastern Beaufort Sea (EBS).

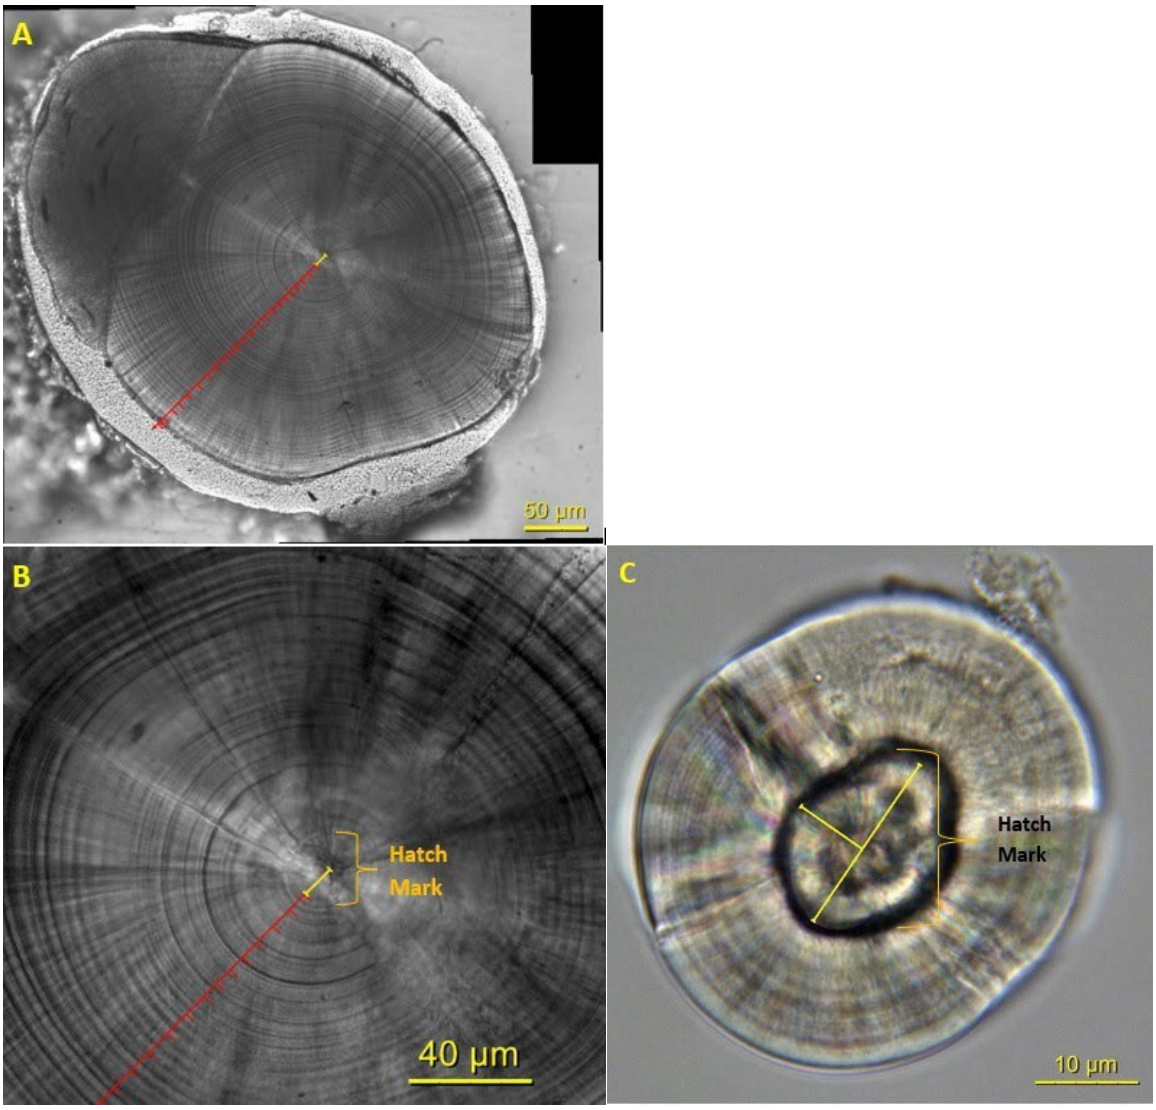

Figure 2: (A) Polished sagittal otolith at 40x magnification with daily growth increments marked at every 5th increment. (B) Cropped image of the same otolith showing the hatch mark. (C) Sagittal otolith at 100X magnification from a lab raised Arctic Cod with the hatch mark outlined.

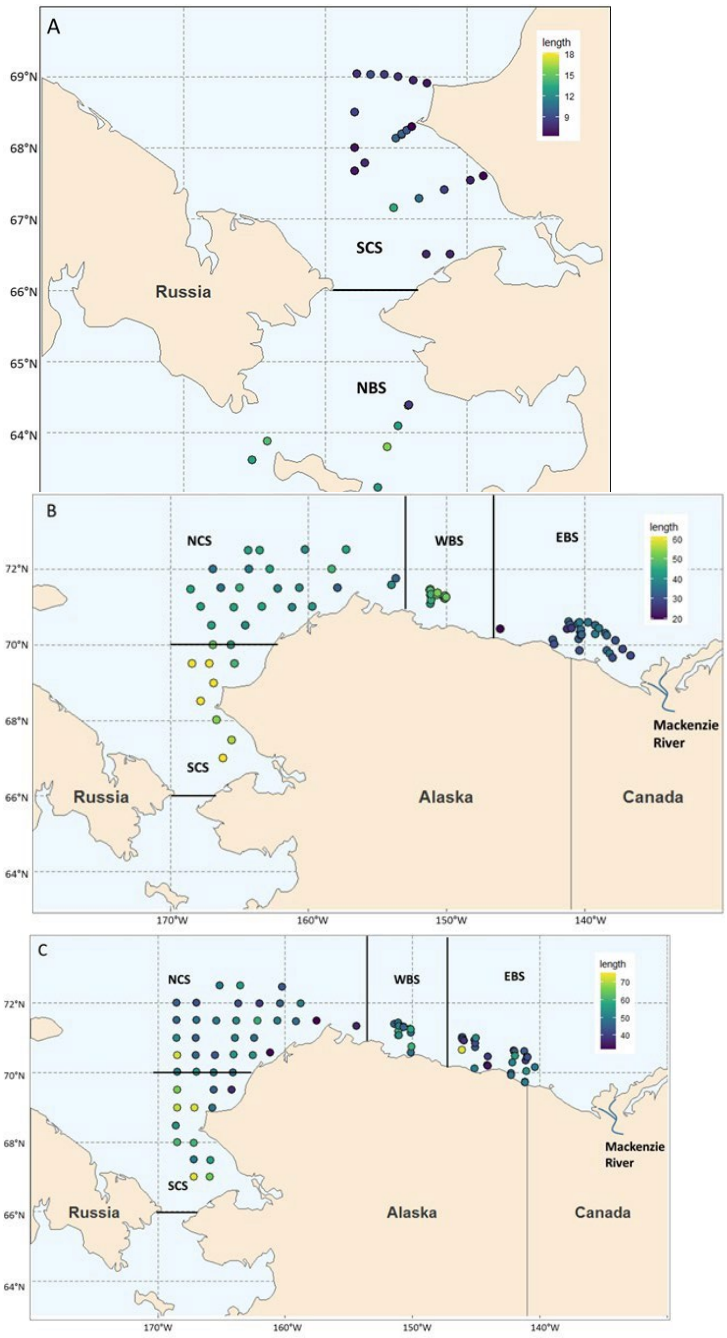

Figure 3: Stations with length data for Arctic Cod. Shading denotes average length by station for Arctic Cod captured during the spring survey in the water column (Bongo nets, A) and during the summer survey in the water column (pelagic trawl, B) and on the bottom (demersal trawl, C).

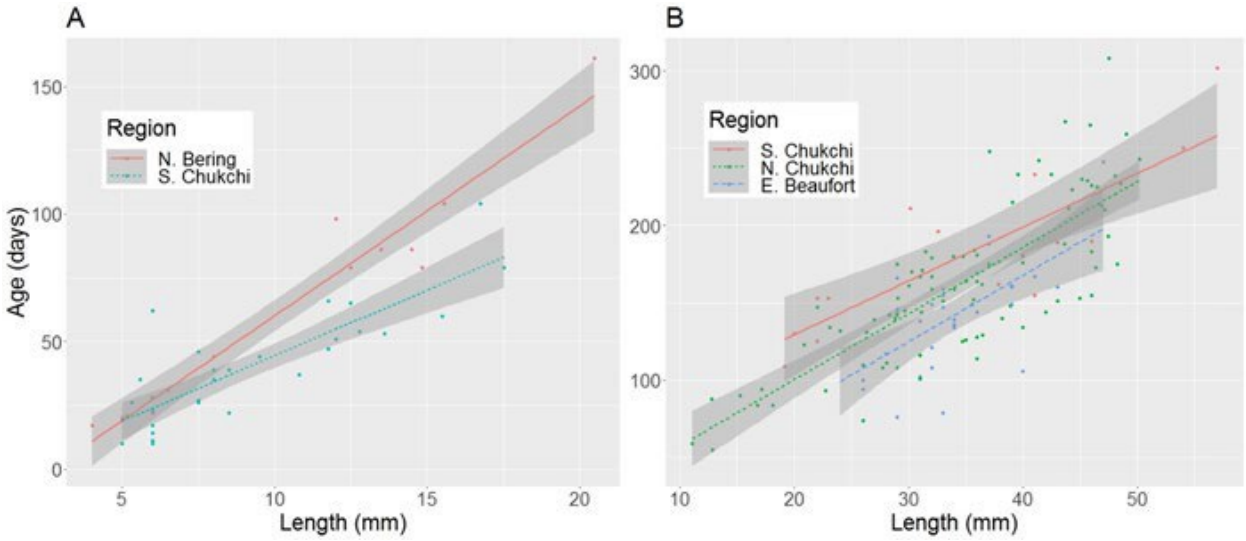

Figure 4: Age-at-length regressions by sampling region for spring (A) and summer (B) captured Arctic Cod with 95% confidence bands. Lengths ranged from 5 to 20 mm in spring (A) and from 10 to 55 mm in summer (B). Ages ranged from 0 to 150 days (A) and 100 to 300 days (B) in the spring and summer, respectively.

Figure 5: Length frequency distributions (x-axis, in mm) of age-0 Arctic Cod sampled in each region by vertical location in the water column. The number of individuals measured in each region is indicated (N).

Figure 6: Estimated hatch date distributions by location in the water column for each region. Northern Bering Sea (NBS); southern Chukchi Sea (SCS); northern Chukchi Sea (NCS); western Beaufort Sea (WBS); eastern Beaufort Sea (EBS).

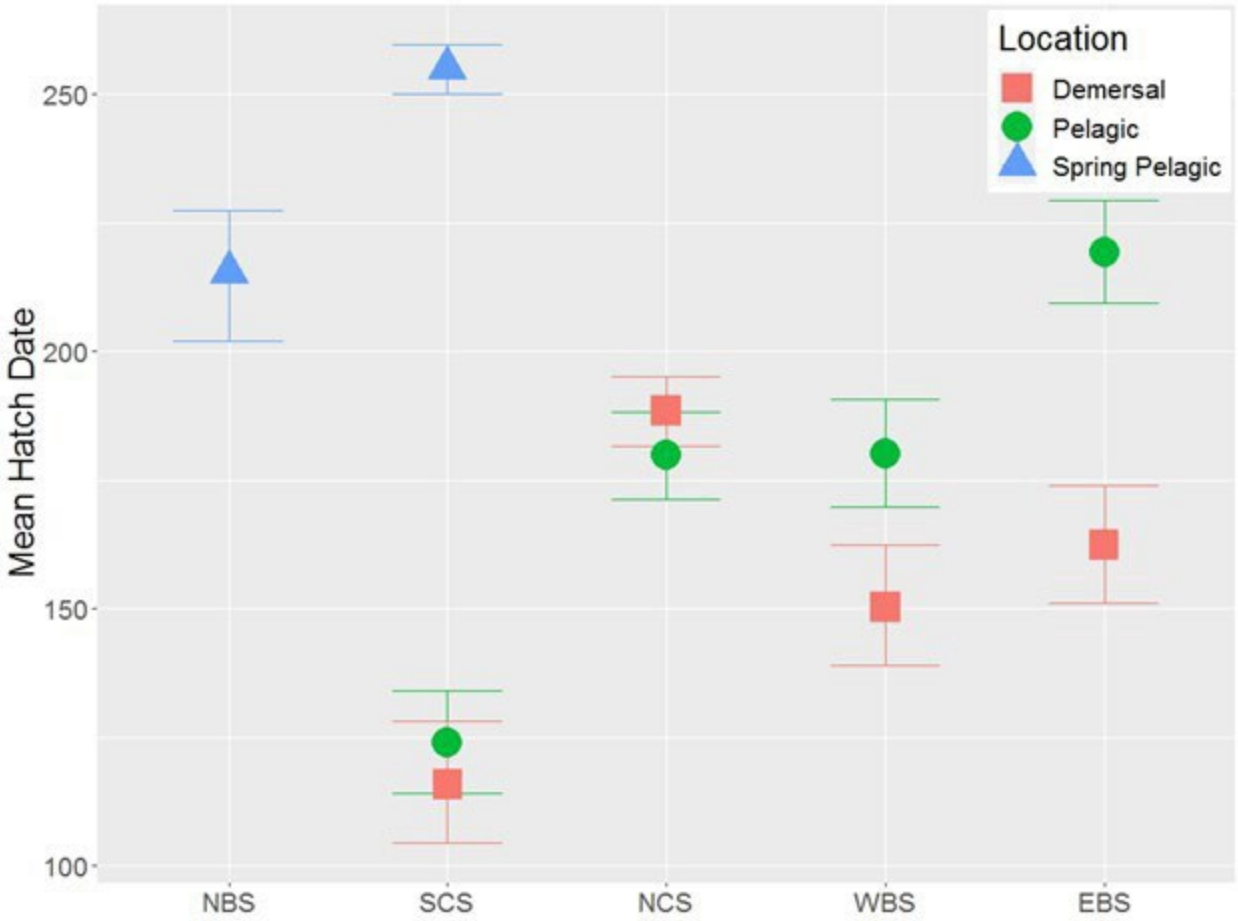

Figure 7: Estimated mean hatch date with 95% confidence limits for each region and vertical location (Pelagic or Demersal). Mean hatch date 100 corresponds to December 12 and hatch date 240 corresponds to May 11.

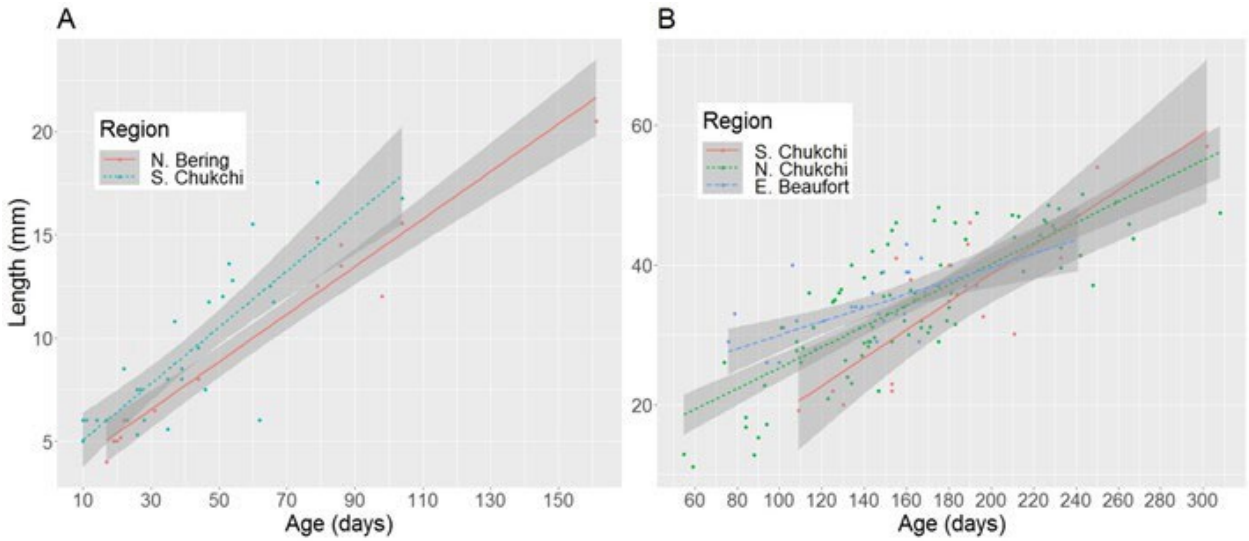

Figure 8: Regressions of length on age to estimate growth rates for spring (A) and summer (B) captured age-0 Arctic Cod by region.

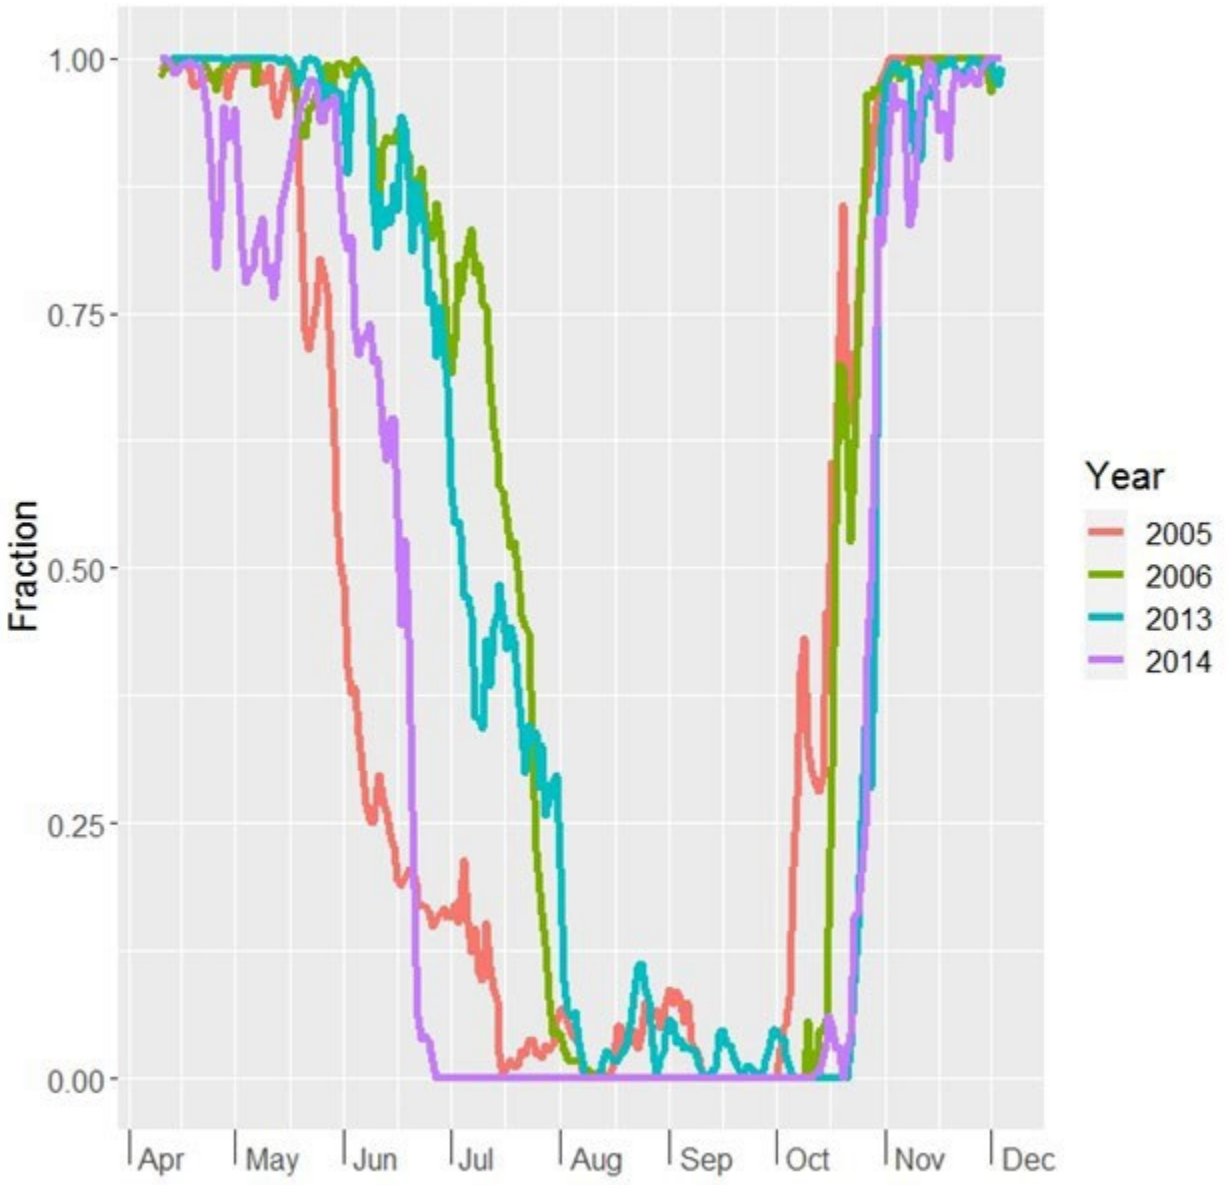

Figure 9: Seasonal trends in sea ice concentration (fraction of area with > 15% sea ice) for the eastern Beaufort Sea sampling region for four selected years with hatch date information.

Table 1: Season, cruise, region, and sampling year with the dates, gear type, number of stations and number of Arctic Cod that were captured with their length range and mean length (mm). Regions are the northern Bering Sea (NBS), southern Chukchi Sea (SCS), northern Chukchi Sea (NCS), western Beaufort Sea (WBS) and eastern Beaufort Sea (EBS). Bongo, IKMT, and Marinovich trawls sampled fish in the pelagic zone and bottom trawls sampled fish in the demersal zone.

Season	Cruise	Region	Year	Sampling Dates	Gear Type	# of Stations	Polar Cod Captured	Length Range	Mean Length
Spring	ASGARD	NBS	2017	Jun-10 – Jun-28	Bongo	7	19	6-19	12
Spring	ASGARD	SCS	2017	Jun-28 – Jun-23	Bongo	23	838	5-17	8
Summer	AMBON	SCS	2017	Aug-6 – Aug-21	IKMT	4	91	18-56	37
Summer	AMBON	SCS	2017	Aug-6 -Aug-21	Bottom Trawl	11	584	28-68	50
Summer	AMBON	NCS	2017	Aug-18 – Aug-22	IKMT	6	1,076	21-51	29
Summer	AMBON	NCS	2017	Aug-9 – Aug-22	Bottom Trawl	50	2,841	11-73	38
Summer	Arctic IES	SCS	2017	Sep13 – Sep-27	Marinovich	9	666	28-74	52
Summer	Arctic IES	SCS	2017	Sep-12 – Sep-27	Bottom Trawl	14	190	34-74	52
Summer	Arctic IES	NCS	2017	Aug-8 – Sep-13	Bongo	25	54	13-40	25
Summer	Arctic IES	NCS	2017	Aug-13 – Sep-13	Marinovich	19	1,256	25-71	42
Summer	Arctic IES	NCS	2017	Aug-10 – Sep-14	Bottom Trawl	30	463	22-73	48
Summer	TB12	WBS	2012	Sep-21 – Sep-29	Bottom Trawl	12	480	15-71	54
Summer	TB12	WBS	2012	Sep-22 – Sep-30	IKMT	13	254	22-71	46
Summer	TB13	EBS	2013	Sep-15 – Sep-30	Bottom Trawl	11	15	30-42	35
Summer	TB13	EBS	2013	Aug-13 – Aug-30	IKMT	27	351	17-47	33
Summer	TB14	EBS	2014	Aug-19 – Aug-31	Bottom Trawl	27	264	27-73	46

Table 2: Number of age-0 Arctic Cod aged by season and region with the range of standard lengths (mm) and estimated ages (days), and parameters of the length-at-age regressions with the slope representing estimated growth rates in mm d^{-1}.

					Length-age regressions		
Season	**Region**	**Total aged**	**Length range (mm)**	**Age range (days)**	**Slope**	**Intercept**	**R^2**
Spring	N. Bering	14	4-21	17-161	0.115	3.075	0.943
Spring	S. Chukchi	29	5-18	10-104	0.183	1.804	0.912
Summer	S. Chukchi	15	19-57	109-302	0.200	-1.290	0.673
Summer	N. Chukchi	77	11-50	55-308	0.149	10.435	0..631
Summer	E. Beaufort	31**	24-47	76-241	0.097	20.250	0.397

** 27 were aged from 2013 survey and four were aged from 2014 survey.

Table 3: Model coefficients, estimates, standard errors and Wald's t-test results for regressions of age in days on standard length (mm) by season. Region-specific intercepts (α) and slopes (β) were estimated in the spring; a common slope was estimated in the summer. Subscript for regions are Northern Bering Sea (NBS), southern (SCS) and northern Chukchi Sea (NCS) and eastern Beaufort Sea (EBS).

Season	Region	Coefficient	Estimate	Std. Error	t-value	P value
Spring	NBS	α_{NBS}	-21.967	6.148	-3.573	0.001
	NBS	β_{NBS}	8.210	0.541	15.185	0.001
	SCS	α_{SCS}	10.484	8.163	1.284	0.207
	SCS	β_{SCS}	5.485	0.763	7.189	0.001
Summer	SCS	α_{SCS}	42.342	9.144	4.631	0.001
	NCS	α_{NCS}	20.538	5.412	3.795	0.002
	EBS	α_{EBS}	3.038	8.973	0.339	0.735
	All	β	4.092	0.238	17.178	0.001

Table 4: Mean and range of hatch dates (HD) by season, region and vertical location in water column. Dates marked with * are from the previous year. Regions are Northern Bering Sea (NBS), southern (SCS) and northern Chukchi Sea (NCS) and western (WBS) and eastern Beaufort Sea (EBS).

Season and Region	Vertical Location	Mean HD	Earliest	Latest
Spring				
NBS	Pelagic	Apr-06	Jan-02	Jun-09
SCS	Pelagic	May-16	Feb-26	Jun-22
Summer				
SCS	Pelagic	Jan-04	Sep-27*	Jul-22
SCS	Demersal	Dec-27*	Sep-27*	Jun-07
NCS	Pelagic	Mar-01	Sep-27*	Aug-06

Table 5: Pairwise comparisons of mean hatch dates among regions by season and vertical location in the water column with bootstrap-based p-values and estimated difference in mean hatch dates. Negative differences in mean HD imply that the first region had an earlier hatch date than the second region.

Regional comparisons	Season	Vertical location	P-value	Difference in Mean HD
Spring				
NBS – SCS	Spring	Pelagic	0.002	-40
Summer				
SCS – NCS	Summer	Pelagic	0.002	-55
SCS – WBS	Summer	Pelagic	0.002	-56
SCS – EBS	Summer	Pelagic	0.002	-95
NCS – WBS	Summer	Pelagic	0.957	0
NCS – EBS	Summer	Pelagic	0.002	-39
WBS – EBS	Summer	Pelagic	0.002	-39
SCS – NCS	Summer	Demersal	0.002	-72
SCS – WBS	Summer	Demersal	0.002	-34
SCS – EBS	Summer	Demersal	0.002	-46
NCS – WBS	Summer	Demersal	0.002	38
NCS – EBS	Summer	Demersal	0.002	-26
WBS – EBS	Summer	Demersal	0.059	-12

CHAPTER 20 - Arctic Cod (*Boreogadus saida*) otolith microchemistry supports regional differences in hatching habitats off Alaska

Objective 5: Further resolve early life history characteristics of Arctic cod and saffron cod and their behavior and connectivity between the Chukchi Sea and western Beaufort Sea.

Abstract

The early life history of many fish species is sometimes poorly understood because of the difficulties observing spawning and sampling early life stages. This is especially true for Arctic Cod (Boreogadus saida), which may hatch in remote areas of the Arctic making direct observations difficult. Although larval and early juvenile Arctic Cod have been collected throughout the Alaskan Arctic, their spawning and hatching locations remain unknown. Otolith microchemistry offers one approach to identifying possible habitat conditions associated with hatching. Therefore, we measured the ratio of eight trace elemental concentrations relative to Calcium near the hatch marks of otoliths sampled in the Chukchi and Beaufort seas using laser ablation inductively coupled mass spectrometry. Trace elemental concentrations were used to compare the regions and to infer the water characteristics during the time of hatching. This was done using previously established relationships between elemental ratios and water properties. The results showed no significant difference in hatch mark chemical signatures between the northern Chukchi Sea and the western Beaufort Sea. The results also indicated at least two hatching populations based on significant differences in five of the eight trace elemental ratios from the eastern Beaufort Sea and samples from the western regions. Differences in trace elemental ratios indicated that Arctic Cod from the eastern Beaufort Sea hatched in less saline waters than those from the western regions, possibly a result of hatching within the relatively fresh Mackenzie River plume. Some samples from the northern Chukchi Sea had elevated levels of Zinc near the hatch mark, which could be due to hatching in Kotzebue Sound, where Zinc concentrations may be elevated due to mining. The results of this study expanded our knowledge of Arctic Cod early life history and showed promise for using otolith microchemistry to improve our understanding of Arctic Cod hatch locations.

Introduction

Arctic Cod (*Boreogadus saida*) have a circumpolar distribution in the Arctic and are a primary food source for many predators. They have a narrow thermal range and are sensitive to high temperatures, especially during their larval stage (Laurel et al, 2015; Kent et al, 2016), making them vulnerable to a changing climate. Because of this vulnerability and their importance to the Arctic ecosystem, understanding their early life history is critical to management and conservation (NPFMC, 2009). Several important aspects of the early life history of Arctic Cod in the Pacific Arctic remain poorly understood, especially with regards to vital hatching and spawning locations. Here I present a pilot study that examines the potential of otolith chemical signatures to differentiate stocks and infer habitat characteristics of Arctic Cod during hatching.

Environmental variables such as water temperature and salinity can be reconstructed by analyzing the chemical composition of fish otoliths (Campana, 1999). Otoliths are acellular and metabolically inert and therefore store many elements in proportion to their concentration in the water masses they inhabit (Campana, 2005). Because otoliths are not reabsorbed, they provide a permanent record of environmental

conditions encountered during an individual's lifetime (Campana, 1999). The concentrations of many trace elements differ among water masses and these differences are recorded in the chemical composition of otoliths. Moreover, the rate at which certain elements are incorporated into the otoliths may depend on environmental conditions such as temperature and salinity, as well as somatic growth rate (Bath et al., 2000; Bath and Thorrold, 2005). Incorporation of Barium and Strontium occurs independent of growth rates, whereas Manganese and Magnesium can be dependent (Bath et al., 2000; Bath and Thorrold, 2005).

Elements used commonly for otolith analyses include Barium (Ba), Lithium (Li), Magnesium (Mg), Manganese (Mn), and Strontium (Sr) because change in these elements can be used to infer changes in temperature and salinity (Bouchard et al., 2015). Elemental concentrations of Ba, Li, Mg, and Sr from the otolith edge are positively correlated with salinity, whereas Mn has a negative relationship with salinity in their environment (Bouchard et al., 2015). Water temperature also plays a role in the elemental composition of the otolith as Li and Mn concentrations are both negatively correlated with water temperature near the time of capture (Bouchard et al., 2015). Other elements such as Zinc (Zn) and Copper (Cu) can be used as identifiers of environmental conditions as they may be associated with freshwater runoff from drainages or mines (Saquet et al., 2002, Halden et al., 2000). Zinc is frequently associated with fresh water sources. In Arctic Char (*Salvelinus alpinus*), zinc concentrations are greatest near the otolith core which is likely associated with a near-shore distribution during their first year (Halden et al., 2000). Using the concentrations of these elements within otoliths may therefore help identify the type of water mass fish inhabited during different life stages.

The elemental composition of otoliths provides a timeline of environmental conditions because of the incremental nature of otolith development. The elemental composition of growth rings along the current edge of the otolith reflects the water mass within a few days of capture because of a lag between the ambient water characteristics and the incorporation into the otolith (Miller, 2011). Similarly, the elemental composition near the hatch mark reflects conditions at the time of hatching when the hatch mark formed. To identify possible hatch locations of juveniles requires calibrating the chemical signature by relating elemental concentrations to water mass characteristics such as temperature and salinity. Calibration should ideally be performed using larvae captured shortly after hatching and these calibrations can be used to determine the origin of juveniles or adults caught at later stages, based on the chemical composition of their otolith cores. For example, otoliths from recently hatched Capelin (*Mallotus villosus*) were analyzed for chemical signatures to create a relationship between these signatures and the chemical concentrations in their environment (Davoren et al., 2015). Using the chemical signatures from the hatch mark of adults from the same brood year, their natal origins can be determined. If early larvae from putative spawning locations or from different known populations are not available, calibration may be performed using relationships between the chemical composition at the otolith edges of juvenile or adult samples and the water masses at the capture location. However, applying water mass associations established for juvenile or adult stages to identify hatch locations based on their core chemical composition can be problematic if larvae occur at different depths with varying chemical compositions (Bouchard et al., 2015). Trace elemental composition may also change seasonally and the rate of uptake of trace elements may change with ontogeny (Hüssy et al., 2020). Nevertheless, establishing relationships between environmental conditions and elemental composition can provide valuable information about potential hatching areas and habitat use during early life (Bouchard et al., 2015).

Several studies on Arctic Cod have used otolith microchemistry to identify relationships between chemical composition and environmental conditions. Trace elemental composition along the edge of Arctic Cod otoliths have been used to infer bottom water mass occupancy across the Chukchi Sea with high confidence, indicating the potential for using trace elements to determine habitat associations of early life stages (Gleason et al., 2016). This study showed that benthic temperatures play a larger role than benthic salinity in differentiating among demersal habitats based on otolith chemical compositions of Arctic Cod because temperature is typically more variable among water masses than salinity (Gleason et

al., 2016). Significant differences in environmental conditions must exist among habitats if the composition of otoliths is to be useful for making inferences about habitat use and distribution. Otolith trace elemental composition along the edge and in the core of Arctic Cod differed between each other and among six different regions across the circumpolar Arctic (Bouchard et al., 2015). Trace elemental concentrations at the otolith edge were related to salinity and temperature at the capture locations. Based on the identified relationship between chemical composition and salinity, otolith trace elemental composition near the otolith core was used as a proxy for salinities at the time of hatching to predict the extent to which hatching occurs in locations influenced by freshwater discharge.
In the Pacific Arctic, the stock structure of Arctic Cod and their spawning and hatching locations are not well known. Therefore, the goal of this study was to assess the use of chemical signatures from the hatch mark of otoliths for differentiating possible hatching populations of Arctic Cod in the Pacific Arctic. Specifically, our objectives were to (1) compare the trace elemental composition of otoliths sampled in three different regions of the Alaskan Arctic and (2) infer habitat differences of early larval stages and possible hatching locations based on previously established relationships between the otolith elemental composition of Arctic Cod and surface water salinity and temperature.

Methods

Study area

Arctic Cod were sampled in three distinct regions, the northern Chukchi Sea (NCS), the western Beaufort Sea (WBS), and the eastern Beaufort Sea (EBS) (Fig 1). Samples in the NCS were all collected on the shallow shelf north of 70° latitude and west of 155° longitude. Samples from the WBS region were collected east of 155°W, while the EBS samples were collected near the U.S Canadian Border near 140°W.

Sample Collection

Arctic Cod samples for this study were collected from three different surveys: The 2017 Arctic Integrated Ecosystem Survey (Arctic IES II) and the 2013 (TB13) and 2014 (TB14) US/Canada Transboundary surveys (Table 1). The samples from the Arctic IES II survey were collected using a Marinovich Trawl, the TB13 samples were collected using an Isaacs—Kidd Midwater Trawl (IKMT), and the TB14 samples were collected with a Plumb—Staff Beam Trawl. All larval and juvenile gadids for this analysis were retained and stored in 95% ethanol or frozen. Arctic IES II samples were shipped to the University of Alaska Fairbanks (UAF) lab in Juneau, Alaska. About 60% of these specimens were validated to be Arctic Cod by larval taxonomists from the National Oceanic and Atmosphere Administration (NOAA). The remaining 40% of the samples were identified by the author after training from NOAA larval taxonomists. The TB13 and TB14 samples were identified, measured for length and weight, had sagittal otoliths removed, and archived at the Fisheries Oceanography lab at UAF. Archived otoliths were shipped to the UAF lab in Juneau, Alaska, for this analysis. All otoliths were extracted, cleaned, and polished and were mounted to slides with thermal plastic cement for laser ablation.
Otolith Chemistry

To address my objectives, I measured the concentration of Calcium (Ca^{40}), Lithium (Li^{7}), Magnesium (Mg^{24}), Manganese (Mn^{55}), Copper (Cu^{64}), Zinc (Zn^{65}), Strontium (Sr^{88}), and Barium (Ba^{137}) along a transect from the center to the edge of 133 otolith samples (Fig. 2). I then selected measurements corresponding to the hatch mark, approximately 11.5 μm from the center of the otolith, to infer habitat conditions at the time of hatching and identify possible hatch locations. The identification of the hatch mark was validated through the use of laboratory raised Arctic Cod from the Hatfield Marine Science Center in Newport, Oregon (Fig.3; Benjamin Laurel, NOAA Alaska Fisheries Science Center, pers. comm.). The ablation at 11.5 μm did not include the hatch mark but was within the first week of life and

reflects water conditions just after hatching. A point just outside of the core was selected to avoid any maternal chemical imprinting. Otoliths were analyzed at the University of Alaska Fairbanks Advanced Instrumentation Laboratory using a New Wave UP213 Laser with an Agilent 7500ce Inductively Coupled Plasma Mass Spectrometer (LA—ICP—MS). Nine otoliths were placed on a slide and processed in a single run. Prior to each run Nist610 and Febs pellets were ablated to ensure a consistent standard. The transects were ablated at 5 μm/s, using a beam width of 25 μm with a pulse frequency of 10 Hz at 55% laser power. Data from the LA—ICP—MS were processed using Igor Pro version 6.37® (WaveMetrics) and Iolite software package version 3.0®. To ensure data quality all transect profiles were analyzed to check for and eliminate unrealistic elemental spikes that are caused by elemental fractionation, which is the transport of aerosol particles from the ablation chamber to the ICP and is not representative of the actual elemental abundance (Limbeck et al., 2015). For statistical analysis all measurements were expressed as ratios relative to Ca to standardize the results for the amount of material ablated.

Statistical Analysis

Multivariate and univariate statistical analyses were conducted to compare otolith elemental compositions among collection regions. Prior to analysis, trace elemental ratios were log—transformed to achieve approximate multivariate normality and were standardized to a mean of zero and a standard deviation of one. Pairwise Euclidean distances among samples were calculated to visualize differences in the elemental composition of the hatching location among regions using a multivariate ordination based on a Principle Components Analysis (PCA). Multivariate analysis of variance (MANOVA) was used to test for overall differences in chemical composition among regions. When overall differences were significant ($p < 0.05$), these were followed by individual ANOVAs to determine which of the elemental ratios differed among regions. Significant ANOVA results were followed by Tukey Honest Significant Difference (HSD) post hoc tests to assess pairwise differences between regions for significance. All analyses were performed using the R statistical computing environment version 3.5.3 (R Core Team, 2019). Samples in the EBS were collected during two different years and were assess for interannual variability in their otolith elemental composition. There was no significant difference between 27 samples collected in 2013 and 10 samples from 2014 for most elements; therefore, samples from the EBS region were pooled to increase the sample size for comparisons with other regions.

Results

The results indicated that the otolith chemical composition around the time of hatching differed between the EBS and the two western regions, but not between the WBS and NCS. Within the EBS, no significant differences were found between 2013 and 2014 for most trace elemental ratios, except for Mg/Ca (t-test: $p = 0.001$) and Ba/Ca ($p=0.042$). The PCA ordination showed considerable overlap in trace elemental compositions among regions (Fig. 4). However, there was an overall statistical difference in the mean elemental composition among regions (MANOVA: Pillai's trace = 0.299, $p = 0.004$). Specifically, the elemental ratios for Mn, Zn, Sr88 and Ba differed significantly among regions (ANOVAs: $p = 0.012$, 0.003, 0.002 and 0.035, respectively, Fig. 5). The Mn/Ca ratio was significantly higher in the EBS than the NCS ($p = 0.011$). Zn/Ca was significantly lower in the EBS than in the NCS ($p = 0.008$) and the WBS ($p = 0.013$). At a 90% significance level, the ratios of Sr88/Ca, and Ba/Ca were all significantly lower in the EBS than in the NCS ($p = 0.009$ and $p = 0.074$, respectively) and WBS ($p=0.062$, $p = 0.008$, and $p = 0.070$). In summary, there were no significant differences for any element between the NCS and the WBS; in contrast, seven out of 15 pairwise comparisons between the EBS and the other two regions were significant (Table 2).

Discussion

The chemical analyses suggest considerable overlap in the trace—elemental compositions of the hatch mark in otoliths from the NCS, WBS, and EBS. Nevertheless, small but statistically significant

differences in individual elemental ratios among regions were found, likely reflecting differences in the range of habitats where hatching occurs within each region. Similarly, Bouchard et al. (2015) found significant differences in several of the same trace elements (Mn, Sr, and Ba) across multiple circumpolar regions. Bouchard et al. (2015) found that Mn/Ca was negatively correlated with salinity, while Sr/Ca and Ba/Ca were positively correlated with salinity. In this study, I found a higher ratio for Mn and reduced ratios for Ba, Sr86, and Sr88 in the EBS compare to the other two regions, suggesting that EBS Arctic Cod hatched in waters with lower salinity than those in the WBS and NCS. Arctic Cod captured in the EBS may have hatched in nearshore waters off the Mackenzie River (Bouchard and Fortier, 2008), a region that receives large amounts of freshwater runoff and is characterized by low salinities (Lansard et al., 2012), consistent with the chemical signature of larval Arctic Cod from the EBS. The high—salinity signature in the otoliths of larvae sampled in the other two regions suggests that they originated in areas with higher salinity, consistent with their hypothesized origin near the Bering Strait region (Vestfals et al., 2021). Otolith elemental compositions at both the core and the edge also differed between Arctic Cod from the same transboundary cruises as this study and samples from the Chukchi Sea near the Wrangel Islands in Russian waters (Frothingham et al., 2020). The difference in elemental composition between these two locations was more pronounced than in this study, likely because of their greater geographical separation, whereas the smaller distances among samples from this study may have resulted in some mixing among regions. However, the observed differences in otolith chemistry support the existence of at least two unique spawning populations in the Beaufort and Chukchi seas, consistent with previous studies on Arctic Cod genetics (Wilson et al., 2017, 2019, Nelson et al., 2020), spatial distribution (Forster et al, 2020) and hatch date distributions (Chapman et al. unpublished manuscript).

Differences between the EBS, which was sampled in 2013/14, and the two western regions, which were sampled in 2017, could have resulted from inter—annual variability in environmental conditions. The chemical signatures for both years are consistent with a low salinity origin. The higher Mg and Ba signatures in 2014 compared to 2013 may reflect lower discharge from the Mackenzie River during the April-June hatching period in 2014 (12.57 thousand m^3/s on average) compared to 2013 (14.00 thousand m^3/s) (https://wateroffice.ec.gc.ca/mainmenu/historical_data_index_e.html, accessed on 10/1/2020). However, other environmental variables could have resulted in the observed differences in elemental compositions between these years such as rain, ice melt, and wind mixing.

The lack of significant differences in chemical signatures between Arctic Cod sampled in the NCS and in the WBS during the 2017 survey suggests that they originated from waters with similar chemical compositions. This supports the hypothesis that they are part of the same spawning population, consistent with similarities in hatch dates (Chapman et al. unpublished manuscript), oceanographic connectivity between the two regions (Forster et al., 2020), and model results suggesting transport of larvae from the Chukchi Sea into the western Beaufort Sea (Levine et al. 2021).

Although the mean concentrations of several elements that reflect salinity variations differed among regions, there was considerable overlap in chemical composition among regions as evident in the PCA ordination. In particular, the concentrations of Lithium, a trace element that primarily reflects temperature variations in the environment (Bouchard et al., 2015), did not differ among regions. Temperature affects otolith elemental concentrations by modifying the uptake of trace elements from the water into the otolith (Collingsworth et al., 2010), thus the lack of significant differences in Li suggest similar temperature conditions across regions at the time of hatching. This is not surprising considering that hatching typically occurs under the ice at temperatures near freezing (Bouchard and Fortier, 2011). Like Li, Mn tends to be negatively correlated with temperature, but also has a negative relationship with salinity (Bouchard et al., 2015). Therefore, the lack of difference in Li in the otoliths among regions suggests that the observed elevated Mn concentrations are due to lower environmental Mn concentrations related to lower salinities in the EBS. Alternatively, the observed difference in Mn could be due to slightly elevated temperatures in the EBS region associated with the Mackenzie River freshwater plume. Arctic Cod hatching in freshwater

plumes are hypothesized to experience slightly elevated temperatures and increased growth rates compared to regions without a strong freshwater influence such as the NCS and WBS (Bouchard et al., 2015). However, the lack of a difference in Li concentrations among regions and lower growth rates in the EBS (Chapman et al. unpublished manuscript) are not consistent with the hypothesis that EBS larvae experienced elevated temperatures at the time of hatching compared to larvae in the NCS and WBS. Differences in most elemental ratios provide some insight regarding salinity and temperature conditions at the time of hatching, but trace elements such as Zn may be associated with anthropogenic sources. Zinc is a biologically important nutrient and occurs naturally in freshwater and seawater. Increased levels of Zn in otolith hatch marks of fishes can be caused by Zn runoff from mine tailings near the hatching area (Saquet et al., 2002; Halden and Friedrich, 2008). In the current study, Zinc levels from the NCS and WBS Arctic Cod were significantly higher than those captured in the EBS. One of the hypothesized hatching areas for Arctic Cod is Kotzebue Sound (Deary et al., in Review), which is located about 50 miles downstream from the world's largest Zinc mine, possibly explaining the higher mean levels of Zn in NCS and WBS Arctic Cod. More targeted sampling of environmental Zinc as a tracer and of Arctic Cod at a range of distances from the potential discharge location are required to support this tentative conclusion and would also help determine the relative importance of Kotzebue Sound as a hatch location.

Conclusion

The results of this study, combined with previous studies on Alaskan Arctic Cod, have provided further evidence of at least two separate populations within the Pacific Arctic. While there was considerable overlap between the regions, statistical differences in several otolith elemental concentrations support the existence of two unique hatching populations. The analysis indicated that the EBS Arctic Cod hatched in waters with a lower salinity than those from the western regions. This is consistent with hypothesized hatching in the Mackenzie River plume. The elevated levels of Zinc in the NCS and WBS fish may be attributed to hatching occurring in Kotzebue Sound downstream from the Red Dog mine. While this study has provided greater insight into Arctic Cod populations within Alaska's waters and where they may hatch, more studies will be needed to accurately pinpoint the hatching locations of Arctic Cod. Using the method from this study with a larger sample size collected over an expanded geographic range where sampling occurred can help better identify the multiple spawning populations that inhabit Alaskan waters.

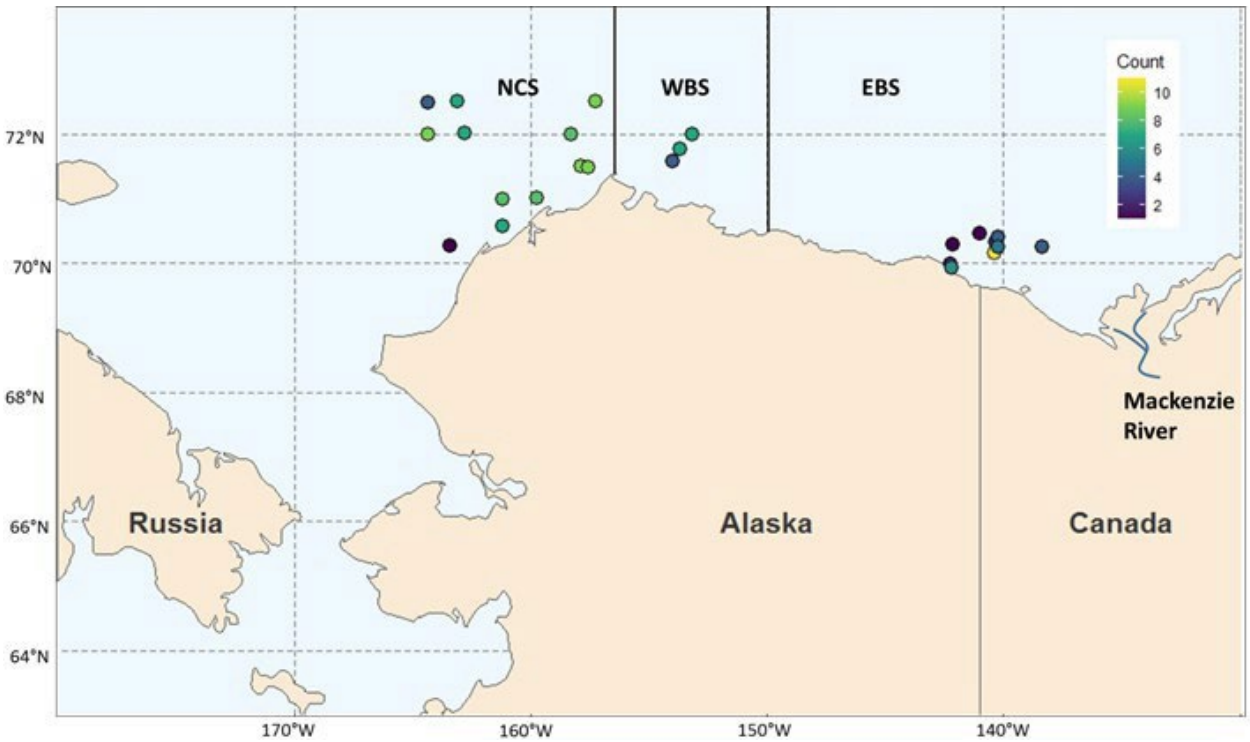

Figure 1: Location of samples from which otoliths were collected for microchemistry analysis from the Arctic IES and Transboundary surveys in the northern Chukchi Sea (NCS), western Beaufort Sea (WBS) and eastern Beaufort Sea (EBS). The number of samples analyzed from each station is indicated by the color change from cool (blue) to warm (yellow).

Figure 2: Polished otolith with ablation scar from laser ablated inductively coupled plasma mass spectrometer for determining trace elemental concentrations. The ablation point used for analysis was at 11.5 µm from the center just past the hatch mark.

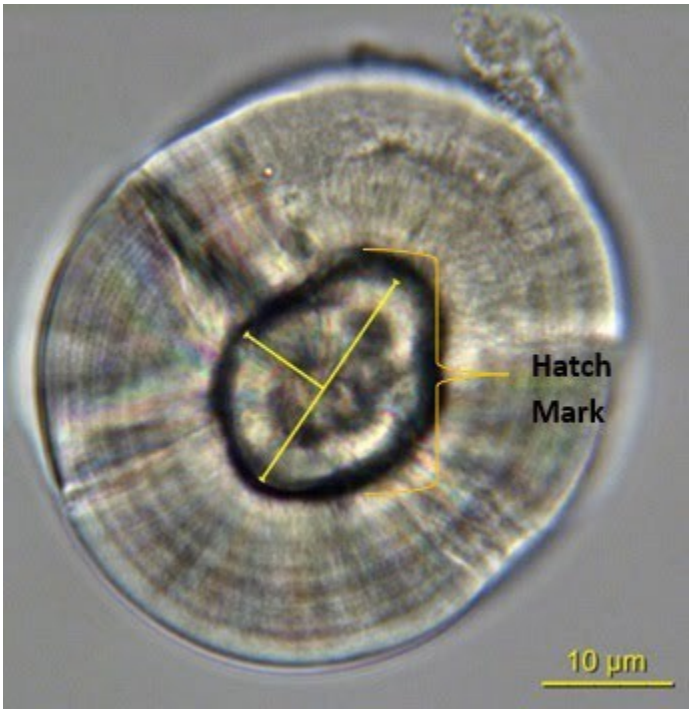

Figure 3: Sagittal otolith at 100X magnification from a lab raised Arctic Cod with the hatch mark outlined.

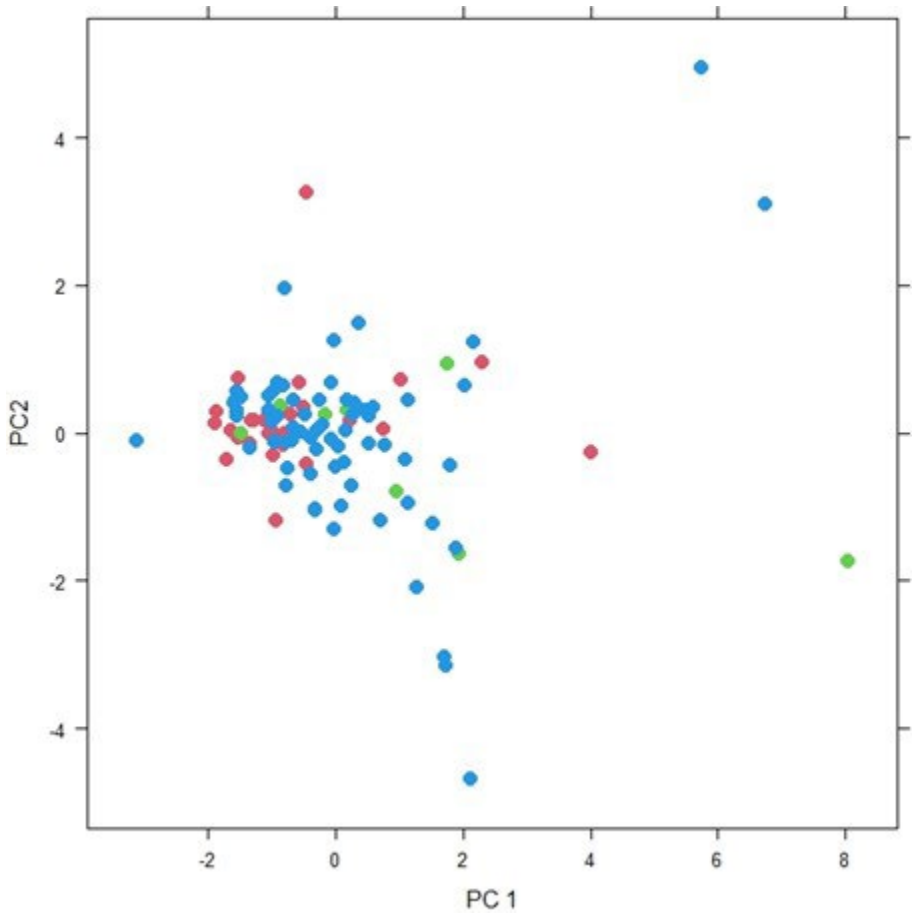

Figure 4: PCA ordination of 104 individual otoliths collected in the northern Chukchi Sea (NCS, blue), western Beaufort Sea (WBS, green), and eastern Beaufort Sea (EBS, red) based on the concentrations of seven trace elements standardized relative to Ca.

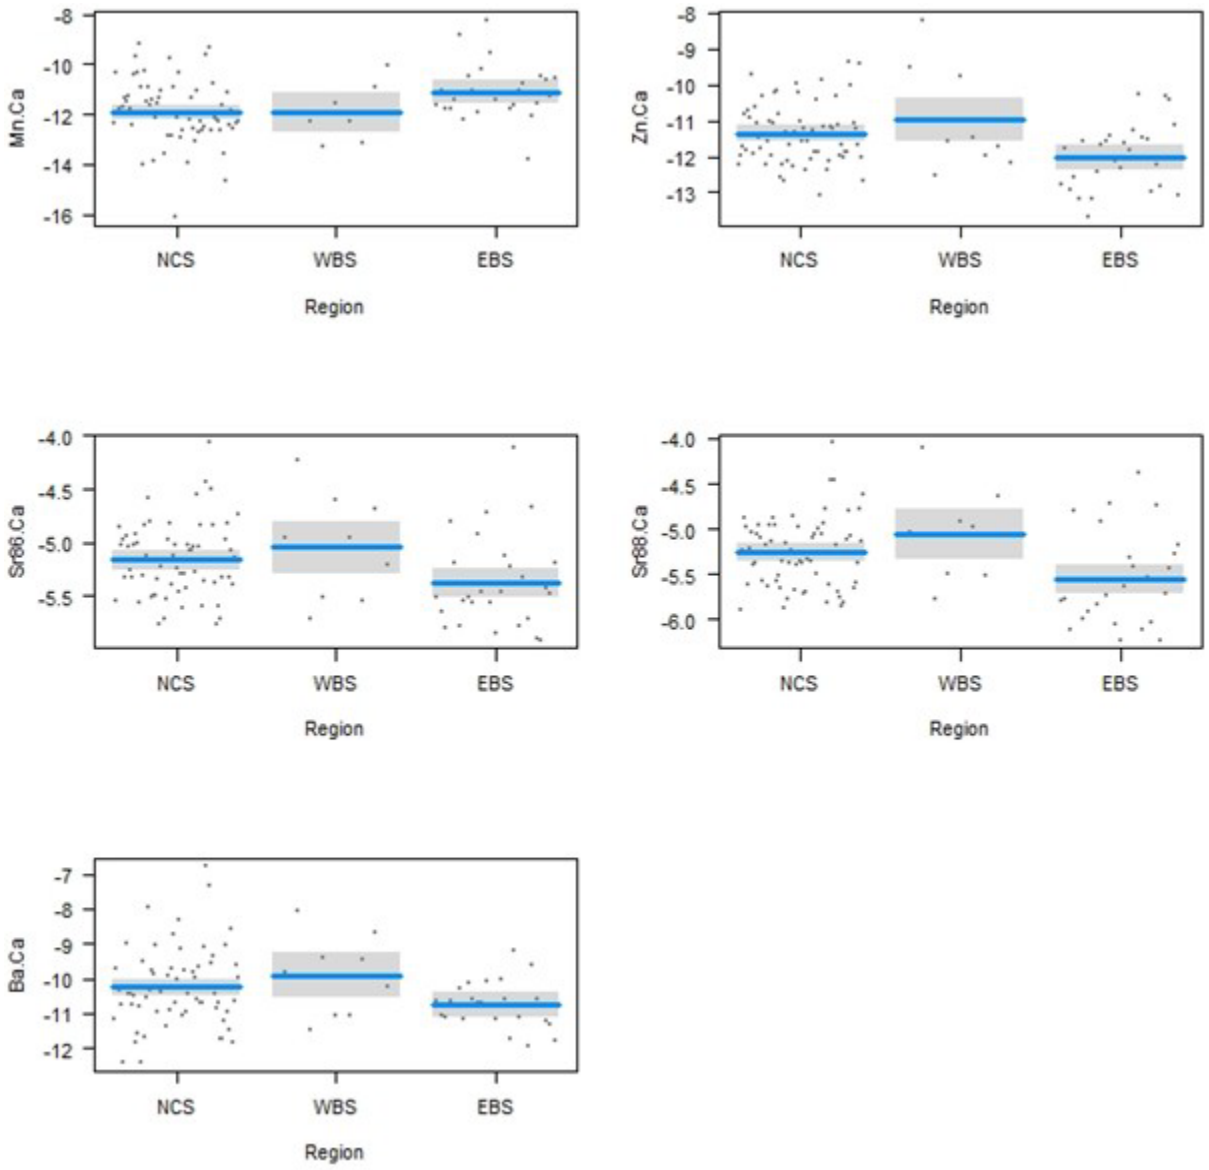

Figure 5: Box plots of mean log—transformed elemental ratios (blue bar) with 95% confidence intervals (grey shading) and partial residuals (black dots) for the five ratios that differed significantly among three regions (Eastern Beaufort Sea (EBS), Western Beaufort Sea (WBS), and Northern Chukchi Sea (NCS).

Table 1: Summary of the sample size, mean, standard deviation, median, and range of the log—transformed elemental ratios for fish captured in the northern Chukchi Sea (NCS), western Beaufort Sea (WBS) and eastern Beaufort Sea (EBS).

CHAPTER 21 - Distributional shifts among seabird communities of the Northern Bering and Chukchi seas in response to ocean warming during 2017-2019.

Objective 6: Quantify the distribution, abundance, and prey association of seabirds in the PAR in relation to oceanographic conditions, prey abundance, and feeding guilds.

Abstract

In the northern Bering Sea and eastern Chukchi Sea, 2017-2019 were record-breaking years for warm ocean temperatures and lack of sea ice. The region supports millions of seabirds that could be affected by shifts in prey distribution and availability caused by changing environmental drivers. However, seabirds are highly mobile and often flexible in diet, and might alter their foraging distributions accordingly. To determine if there was evidence of long-term changes in abundance of seabirds, or if seabirds used the offshore habitat differently during recent warm years, we compared species richness, community composition, and distribution and abundance of selected species and Total seabirds (all species combined) between two periods, 2007-2016 and 2017-2019. We also evaluated annual changes in abundance during 2007-2019. We used 79,426 km of transects from vessel-based surveys conducted July through September. Total seabird density for the entire study area increased by ~20% during 2017-2019, but changes were not consistent across the study area, nor among species, and species richness declined except for a slight increase in the northern Chukchi Sea. Total seabird density declined most in the northern Bering Sea (-27%), although it increased in the Chirikov Basin by 73%. During 2017-2019, abundance of piscivorous murres (*Uria* spp.) decreased everywhere, whereas planktivorous *Aethia* auklet density increased by 70% in Chirikov Basin; auklets apparently abandoned their post-breeding migration to the Chukchi Sea. Short-tailed shearwaters (*Ardenna tenuirostris*) expanded farther into the northern Chukchi Sea, with nearly twice the density of the previous decade. We identified five seabird community types, three of which (all dominated by an alcid species) contracted spatially in the later period, and shifted south or near colonies. In contrast, a short-tailed shearwater dominated community expanded northward, and a community defined by low seabird density expanded throughout the eastern portion of both the northern Bering and Chukchi seas, suggesting higher-density communities had shifted westward. The variable responses among species correspond to documented changes in the environment as well as their natural history.

Introduction

The Bering and Chukchi seas have been undergoing warming events and subsequent alteration of biological ecosystem components over the last 20 years (Grebmeier et al., 2006; Stabeno and Bell, 2019). However, events during 2017-2019 appear to have been distinctively disruptive of long term physical and biological patterns. Sea ice plays a critical role in primary productivity of these marine ecosystems. The formation of ice algae feeds phytoplankton blooms as the ice retreats (Brown and Arrigo, 2013), supporting zooplankton production (Campbell et al., 2016; Stabeno et al., 2010), and ultimately upper trophic levels. Early ice retreat, or lack of sea-ice formation, impacts these mechanisms with repercussions throughout the food web (Hunt et al., 2011). In the northern Bering Sea, warm conditions lead to early ice retreat, resulting in early and high primary productivity, particularly near the ice edge (Brown et al., 2011; Brown and Arrigo, 2013).

During 2017, sea ice formed over the eastern Bering Sea shelf, but there was an unusual and early retraction of ice over the northwestern Bering Shelf, attributed to persistent southerly winds. As a result, the northern Bering Sea was characterized by ice conditions similar to those of a 'warm' year, despite ice coverage farther south (Siddon and Zador, 2018). In 2018 and again in 2019, ocean temperatures were above normal in winter, and ice extent in the Bering Sea was the lowest recorded in four decades. In both years, sea ice retreated north of Bering Strait before spring (Siddon and Zador, 2018, 2019; Cornwall, 2019). The extremely low ice cover during 2017-2019 in the northern Bering Sea and Chukchi Sea resulted in altered oceanographic and biological conditions; these were most evident in 2018, and included impacts to lower and upper trophic levels (Duffy-Anderson et al., 2019).

Seabirds are indicators of ocean conditions (Murphy, 1936; Piatt et al., 2007 and references therein; Velarde et al., 2019). By understanding responses of seabirds to broad-scale ecological shifts we may better predict impacts to upper trophic-level taxa in a rapidly changing environment. In the Bering Sea, recent responses of seabirds to ocean warming have included mass mortality (Jones et al., 2019), failed nesting attempts and low reproductive success (Dragoo et al., 2020; Romano et al., this issue). Since 2015, seabird mass mortality events have occurred almost annually in the Bering Strait region (Duffy-Anderson et al., 2019). Species-specific mortality events and seabird reproductive success at monitored colonies can be indicative of food web changes (Abraham and Sydeman, 2004; Jones et al. 2019; Piatt et al., 2020). However, these metrics do not necessarily provide insight into how the broader seabird community has responded to an altered ecosystem.

Seabirds are long-lived, with adaptations to buffer variability in their environment. Forgoing a breeding season or undergoing a few years of low breeding success may not necessarily lead to substantial population-level repercussions (Cairns, 1992; Velarde and Ezcurra, 2018). Seabirds are also highly mobile, and can search for prey over a large area, particularly when not attending a colony. Further, seabirds spend most of their lives at sea, and their temporal and spatial distribution across the seascape often reflects the productivity and foraging conditions of large marine areas (Ballance et al., 1997; Gall et al. 2013; Suryan et al., 2012; Yen et al., 2006). Here, we examine broad-scale responses of seabirds to a warm period (2017-2019) in the Northern Bering and Chukchi Sea Large Marine Ecosystem (LME) relative to the preceding decade (2007-2016). Specifically, we use vessel-based surveys to assess how seabirds differed in species-specific and community-level abundance and distribution between these two time periods.

Methods

Study area

Our study area encompassed offshore waters of two regions, the northern Bering Sea (hereafter, Bering Sea) and eastern Chukchi Sea (hereafter, Chukchi Sea) (Fig. 1), and we considered southern and northern subregions within each region. We refer to the subregions (Fig. 2) as the Northern Bering (59.5°N to St. Lawrence Island; distinct from the general northern Bering Sea), the Chirikov Basin (St. Lawrence Island to Bering Strait at ~65.8°N, including Little Diomede Island), the Southern Chukchi (Bering Strait to 70°N) and Northern Chukchi (70°N to 72.5°N). The western boundary of all regions followed the U.S. Exclusive Economic Zone to 175°W and the eastern boundary followed an offshore buffer bordering coastal Alaska, to include only waters where our surveys occurred in most years (Fig. 2).

The northern Bering Sea is hydrographically and biologically distinct from the southern Bering Sea, separated at approximately 60°N (Stabeno et al., 2010; Sigler et al., 2011, 2017). The shallow continental shelf of the northern Bering Sea includes the Inner Shelf domain (<50 m deep) and Middle Shelf domain (50-100 m deep), with some influence from the more dynamic Outer Shelf and slope domains, which are beyond our study area. The Inner Shelf is bordered by the Alaska Coastal Current on the east side and the

more saline, colder and nutrient rich waters of the Anadyr Current in the west (Fig. 1). Both of these water masses pass through Bering Strait and, as Bering Sea Water, facilitate structure of the Chukchi Sea. The Chukchi Sea is also structured by the Siberian Current, which flows eastward along the northern coast of Russia. The Chukchi Sea, particularly in the north, is also heavily influenced by fresh, cold winter water, derived from sea-ice melt (Coachman et al., 1975; Weingartner et al., 2005, 2013). North of Bering Strait, the Bering Sea waters split and branch westward and eastward, encircling the bathymetrically complex, shallow, and nutrient rich Hanna Shoal in the northern Chukchi Sea (Coachman et al., 1975; Dunton et al., 2017; Fig. 1).

Sea-ice is a primary driver of both Bering and Chukchi ecosystems. The extent of ice coverage and the timing of ice retreat in the spring drives annual primary productivity by affecting sea surface temperatures and light availability for photosynthesis, and by providing a platform for epontic algal growth (Arrigo, 2003). Ultimately, the effects of spring conditions cascade to lower and upper trophic levels (Stabeno et al., 2010; Hunt et al., 2011, 2018). Sea ice generally retreats north of Bering Strait throughout late spring and summer, with the ice minimum occurring between September and October. However, ice extent and duration was minimal overall during 2017-2019 (Siddon and Zador, 2018, 2019).

The study area includes large seabird colonies (Stephensen et al., 2003) with an estimated 12 million birds nesting in the Northern Bering and Southern Chukchi subregions (USFWS, 2014). The largest colonies are on St. Matthew and St. Lawrence islands in the Northern Bering, the two Diomede islands in the Bering Strait, and Cape Thompson and Cape Lisburne in the Southern Chukchi (Fig. 1). In late summer and early fall this LME is also used by equal numbers of migratory birds (Kuletz et al., 2015, 2019), particularly short-tailed shearwaters (*Ardenna tenuirostris*), which nest in the southern hemisphere. Other seasonal visitors that nest south of the study area include members of the Alcidae and Laridae families, as well as waterfowl (Anatidae), phalaropes (Scolopacidae), and loons (Gaviidae), which pass through from Alaska's North Slope after breeding.

Data collection

At-sea distribution and abundance of seabirds were obtained from surveys conducted from research vessels using U.S. Fish and Wildlife Service protocols (Kuletz et al., 2008). A single observer recorded all birds on one side of the vessel, within 300 m and a 90° arc from the centerline of travel. The observer recorded species, number of individuals, and behavior (on water, on ice, foraging, in air) and perpendicular distance from the centerline (using distance bins). Birds were identified to the lowest taxonomic level possible, using 10x binoculars, and sometimes a digital camera, to assist with species identification. Birds on water or actively foraging were recorded continuously, whereas birds in the air (not actively foraging by touching the water surface) were recorded during quick scans within the transect window, at approximately $1 \cdot min^{-1}$ (varying with respect to vessel speed), and avoiding double counting. Surveys were conducted with seas of Beaufort scale ≤ 6 and were discontinued when dense fog or precipitation impeded visibility. Observations were entered into a laptop computer connected to a Global Positioning System (GPS), using software DLog3 (R.G. Ford, Portland, OR). Every record entry was stamped with time, latitude and longitude, and environmental conditions, and automatically updated at 20 sec intervals to record effort. We divided survey transect lines into ~3 km segments, with the segment centroid serving as sample location, and calculated density of birds ($birds \cdot km^{-2}$) for each transect segment. Transect widths were narrowed from 300 m to 200 m or based on observation conditions.

Data treatment and analysis

Survey effort (Table 1, Fig. 2) within the study area during 2007-2019 totaled 79,426 km, using only surveys conducted 1 July to 30 September; these months reflect peak breeding season for seabirds in the study area, and omit June, when we had little survey effort. We compared species richness, community

composition, and abundance of key species within the subregions between two time periods, 2007-2016 and 2017-2019. The latter years were characterized by anomalously low sea-ice coverage in the study region, with the warmest year (2018) exhibiting the highest record of seabird mortalities and reproductive failure (Duffy-Anderson et al., 2019; Romano et al., this issue). We also examined annual differences in abundance of key species and Total seabirds (all species combined, including phalaropes and seaducks but excluding other shorebirds, waterfowl, land birds, and birds of prey; Appendix A).

Species richness

Because sampling effort was not consistent among the four subregions and two time periods, we used rarefaction curves to examine species richness during each time period and within each subregion. We randomly resampled 3-km segments (without replacement) and generated plots of number of species observed vs. number of segments sampled, with 95% confidence intervals calculated using quantiles from 2000 random draws for each sample size. During surveys, it was not always possible to identify sightings to the species level, for example due to a brief or inadequate view. In the rarefaction analysis, a higher-order taxon was counted as a unique species if and only if a corresponding lower-order taxon was not present in the sample. For example, an unidentified murre (*Uria* spp.) would be counted as a species if and only if no common murres (*U. aalge*) or thick-billed murres (*U. lomvia*) occurred in a sample.

For the remaining analyses, we applied a 30-km hexagonal cell grid to the study area, and derived density of each species by cell using the mean of 3-km segments within each cell. Birds that had not been identified to species were apportioned from higher-order taxa to species based on the ratio of identified birds within a cell and year. If there were no identified species within a higher-order taxon in a given cell and year (ranging from 0-7% of cells, with an average of 1%, depending on taxon), unidentified birds were prorated to species based on spatial interpolation of species ratios derived from kriging surrounding cells; kriging applied a cutoff distance of 60 km (~ 2 grid cells).

The number of sampled cells within a subregion varied among years, ranging from 98 to 371 cells for a given year. Because spatial differences in sampling among years could bias comparisons, we imputed species densities for grid cells missing years using methods described in Renner et al. (2013) and Kuletz et al. (2014). Species densities of grid cells not surveyed in a given year were interpolated through time (not space). Within each grid cell, densities in any missing years were imputed using linear interpolation. Any missing values at the beginning or end of the time-series were imputed by replacing missing values with the closest neighbor in time (rather than projecting trends).

Abundance and distribution

During preliminary analyses, we examined the distribution and abundance of four foraging guilds (surface planktivore, diving planktivore, surface piscivore, diving piscivore) along with individual species. Because the foraging guild patterns were largely driven by the most abundant species within each guild, here we present results for Total seabirds and seven focal species: thick-billed murre, common murre, crested auklet (*Aethia cristatella*), least auklet (*A. pusilla*), northern fulmar (*Fulmarus glacialis*), black-legged kittiwake (*Rissa tridactyla*), and short-tailed shearwater. We selected these focal species because they were widespread in the study area (Appendix B) and relatively abundant during all years (Appendix A). Five of them were the predominate species for seabird communities identified in this LME during 2007-2015 (Kuletz et al., 2019).

We used two methods to evaluate distribution and abundance of these species and groups. First, we calculated annual density estimates for species or species groups from the cell means within a subregion and year. The grid cell means for each species were used to plot standardized mean anomalies for each subregion and time period (2007-2016 and 2017-2019). Near the coastline, some cells were truncated,

thus we used weighted averages based on the area of each hexagon cell; this avoided over-representation in the overall average due to the presence of large flocks in small cells. Second, we examined the spatial distribution of increases or decreases in seabird densities (by species) by subtracting mean densities (by cell) for 2007-2016 from mean densities for 2017-2019, and mapping these differences.

Community composition

To identify seabird communities in the study area and compare their distribution between the two time periods, we used K-Means Cluster analysis (Hartigan and Wong, 1979). In the first step, we grouped the 30-km hexagon grid cells based on similarity in densities of birds, using log-transformed densities. Clustering was based on species densities, not geographic coordinates, and performed on all years combined, 2007-2019. Five communities were identified in the study area, based on the inflection point of within-group sum of squares vs. the number of clusters (Hartigan and Wong, 1979). In the second step, the clusters were then redistributed to their respective time-period maps (2007-2016 or 2017-2019).

We used R functions and scripts for analyses (R Core Team, 2015), with kriging for species' ratios applying function *krige* in package gstat (Pebesma, 2004). Cluster analysis used the R function *kmeans* (Hartigan and Wong, 1979).

Results

Species richness

Estimated species richness was higher in the Bering Sea (~40 species) than in the Chukchi Sea (~30 species) during both time periods. Within the two Bering subregions, species richness was slightly lower during 2017-2019, whereas it remained similar overall in the two Chukchi subregions (Fig. 3). However, in both the Bering and Chukchi regions, there was a reversal in richness between subregions; i.e. during the later period the Chirikov Basin had slightly higher species richness than the Northern Bering, and the Northern Chukchi had higher richness than the Southern Chukchi (Fig. 3).

Spatial changes in density

Compared to 2007-2016, Total seabird density was higher in 2017-2019 (Table 2), but the direction of changes in density were not equal across the study area, nor among species. Mean densities indicated both murre species declined in the later period, whereas both auklet species and black-legged kittiwakes increased slightly, and short-tailed shearwaters nearly doubled in density (Table 2). During the later time period, Total seabird density increased along the Anadyr Current, and in the northern Hope Basin, the western portion of the Northern Chukchi, and over Barrow Canyon (Fig. 4a). Decreases occurred in most of the Northern Bering, but also in the eastern Chirikov Basin to southern Hope Basin and the eastern coastal waters of the Northern Chukchi. This pattern largely reflects that of short-tailed shearwaters, a numerically dominate species, although shearwaters also showed large increases in 2017-2019 northwest of Cape Lisburne and over the Hanna Shoal and Barrow Canyon areas (Fig. 4b). Northern fulmars did not have a clear pattern of spatial change, with both increases and decreases scattered throughout the study area and large areas with no change (Fig. 4c). Black-legged kittiwakes also showed little evidence of a clear pattern, although there were more increases in Hope Basin and northwest of Cape Lisburne (Fig. 4d).

Common murres showed few increases in abundance, with those mainly in the Northern Bering, and they otherwise decreased, particularly in the Southern Chukchi (Fig. 4e). Thick-billed murres increased in later years northwest of Cape Lisburne, but primarily decreased throughout the study area, including near the St. Matthew colony (Fig. 4f). Least auklets had large increases in the Chirikov Basin, but mainly

decreased throughout the Chukchi Sea (Fig. 4g). Crested auklets increased near the Anadyr Current in the Chirikov Basin and in the northern edge of the Northern Chukchi, but declined in other areas of the Northern and Southern Chukchi (Fig. 4h).

Annual trends in abundance

For Total seabirds, the annual trends in abundance indicated a general northward shift in distribution. This shift began around 2014 in the Bering Sea, 2015 in the Southern Chukchi, and 2016 in the Northern Chukchi, although relative abundance was below the long-term mean in 2019 for all but the Northern Chukchi (Fig. 5a). In contrast, abundance in the Northern Bering was below the long-term mean for most years after 2013. This general pattern reflected the influence of the most abundant avian species in the study area, the short-tailed shearwater, the least auklet, and the crested auklet (Table 2). Short-tailed shearwaters differed from Total seabirds in having extremely high abundance in the Chirikov Basin and the Southern Chukchi in 2015 (Fig. 5b). Trends of northern fulmars were mixed, with fluctuations between subregions of the Bering and in the Southern Chukchi, but generally lower use of the Northern Chukchi after 2010 (Fig. 5c). Abundance of black-legged kittiwakes shifted from the Northern Bering during 2007-2011 to the Chirikov Basin during 2012-2015, and to the Chukchi subregions from 2014-2019 (Fig. 5d).

In general, the diving alcids declined in recent years in the Chukchi, with the *Aethia* auklets increasing in the Chirikov Basin and Northern Bering, and the murres mostly decreasing throughout the study area after 2013. Starting in 2014 both common murres (Fig. 5e) and thick-billed murres (Fig. 5f) showed steadily declining trends in the Northern Bering and below average abundance (common murre) or very low abundance (thick-billed murre) in the Chirikov Basin. Abundances of both murre species were below the long term mean in the Chukchi subregions for most years after 2013. In contrast, least auklets, which were highly abundant in the Chukchi during 2010 to 2012, increased abruptly in the Chirikov Basin and Northern Bering during 2017-2019 (Fig. 5g). Crested auklets showed a similar pattern, although they were sporadically abundant in the Northern Chukchi and did not substantially increase in the Chirikov Basin until 2018 (Fig. 5h).

Seabird communities

Within our study area we identified five clusters of grid cells that differed from each other in seabird community composition and densities (Appendix C). Four of the clusters had the same primary species as the community types identified by Kuletz et al. (2019); these clusters were dominated by thick-billed murres, least auklets, crested auklets, and short-tailed shearwaters, plus a 'Low Density' cluster type defined by low total densities and no definitive predominant species (no species had a mean density of >0.54 birds·km^{-2}). A sixth community type identified by Kuletz et al. (2019), dominated by northern fulmars, was not distinguished in this new analysis, reflecting the omission of more southerly waters of the outer Bering Sea shelf that were part of the previous study.

The distribution maps for the five community clusters in each time period depicted a spatial contraction of the thick-billed murre, crested auklet, and least auklet-dominated clusters during 2017-2019 (Fig. 6). During the late period the thick-billed murre cluster was less extensive throughout the study area and was located primarily near St Matthew Island in the Northern Bering and the Cape Thompson and Cape Lisburne colonies in the Southern Chukchi. The crested auklet cluster covered a much smaller area and was concentrated in the northeastern portion of its previous range in the Chukchi Sea, although there were also isolated, scattered cells between Chirikov Basin and Hope Basin (Fig. 6). The least auklet cluster also covered less area in 2017-2019, and was found primarily south of Bering Strait, abandoning its earlier occupation of Hope Basin.

In contrast to the three alcid-dominated clusters, the short-tailed shearwater-dominated cluster expanded during 2017-2019, and was located primarily in the Chukchi Sea. Its increase was greatest in Hope Basin and contiguously along the western edge of the study area and in a band from Hanna Shoal to Wainwright and Point Barrow – the Barrow Canyon area (Fig. 6). The Low-Density cluster also expanded in the later period. During 2017-2019, this cluster covered more area (compared to 2007-2016) throughout the Bering Sea shelf, particularly in the Northern Bering subregion. Its distribution in the Southern Chukchi did not change much between time- periods, but in the eastern half of the Northern Chukchi, it greatly expanded during 2017-2019 (Fig. 6).

Discussion

During the exceptionally warm, low-ice years of 2017-2019, we found evidence of broad-scale shifts in distribution of individual species and of identified seabird communities compared to the previous decade. Sea-ice extent in the northern portion of the Bering Sea was the lowest on record during the late period of our study. In 2017, sea ice failed to form over the northwestern Bering Shelf due to atypical southerly wind patterns. Unprecedented open water predominated throughout the Northern Bering and Southern Chukchi subregions in 2018 and 2019 as well (Siddon and Zador, 2018, 2019). Nonetheless, density of Total seabirds increased approximately 20% during this period, with the increase largely due to short-tailed shearwaters in the Chukchi Sea, and least and crested auklets in the Chirikov Basin.

Short-tailed shearwaters breed on islands off Australia's southern coast during the austral summer. After breeding they migrate to Alaska for the boreal summer, and reach the northernmost extent of their migrations in the Chukchi Sea. Untethered from nesting colonies during their non-breeding season, shearwaters can readily respond to shifts in prey distribution. In contrast, the two species of auklet nest during summer in dense colonies on islands in the Chirikov Basin and Northern Bering, although some auklets in the offshore waters could have originated from colonies in the Aleutian Archipelago (Will et al., 2017) or the Siberian coast (USFWS, 2014). What all three species have in common is a diet primarily composed of zooplankton. The short-tailed shearwater is considered an omnivore, with a varied diet that includes euphausiids, copepods, cephalopods, amphipods, and larval and juvenile fish (Hunt et al., 2002; Ogi et al., 1980), but recent studies suggest it primarily feeds on euphausiids while in Alaska (Nishizawa et al., 2017, this issue). Both auklet species are planktivorous, with the smaller-bodied least auklet feeding mainly on *Neocalanus* copepods, and the larger crested auklet feeding on a variety of large copepod taxa, euphausiids, and occasionally, larval fish (Sheffield-Guy et al., 2009; Gall et al., 2006).

The Chukchi Sea has a late seasonal plankton bloom tied to the timing of ice retreat, long daylight hours, and stratification, which makes copepods available into late summer (Weingartner et al., 2013, 2017; Danielson et al., 2017). In comparison to historic patterns (1940s to 1990s), seasonally early ice retreat in the 2000s was associated with higher primary productivity and larger biomasses of lipid-rich copepods (such as *Calanus glacialis*), euphausiids (*Thysanoessa* spp.) and amphipods (*Themisto* spp.) (Ershova et al., 2015; Matsuno et al., 2011). This may be why Gall et al. (2017) found higher predicted abundance of short-tailed shearwaters and crested auklets with earlier ice retreat, based on survey data from the Chukchi Sea during 1975-2012. Our shearwater observations during 2017-2019 are consistent with that model. However, planktivorous seabirds, primarily short-tailed shearwaters and crested auklets, did not predominate in the offshore waters of the Chukchi Sea until sometime between the 1980s and 2007 (Gall et al., 2017). The late summer and fall presence of crested and least auklets far from breeding colonies were presumed to be post-breeding birds replenishing body reserves before migrating back to the Bering Sea for winter (Kuletz et al., 2019; Will et al., 2017).

During the current decade, sea ice has further diminished. Zooplankton communities in the Chukchi Sea have shown highly localized influences of shifting water masses, resulting in high interannual variability (Pinchuk and Eisner, 2017; Spear et al., 2019). The irregular pattern of abundance exhibited by crested

auklets in the Northern Chukchi may reflect these localized fluctuations (Fig. 5h). Preliminary examination of zooplankton samples from the Northern Chukchi found that large copepods were more abundant in 2017 than in 2019, albeit both years had lower copepod abundance than during cooler years of 2012-2015 (D. Kimmel, unpubl. data). Our observations suggest that crested auklets and short-tailed shearwaters took advantage of aggregations of large copepods and euphausiids in the Northern Chukchi, particularly in 2017 (Fig. 5 b, h).

The abundance of crested auklets in the Northern Chukchi suggests that a portion of the Alaska-wide metapopulation rely on the prey in these cooler waters. However, the dynamics of sea ice, water temperature, primary productivity, and zooplankton are complex. Longer periods of open water and thinner sea ice have been linked to increased open water primary productivity in the Arctic (Arrigo et al., 2008; Brown et al., 2011) and an increase in advected Pacific-Bering zooplankton (Ershova et al., 2015). At the same time, warm, low-ice conditions have been associated with a decrease in production by ice algae, which are rich in long-chain omega-3 fatty acids (Søreide et al., 2010), and also with potentially lower local production of Arctic zooplankton fauna, including *C. glacialis* (Spear et al., 2019). In studies during the relatively cool years of 2010-2012, Spear et al. (2019) found highest concentrations of *C. glacialis* along the eastern waters of the Northern Chukchi, from Icy Cape to Barrow Canyon. Indeed, during those years the crested auklet community cluster extended well into these waters (Kuletz et al., 2019), whereas during the warmer period of 2017-2019 (this study), the Low Density seabird community predominated in this area (Fig. 6).

Although least auklets also appear to move into the Chukchi Sea in summer and fall, they primarily occur in the Southern Chukchi (Kuletz et al., 2015, 2019). Small copepods, which least auklets consume, are often abundant in Hope Basin and remained available there in 2017 and 2019 (no data are available for 2018; Kimmel, unpubl. data). Small copepod taxa (*Acartia* spp., *Pseudocalanus* spp., and *Oithona* spp.), were also abundant in the Northern Bering and Chirikov Basin in 2018 (Kimmel et al., 2018), when least auklets shifted to those subregions (Fig. 5g).

Concurrent with decreases in sea ice, northward flow from the Bering Sea has been increasing (Woodgate et al., 2012), which could increase advection of zooplankton and larval fish from the Bering shelf to Hope Basin and Hanna Shoal in the Chukchi Sea (Grebmeier et al., 2006; Dunton et al., 2017). Since the 2000s, zooplankton biomass has also increased along the Chukchi shelf break (Lane et al., 2008). Despite unusually high densities of least and crested auklets in the Chirikov Basin during 2017-2019, the Chukchi Sea will likely remain important post-breeding foraging habitat for these species, as evident in their overall distributions (Appendix B) and observed increases in some locations of the Northern Chukchi (Fig. 4 g, h).

An important feature of the Northern Chukchi is Barrow Canyon, which is a recognized hotspot of seabird activity (Kuletz et al., 2015), and where we found increased densities of several species in 2017-2019. Abundance of short-tailed shearwaters, and to lesser extent black-legged kittiwakes and northern fulmars, increased in the Barrow Canyon area during the late period. These surface feeders may forage over the canyon and adjacent waters because of the associated upwelling and concentration of euphausiids (Okkonen et al., 2011), as well as a variety of forage fishes attracted to large biomasses of copepods there (Logerwell et al., 2018).

The northward distributional shift observed for seabirds during this study was most evident for short-tailed shearwaters; higher densities began in the Chirikov Basin in 2014, the Southern Chukchi in 2015, and the Northern Chukchi in 2016, although shearwater abundance was near the long-term mean in 2018 and 2019 (Fig. 5b). This pattern coincides with seabird mortality events that included shearwaters in the Bering Strait region in summers of 2017-2019. The short-tailed shearwater was the main species impacted by the largest die off in the Bering Sea in recent years, in the southeast Bering Sea in 2019 (Siddon and

Zador, 2019; USFWS, unpubl. data). Necropsies revealed birds were emaciated and starved, thus the large increases in shearwaters observed in the Chukchi Sea suggest foraging conditions were forcing ever-farther migration north to obtain energy stores for the migration back to breeding grounds. The extra distance may have contributed to the late arrival of shearwaters to breeding sites in Australia recorded in October-November of 2019 (Liao 2019).

Piscivorous seabirds could also have been impacted by changes in their prey. A variety of forage fish are available in the study area, with the lipid-rich Arctic cod (*Boreogadus saida*) the most abundant (De Robertis et al., 2017; Logerwell et al., 2018). Age-0 Arctic cod were particularly abundant in the Northern Chukchi during 2012 and 2013, suggesting it is an important nursery ground for the species (De Robertis et al., 2017). In the northern Bering Sea, forage fish biomass in summer 2019 was low compared to previous years, indicating poor conditions for fish growth and survival, or alternatively, that the fish migrated north for better foraging (Yasumiishi et al., 2019). Arctic cod prefer cold, high salinity water masses, where there tends to be high biomass of large copepods (De Robertis et al, 2017; Logerwell et al., 2020). While the effects of warm conditions during 2017-2019 are not yet fully understood, evidence suggests that key seabird prey species, at least in the Bering Sea, were either low in abundance or shifted distribution (Duffy-Anderson et al., 2019; Siddon and Zador, 2018, 2019). These changes in prey availability could have differentially affected breeding seabirds, or birds that have restricted foraging ranges. Murres, which have high wing loading, tend to forage where prey patches are persistent and highly aggregated, or forage closer to their colony (Decker and Hunt, 1996; Sigler et al., 2012).

Both species of murres also experienced mass mortality events in the Bering Sea during 2017-2019, with evidence of starvation (Romano et al., this issue; Siddon and Zador, 2018, 2019) and potentially avian disease (A. Will et al., this issue). The low numbers of murres at colonies in 2018 (Romano et al., this issue; Will et al., this issue), together with broad-scale reductions in offshore densities (this study) concurrent with the mortality events, suggest major reductions in murre populations have probably occurred. Notably, Piatt et al. (2020) speculated that based on satellite-tagged murres, the huge mass mortality of common murres in the Gulf of Alaska during the winter of 2015-2016 could have included birds from the Bering Sea. This would be consistent with the trend of lower abundance in offshore waters of our study area, although we show a decline in abundance of murres starting in 2014 (Fig. 5e, f). In addition, euphausiids make up a high proportion of the diets of adult thick-billed murres, but not common murres. The greater dietary diversity of thick-billed murres may be one reason their densities were more stable than that of common murres, particularly in the Chukchi Sea.

Despite broad-scale declines in abundance at sea, murre (and kittiwake) plot counts at the Cape Lisburne colony in the Southern Chukchi increased at a rate of 6-7% in 2019, with an average increase of ~ 4% per annum over the past decade (Dragoo et al., 2020). The unusually high rate of growth would likely require immigration (D. Dragoo, pers. comm.), perhaps an indication of better foraging conditions near Cape Lisburne. In contrast, the murre colony at Cape Thompson (~100 km over water to the south) has decreased since the 1960s (Dragoo et al. 2000), indicating that murre breeding population trends have not been consistent among Chukchi Sea colonies. Nonetheless, it is noteworthy that at least the northernmost large colony in the Chukchi Sea shows increases in murres and kittiwakes, while the four colonies monitored by the Alaska Maritime National Wildlife Refuge in the southern Bering Sea show evidence of declines in murres, particularly common murre, and three of these colonies show declines in kittiwakes (Dragoo et al. 2000). The decrease in abundance of murres that we detected in offshore waters may reflect population declines in murres throughout the Bering Sea. Black-legged kittiwakes show a similar but less conclusive pattern of convergence between colony and offshore trends.

During 2017-2019, seabird species richness of the Northern Chukchi increased, while richness of other subregions converged at a slightly lower level than during the prior decade. This suggests that less-abundant seabird species were occurring in the Northern Chukchi with increasing frequency during the

later period. The convergence of species richness estimates between the Bering and Chukchi regions was mainly due to a decrease in species richness in the Bering Sea, and was concurrent with the expansion of the Low Density community cluster. Notably, the expansion of the Low Density community during the three warmest years (2017-2019) was nearly entirely along the eastern side of the study area. This expansion occurred in the Northern Bering and Chirikov Basin throughout the Inner Shelf, including areas east and south of St. Lawrence Island, which has large seabird colonies (Fig. 6). The Low Density community primarily displaced the short-tailed shearwater and thick-billed murre community clusters in the Bering Sea, and in the Northern Chukchi it displaced the short-tailed shearwater, thick-billed murre, and crested auklet communities. Thus, multiple foraging guilds appear to have been affected by conditions that concurrently led to the expansion of the Low Density community type.

The Inner Shelf waters of the Bering Sea, influenced by the fresher, warmer waters of the Alaska Coastal Current, have long been recognized as being nutrient-poor. These waters tend to have smaller zooplankton species, lower fish biomass (Eisner et al., 2013) and fewer seabirds compared to Anydyr waters to the west (Piatt and Springer, 2003; Sigler et al., 2017). The expansion of a Low Density seabird community in recent years suggests that large-scale ecosystem changes are altering the Inner Shelf, and to some degree the Middle Shelf and associated currents, thereby expanding the area of low productivity. In contrast, seabird density remained high near the Anadyr Current and western portions of the northern Bering and Chukchi seas. However, we lack sufficient data on seabird distribution west of the International Dateline to determine how far west those conditions exist. A long-term examination of marine fish from the Bering and Chukchi seas found that taxa respond to climate-related changes at different spatial and temporal scales (Alabia et al., 2018); similarly, we show that seabird species demonstrate a diversity of distributional responses, which may provide some level of resilience to their long-term prospects in the Pacific Arctic.

Acknowledgements

The seabird survey data was collected by the authors and a number of dedicated observers throughout the years. The surveys were supported by funding from the North Pacific Research Board (NPRB Projects 637,2007-2008 and B64,2008-2010), and by Intra-Agency Agreements from the Bureau of Ocean Energy Management (2010-2019; BOEM IAs M10PG00050, M17PG00017, and M17PG00039). We thank the many research vessel crews, chief scientists, and collaborating researchers that made our surveys possible, including but not limited to the Arctic Integrated Ecosystem Research Project (E. Farley, F. Mueter), Arctic Marine Biodiversity Observing Network (K. Iken), the Distributed Biological Observatory (J. Grebmeier, J. Nelson), Hokkaido University (T. Hirawake, Y. Watanuki), various National Science Foundation funded studies (C. Ashjian, S. Danielson, R. Pickart, R. Hopcroft), and NOAA Surveys (C. Berchock, J. Murphy). The findings and conclusions in this article are those of the authors and do not necessarily represent the views of the US Fish & Wildlife Service, the NPRB, or BOEM.

* Includes all species observed, see Appendix A											

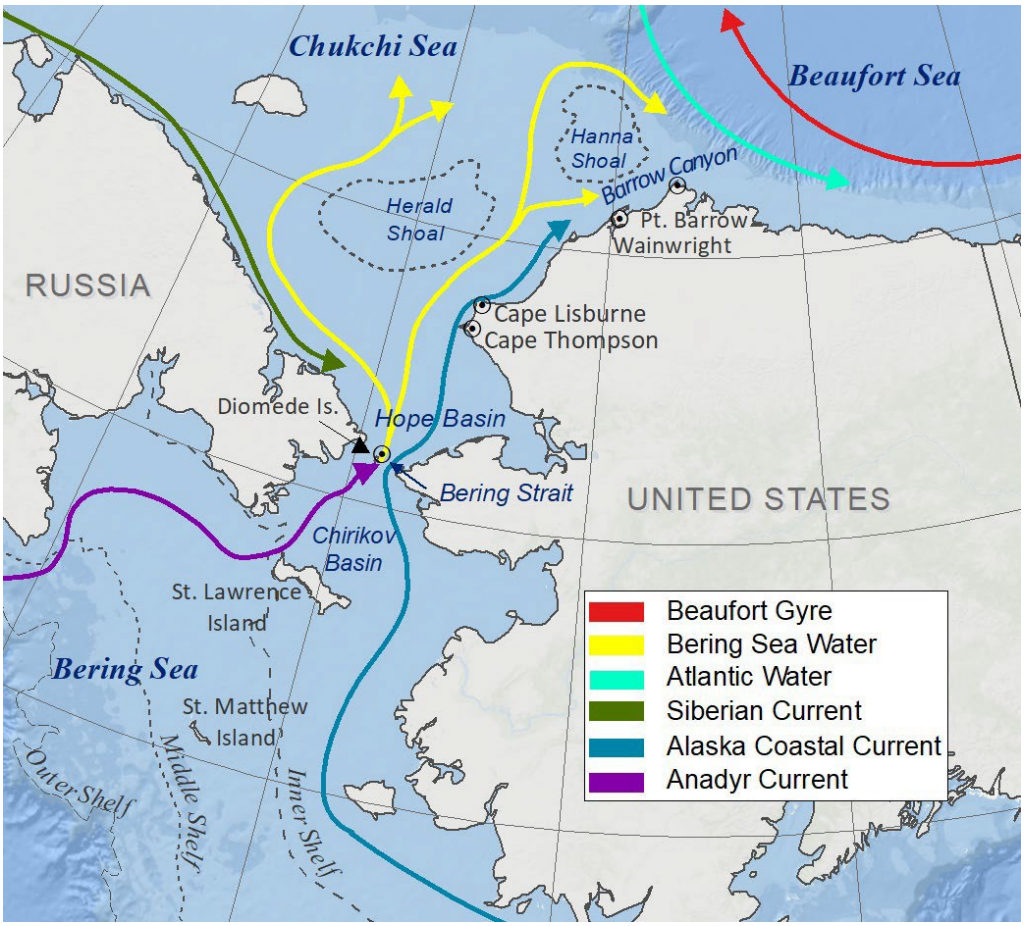

Figure 1. The Bering Sea and Chukchi Sea study area, showing generalized trajectories of major water masses. Map by EAL, based on Dunton et al. (2017).

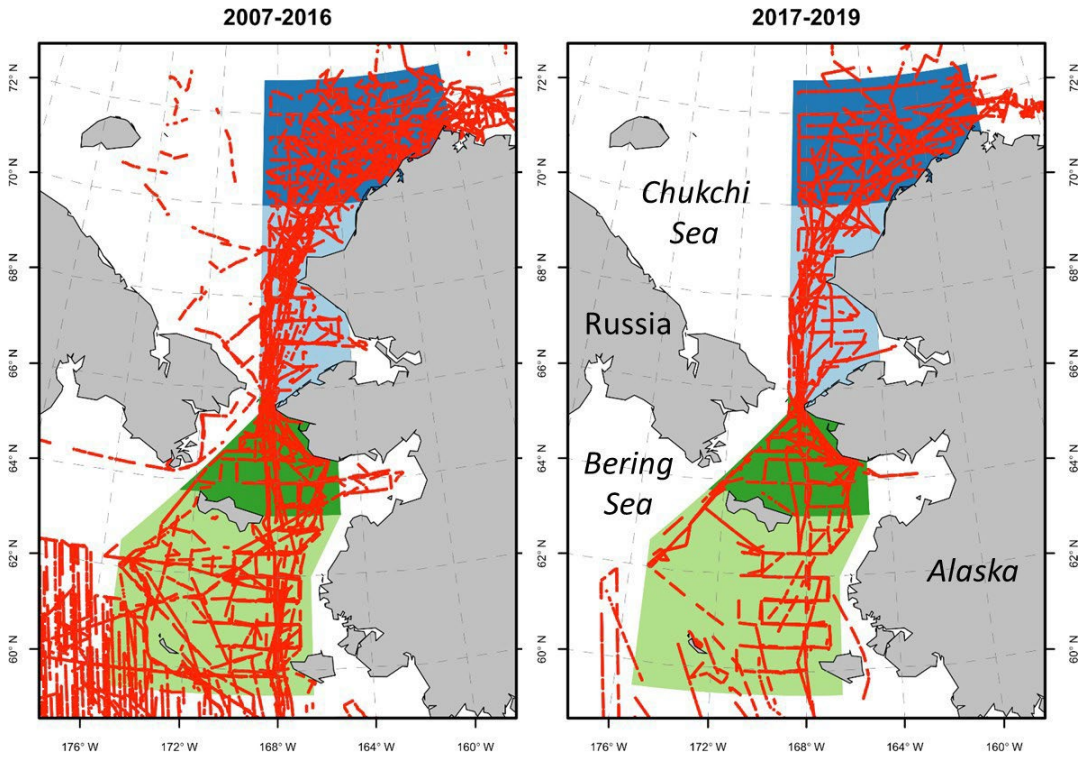

Figure 2. Four subregions of the study area: Northern Bering (light green), Chirkov Basin (dark green), Southern Chukchi (light blue) and Northern Chukchi (dark blue), with seabird survey transects overlaid for each time period.

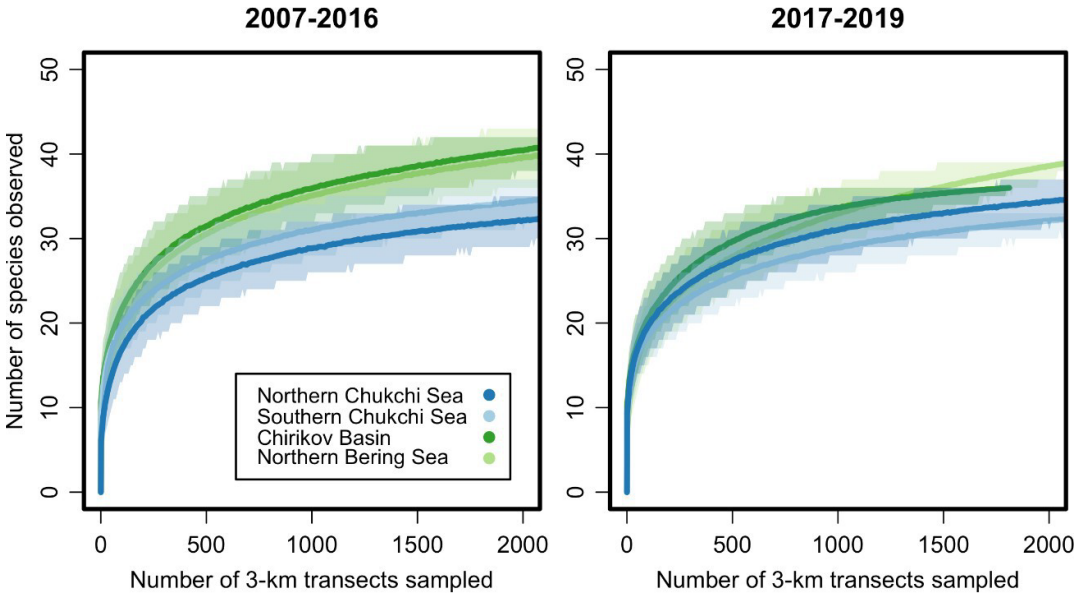

Figure 3. Species richness (rarefaction curves) in four subregions of the study area, for 2007-2016 and 2017-2019. Mean (solid lines) and 95% confidence intervals (shading) were derived from random selection of 3-km transect segments from surveys conducted during each time period and subregion.

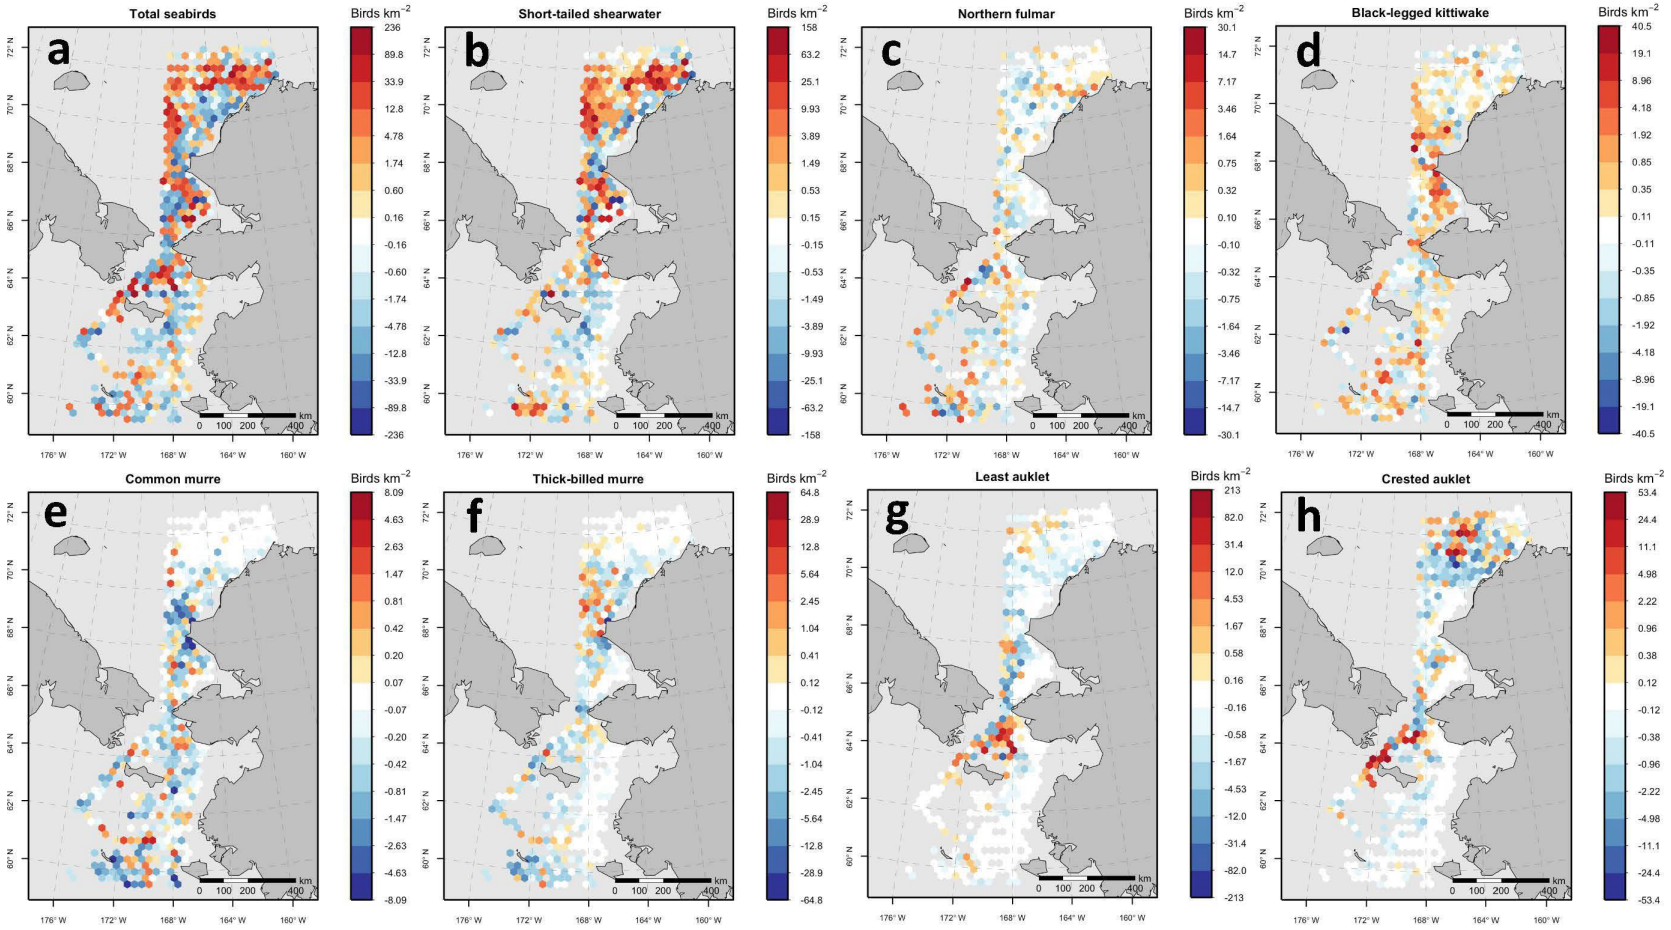

Figure 4. Distribution of increases (oranges) and decreases (blues) in densities of Total Seabirds and seven focal species in 2017-2019, compared to 2007-2016. Mean densities were calculated per 30-km grid cell within each time period for cells surveyed in both time periods.

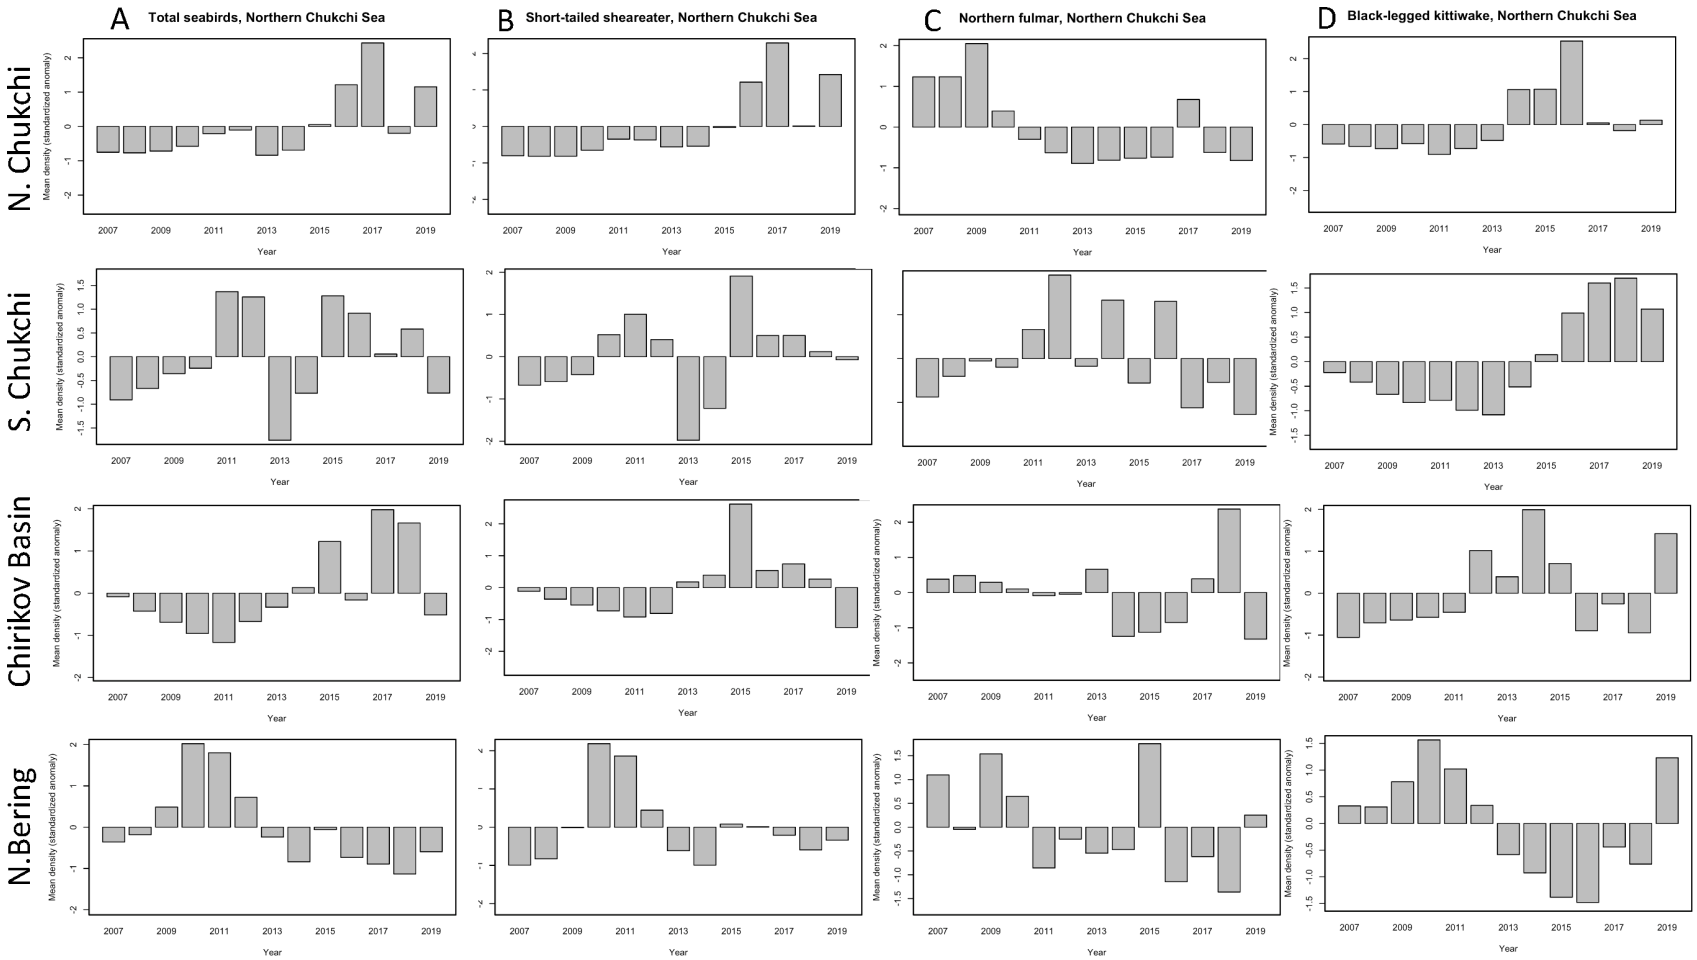

Figure 5. Standardized mean anomalies for Total Seabirds and seven focal species, for each subregion across all years, 2007-2019.

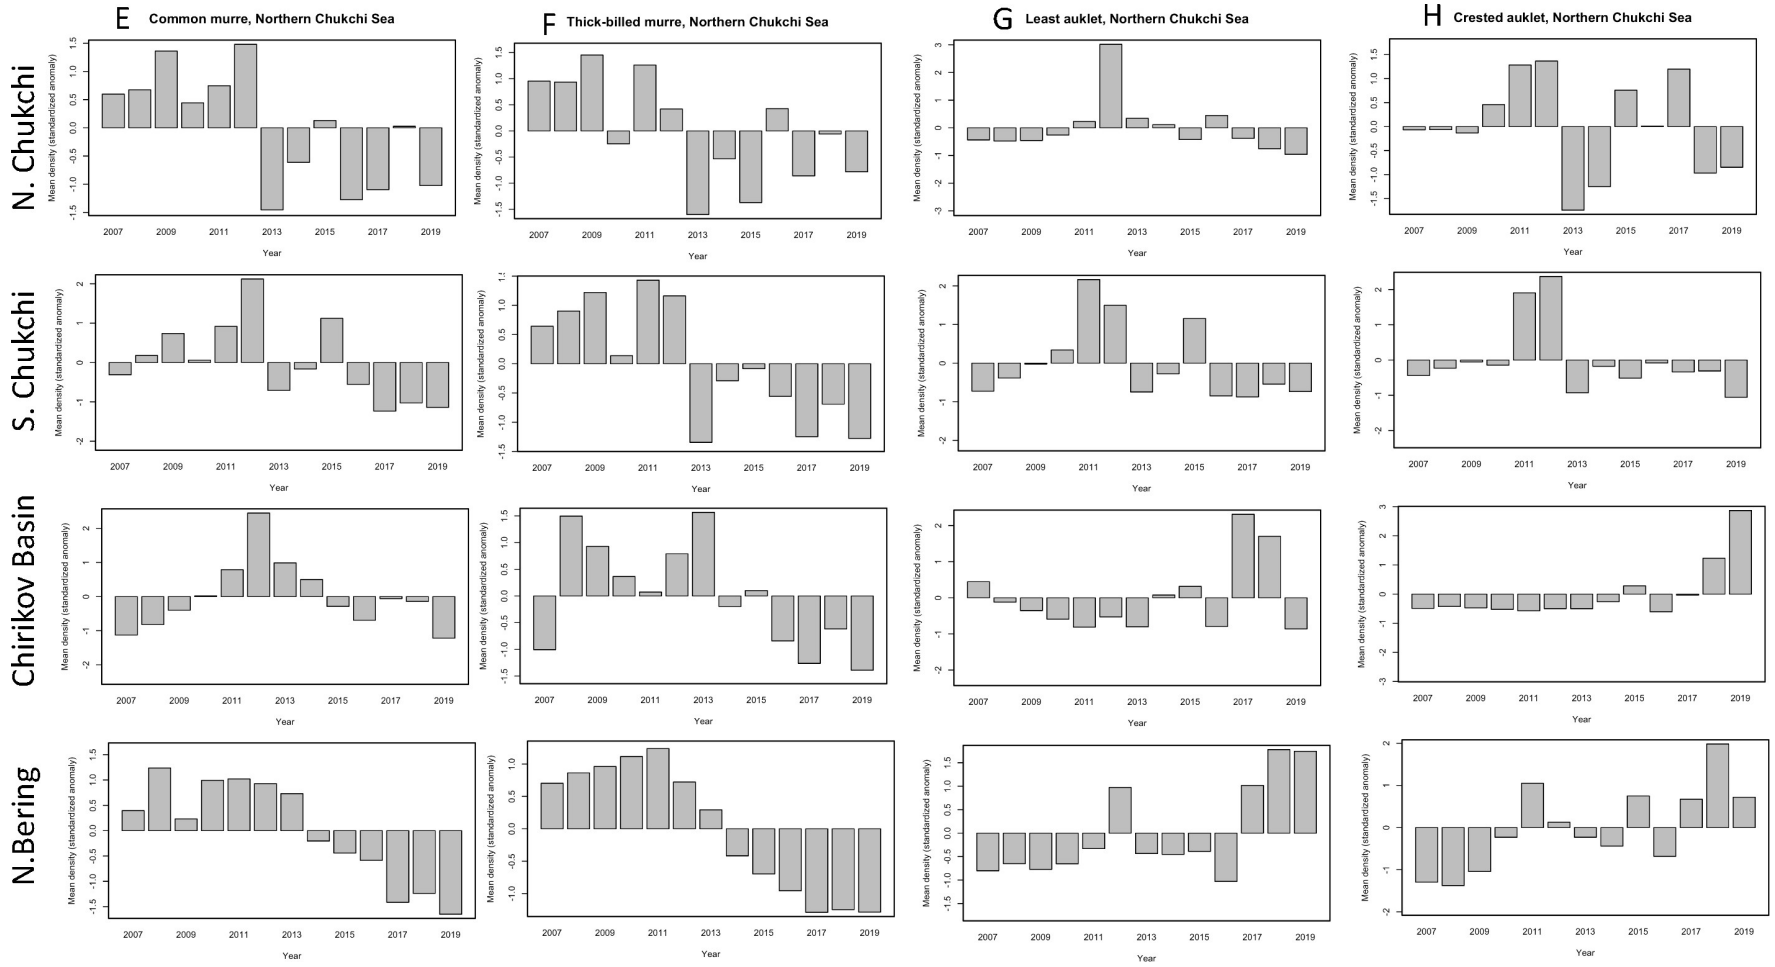

Figure 5. continued

Appendix A. Mean densities (birds/km^2), by species, and subregion, during two time periods, 2007-2016 and 2017-2019. Asterisk indicates densities were < 0.01.

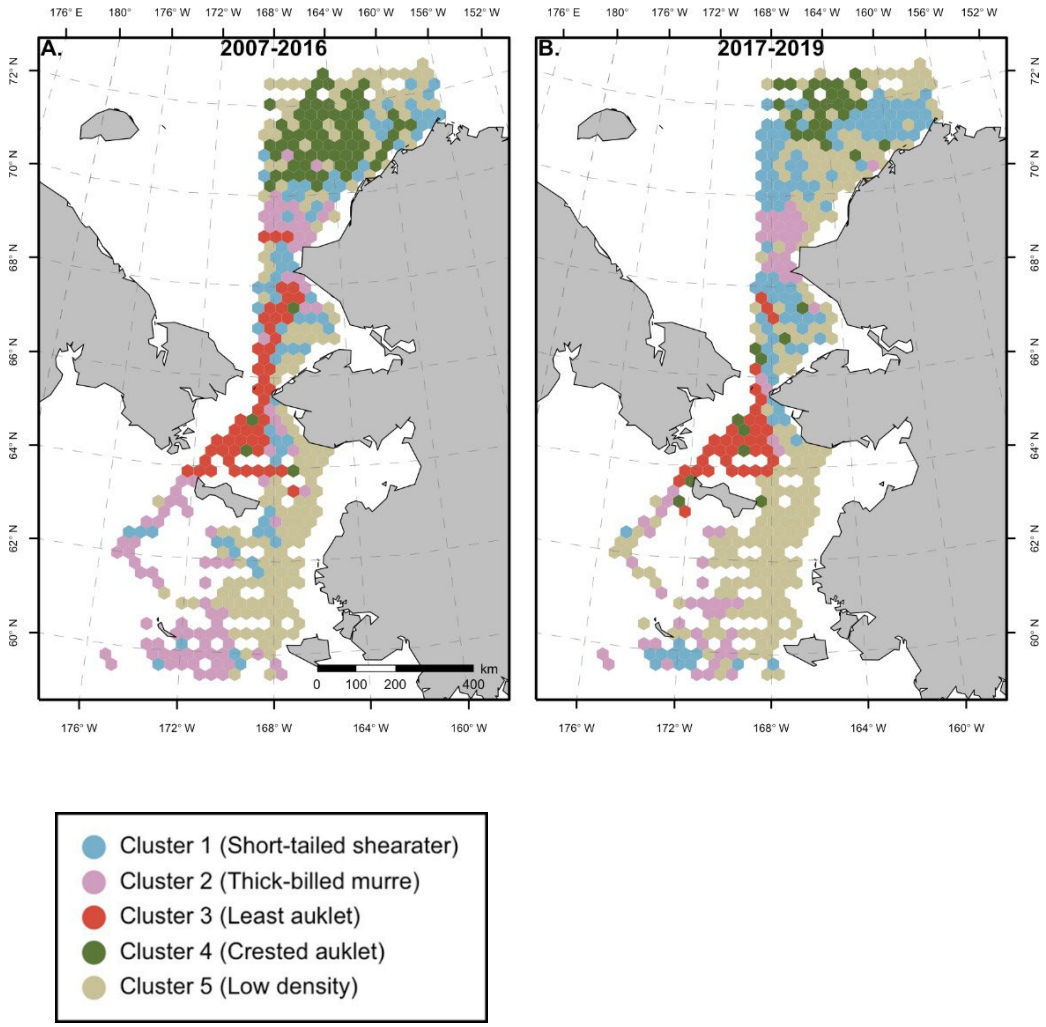

Figure 6. Distribution of five identified seabird community types (clusters) during two time periods, based on K-means Cluster Analysis. Colors represent community types referred to by the most abundant species (Clusters 1 – 4), or by low density and lack of a dominant species (Cluster 5).

Appendix A. Mean densities (birds/km^2), by species, and subregion, during two time periods, 2007-2016 and 2017-2019. Asterisk indicates densities were < 0.01.

CHAPTER 22 - Growth rate potential for juvenile Chum salmon in rapidly warming northern Bering and southern Chukchi seas.

Objective 7: Develop spatially explicit bioenergetics models for Arctic cod and saffron cod as well as for juvenile pink and chum salmon and test the impact of warming summer temperatures on their growth and distribution

Key Words
Chum Salmon, Western Alaska, Chukchi Sea, Growth Rate Potential, Distribution

Abstract

A spatially explicit bioenergetics model was used to estimate the growth rate potential (GRP; %body weight per day) of juvenile Chum salmon in the northern Bering and Chukchi seas. Annual averages of GRP ranged from a low of 0.9 (2003) to a high of 12.3 (2007) in the northern Bering Sea and from 0.1 (2003) to 39.3 (2007) in the Chukchi Sea. Analyses of juvenile Chum salmon spatial distribution in relation to GRP within each region indicated that they were generally not distributed in regions of higher GRP. There was a significant positive relationship between average seasonal transport through the Bering Strait and juvenile chum salmon GRP, suggesting summer transport of heat (and likely pelagic prey) improves early marine growth potential for juvenile chum salmon in the southern Chukchi Sea region. The year 2007 stands out as an anomaly within the 18 year time series with the highest GRP and catch per unit effort of juvenile chum salmon in both regions. In addition, further examination of juvenile Chum salmon stomach contents and relative abundance are warranted to better understand how anomalous warming during 2017 through 2019 may be linked to the dramatic decline in adult Chum salmon returns to the regions during 2020 and 2021.

Introduction

Marine environments in the Arctic regions (including the northern Bering, Chukchi, and Beaufort seas) are experiencing accelerated warming and extremes in seasonal sea ice extent (Frey et al., 2014; Baker et al., 2020; Danielson et al., 2020). Loss of seasonal sea ice is linked to increased primary and secondary production during spring and summer months (Arrigo and van Dijken, 2011) and advection of sub-Arctic waters and biota into the polar basins, creating conditions favorable for increased heat and expansion of Pacific species into the Arctic interior (Polyakov et al., 2020; Levine et al., 2020). These changes could shift colder Arctic marine ecosystems from benthic to pelagic state (Grebmeier et al., 2006).

Pacific salmon spend much of their marine life history feeding and growing in the pelagic waters of the North Pacific Ocean. The most common salmon species in the Pacific Arctic include Pink and Chum salmon (Nielsen et al., 2013; Carothers et al., 2013; Stephenson, 2006). Of these two salmon species, Chum salmon have the highest biomass in the North Pacific Ocean (Ruggerone and Irvine, 2018) and are broadly distributed in the Arctic from the Yukon River to the Mackenzie River. Adult Chum salmon in the northern regions return to rivers during July to October to spawn and their eggs hatch during late winter and into spring (Urawa et al., 2018). Fry enter the marine environment during late May through July (Vega et al., 2016; Howard et al., 2017), and they spend the summers as juveniles in the near coastal regions and then migrate offshore to spend one or more additional years in the North Pacific Ocean before returning to spawn.

Early marine research on juvenile Chum salmon in the northern Bering Sea and Chukchi Sea suggest that these salmon will likely do better under warming ocean conditions. In the northern Bering Sea, warm spring thermal regimes was linked to increased energy allocation and growth of juvenile Chum salmon (Wechter et al., 2017). During 2007, large numbers of juvenile Chum salmon were captured in the southern Chukchi Sea, and those juvenile salmon were larger and fed upon higher energy prey than those sampled in the northern Bering Sea (Moss et al., 2009). Interannual differences in the size and lipid storage of Pacific salmon during their early marine residence can have a strong influence on survival during subsequent marine life-history periods (Parker, 1968; Willette et al., 1999; Beamish and Mahnken, 2001; Farley et al., 2009). For temperate fishes, energy is generally allocated to growth early on when fish are small, but shifts to lipid accumulation during late summer and fall when fish are larger (Post and Parkinson, 2001). For juvenile salmon, rapid growth during early marine residence may reduce size- selective predation (Parker, 1968), whereas the size and lipid storage attained after their first summer at sea may affect winter survival (Beamish and Mahnken, 2001).

To develop a better understanding of the link between juvenile Chum salmon prey demand and supply, we use a bioenergetics model to estimate growth rate potential (GRP) over a 16-year period within the northern Bering Sea and 10-year period within the Chukchi Sea. Previous bioenergetics models for Chum salmon on the eastern Bering Sea shelf indicate that years with warmer spring and summer sea temperatures had higher annual averages of GRP (Farley and Moss, 2009). That model used a 4-year time series of data collected along the eastern Bering Sea shelf; we plan to extend the time series by 12 years for the northern Bering Sea and include data from the Chukchi Sea thereby capturing a period warm, cool and extremely warm sea temperatures (see Stabeno and Bell, 2019; Thoman et al., 2020) within this region. In addition, we report new estimated temperature and weight dependence parameters for juvenile Chum salmon obtained from laboratory experiments. The model estimates of body size and growth using the newly developed parameters more closely align with observed juvenile Chum salmon body size and growth as compared with model estimates using Pink salmon model parameters. The objective of this study is to compare juvenile Chum salmon GRP among years and between the northern Bering Sea and Chukchi Sea to examine the changes in juvenile salmon habitat quality during this period of rapid warming.

Materials and methods

Study Area and Sampling Protocols

Stations along the northern Bering Sea and southern Chukchi Sea shelf were sampled during August-September, 2003 – 2019 (except 2008) and during 2003, 2007, 2012, 2013, 2017-2019, respectively (Fig. 1). Juvenile Chum salmon were collected using a model 400/601 rope trawl, made by Cantrawl Pacific Limited of Richmond, British Columbia. The rope trawl was 198 m long and constructed with hexagonal mesh in the wings and body, and a 1.2-cm mesh liner in the codend. The trawl was rigged with buoys on

the headrope to sample from near surface to approximately 20–25 m depth. During 2019, juvenile Chum salmon in the Chukchi Sea were sampled using a Nordic 264 rope trawl.

Sampling stations were generally completed during daylight hours (0730–2100 Alaska Daylight Savings Time). All trawl deployments lasted 30 min and covered between 2.8 and 4.6 km. Sampling stations were located along longitudinal meridians spaced every ? (i.e., along longitudinal meridians at stations spaced every ? degrees of latitude). A Seabird SBE-911 conductivity-temperature-depth (CTD) device was deployed at each station to measure the vertical profiles (from near bottom to surface) of ocean temperature. Observed sea surface temperatures at 5 m depth taken from CTD profiles were used for bioenergetics modeling. At each trawl station, juvenile Chum salmon were selected at random (maximum 50) and standard biological attributes, including fork length (nearest 1.0 mm) and body weight (nearest 1.0 g) were measured on board. Subsamples of juvenile Chum salmon from each trawl were frozen whole and taken back to the laboratory for energetic analyses. The catch per unit effort (number/km2) of juvenile Chum salmon at each station was estimated by multiplying the the number of juvenile Chum salmon caught at each station by the distance traveled (km) when the trawl net was fishing and the estimated trawl net opening (km) during fishing operations.

Bioenergetics Model

GRP of juvenile Chum salmon (see Table 1 for details) for the northern Bering Sea and Chukchi Sea shelf was estimated using the bioenergetics model developed by Ware (1978), incorporated modifications to the model developed by Trudel and Welch (2005) and Farley and Trudel (2009), and utilized new parameters for consumption rates of juvenile Chum salmon developed here (see Appendix A). The GRP model:

$$G_{i,s} = \tau \cdot I_{i,s} - (SMR_{i,s} + ACT_{i,s}) \quad (1)$$

accounts for optimal cruising speed, where $G_{i,s}$ is the GRP (cal/s) for juvenile Chum salmon during year i at station s, τ is the proportion of food that can be metabolized (Trudel and Rasmussen 2006), $I_{i,s}$ is the feeding rate (cal/s), $SMR_{i,s}$ and $ACT_{i,s}$ are, respectively, the standard metabolic rate (cal/s) and activity costs (cal/s). For simplicity, we assumed that τ was constant and not affected by water temperature, as the sum of fecal and urinary losses and specific dynamic action is often nearly constant in bioenergetics models (Trudel and Rasmussen 2006).

The relationship between salmon feeding rate and prey density was assumed to be described by a type II functional response (Holling 1965; Ware 1978):

$$I_{i,s} = ED_{i,s} \cdot \frac{\rho_{i,s}\gamma_{i,s}U_{i,s}}{1 + \rho_{i,s}\gamma_{i,s}h_{i,s}U_{i.s}} \quad (2)$$

where ρ is prey density (g/cm^3), γ is the cross-sectional area of the reactive field (cm^2), U is the optimum swimming speed (cm/s), h is handling time of prey (s/g), and ED is sum of prey caloric content (cal/g$_{wet}$) estimated as:

$$I_{i,s} = ED_{i,s} \cdot \frac{\rho_{i,s}\gamma_{i,s}U_{i,s}}{1 + \rho_{i,s}\gamma_{i,s}h_{i,s}U_{i.s}} \quad (3)$$

where p = the number of prey species z. Consumption rates were equal to zero when no prey were available.

The equations for handling time were developed in Farley and Trudel (2009):

$$h = \underline{W_i}^{CB-1}/(CA * f(T)) \quad (4)$$

where $\overline{W}_i$ is the average Chum salmon weight (g) during year *i*, *CA* and *CB* are, respectively, the weight coefficient and exponent for maximum feeding rate for Chum salmon, and *f(T)* is the Thornton and Lessem (1978) temperature dependence function for cold-water fish species (see Table 1 for definition and parameters).

The energetic costs associated with the standard metabolic rates and activity costs of juvenile Chum salmon were estimated using empirical models derived for Sockeye salmon by Trudel and Welch (2005). Specifically, standard metabolic rates were modeled as a function of weight and water temperature (ºC):

$$SMR_{i,s} = \alpha_1 \overline{W}_i^{\beta} e^{\varphi T_{i,s}} \quad (5)$$

where α_1, β, and ϕ are regression coefficients (Table 1). Activity costs were modeled as a function of weight and swimming speed:

$$ACT_{i,s} = \alpha_0 \overline{W}_i^{\delta} U_{i,s}^{\lambda} \quad (6)$$

where α_0, δ, and λ are regression coefficients. We used the optimal cruising speed model derived by Trudel and Welch (2005) to estimate the swimming speed of juvenile Chum salmon (Table 1).

Chum salmon Energy Density

Energy density of juvenile Chum salmon was determined using bomb calorimetry on dried samples of homogenized whole fish tissues following procedures modified from Fergusson et al. (2010). Samples through 2015 were dried to constant mass by heating at 55°C in a drying oven, and samples from 2016-2019 were dried by heating at 135°C in a LECO Thermogravimetric Analyzer 701. The two drying methods were known to yield moisture estimates differing by less than 1% (Vollenweider et al 2011) and thus had negligible effects on dry mass energy estimates. Calorimetry data accuracy was verified using benzoic acid and internal fish tissue standards, and precision verified using sample replicates. The energy density units (Joules/g_{wet}) were converted to (cal/g_{wet}) by dividing the value by 4.184.

For the NBS region, energy density data were available for all years except 2006, 2007, and 2013. To enable estimates of GRP for years that data were not available, we used the average energy density for all available data across years from the NBS region (average = 1,164 cal/gram, n = 673). For the SCS region, energy density data were available for all years except 2017 and 2019. To enable estimates of GRP for years that data were not available, we used the average energy density for all available data across years from the SCS region (average = 1,253 cal/g, n = 55)

Chum Salmon Stomach Contents (Prey)

Stomach contents were examined either at sea or in a laboratory setting. Stomach processing followed standard methods developed by Tikhookeanskiy Nauchno-Issledovatelskiy Institut Rybnogo Khozyaystva I Okeanografiy (Chuchukalo and Volkov, 1986; Volkov and Kuznetsova, 2007; Moss et al., 2009; Coyle et al., 2011). Typically, the contents of up to 10 stomachs from randomly sampled juvenile Chum salmon were combined from each station. Contents were removed from the esophagus to the pylorus. Prey taxa were identified to the lowest possible resolution using a dissecting microscope. Prey composition was recorded as a stomach content index (SCI) and a stomach fullness index (SFI). The SCI represents individual prey item weight (g), scaled by predator body weight (g), and multiplied by 10,000. Prey items were typically weighed to 0.001 g, when possible. The SCI for a given prey taxa *x* at the *i*-th station was calculated as:

$$SCI_{i,x} = [\ Prey_{i,x}/Predator_i * 10{,}000\ ]$$

where $Prey_{i,x}$ was the weight (g) of prey taxa *x* at station i and $Predator_i$ was the weight (g) of the predator at station *i*.

$$SFI_{i,} = \sum SCI_{x\text{-}n,i}$$

The SFI_i is the sum of all SCI values from prey items *i-n* at a given station *x*.

Stomach content data was pooled into broader categories prior to calculating the percent SCI composition for each predator species. Categories were selected either as prey of interest (*Calanus glacialis*), or as similar prey types. Categories that represented less than 10% of the total SCI were grouped together. Any categories that could not be grouped within a taxonomic or functional group were combined into an "Other" category.

Prey Biomass

Zooplankton prey were collected using a 60 cm bongo sampler with 505 μm mesh net. The net was towed obliquely to near bottom (max 200 m depth) and the volume of water flowing through the net was measured using a General Oceanics 2030R flowmeter. Zooplankton samples were preserved in a buffered-formalin (5%) solution and processed at the University of Alaska Fairbanks (see: Coyle and Pinchuk 2002) laboratory and the Plankton Sorting and Identification Center (PSIC) in Szczecin, Poland (see: Napp et al. 1996, Incze et al. 1997, Kimmel et al. 2018). Samples identified at the PSIC were verified at the Alaska Fisheries Science Center, Seattle, Washington, USA. Zooplankton abundances were converted to biomass using individual weights in g (Table 2).

Zooplankton prey density (g/cm^3) at each station was determined as:

$$\rho_{i,s} = \sum_{z=1}^{p} N_{i,s,z} \cdot \bar{W}_{i,s,z} \quad (10)$$

where $N_{i,s,z}$ and $W_{i,s,z}$ are the number and average weight of zooplankton species z (z = 1 to p) at station s during year i. The stomach content analysis did reveal that juvenile Chum salmon feed upon small fishes such as age-0 walleye Pollock and small sandlance (Fig. 2). Sandlance are not captured very frequently in the surface trawl (n < 5 over the time series) and age-0 walleye Pollock were only found in stomach contents of juvenile Chum salmon during 2003 and 2004, even though age-0 walleye Pollock were consistently captured in the NBS throughout the time series (reference).

GRP in cal/s (calories per second) was converted to cal/d (calories per day) by multiplying $I_{i,s}$ by the number of seconds in a 15-hour day (estimated time juvenile Chum salmon spend feeding per day during August and September) and by multiplying $SMR_{i,s}$ and $ACT_{i,s}$ by the number of seconds in a 24-hour day. Estimated daily GRP (cal/d) at each station s was then expressed as a percentage of body weight (% body weight/d) for each station s by dividing estimated daily GRP (cal/d) by the total energy per fish (cal) as in (Perry et al. 1996):

$$\underline{E_{i,s}} = \underline{ED_i} * \underline{W_i} \quad (11)$$

where $\overline{E}_{i,s}$ is the average total energy per fish (cal), $\underline{ED_i}$ is the average caloric content in juvenile Chum salmon (cal/g_{wet}) during year i, and $\overline{W}_i$ is the average weight (g) of juvenile chum salmon. Annual averages of juvenile Chum salmon weight and energy density were used as opposed to average weight and energy density of these fish at each station because there were stations within a year where no juvenile Chum salmon were caught.

Inputs into the GRP model including sea surface temperature at each station, caloric content for zooplankton prey, annual mean estimates of juvenile Chum salmon caloric content, and annual average juvenile Chum salmon weight are provided in appendix 1.

Model Applications

Temporal and spatio-temporal estimates of mean GRP and catch per unit effort (CPUE) were estimated using the VAST package (version 3.7.0, cpp 13_0_0) and FishStatsUtils package (version 2.9.1) with RStudio (version 1.2.1335) (RStudio Team 2020) (Thorson et al. 2015, Thorson et al. 2016, a, b; Thorson 2019a). The GRP and CPUE estimates were initially separated by region: 1) northern Bering Sea (59.5° N to 65.5° N, -173 to -161.5) during 2003 to 2019 (missing 2008) and southern Chukchi Sea (65.54° N to 68° N, -168.5 to -164) during 2003, 2007, 2012, 2013, 2017-2019. Initial efforts found that the VAST model would not converge for GRP or CPUE data within the southern Chukchi Sea region. Therefore, we modeled these data over the entire survey area (NBS and SCS) and then separated the spatial-temporal estimates of GRP and CPUE by region for our analysis.

The VAST model is a delta geostatistical model that includes two linear predictors, one for the probability of encounter and the other for positive catch rate (Thorson et al. 2015, Thorson 2019a, b). Each linear predictor includes spatial and spatio-temporal effects to improve density predictions under a spatially- unbalanced sample design, in areas with few or missing data (Shelton et al. 2014). The first linear predictor, encounter probability for sample *i* is given as:

$$p_1(i) = \sum_{f=1}^{n_{\omega 1}} \omega_1(s_i) + \sum_{f=1}^{n_{\varepsilon 1}} \varepsilon_1(s_i, t_i) + \sum_{p=1}^{n_p} \gamma_1(t_i, p) X(x_i, t_i, p)$$

where $\sum_{f=1}^{n_{\omega 1}} \omega_1(s_i)$ is the spatial effect and $\sum_{f=1}^{n_{\varepsilon 1}} \varepsilon_1(s_i, t_i)$ is the spatio-temporal effect. Symbols include s_i for knot location, t_i is year, and *i* is sample or station. We specified effects of covariates using linear and nonlinear formulas. Parameters include omega (ω), epsilon (ε), and gamma (γ). Positive catch rates $p_2(i)$ the second component given as

$$p_2(i) = \sum_{f=1}^{n_{\omega 2}} \omega_2(s_i) + \sum_{f=1}^{n_{\varepsilon 2}} \varepsilon_2(s_i, t_i) + \sum_{p=1}^{n_p} \gamma_2(t_i, p) X(x_i, t_i, p)$$

These linear predictors are used to predict indices of density and abundance, see Thorson (2019) for additional model details. Including spatio-temporal variation in the estimates of density can improve predictions in areas with little data (Shelton et al., 2014), ideal for our survey with limited coverage in some areas and years (Fig. 1).

Total biomass $\big(I(t)\big)$ of juvenile chum salmon in the surveyed area was predicted from density for the entire survey area by year *t* (Thorson et al. 2015):

$$I(t) = \sum_{s=1}^{n_s} \big(a(s) \times d(s,t)\big)$$

where $a(s)$is the area associated with extrapolation-cell s (Shelton et al., 2014; Thorson et al., 2015). Standard error was calculated with Template Model Builder, an auto differentiation software library and plotted (Kristensen et al., 2016) where the average GRP or catch per unit effort was:

$$\underline{d}(t) = \sum_{s=1}^{n_s} \frac{a(s) \times d(s,t)}{I(t)} d(s,t)$$

For GRP, we model the 2nd linear predictor and not the 1st linear predictor, due to the 100% occurrence of the GRP index, a value at each sample location. A Poisson-link delta-model for positive catch rates with fixed encounter probability=1 for all years because GRP was given for all observations (ObsModel=c(1,4)) and set area swept to a constant 1. For Catch, we used a conventional delta-model for encounter probability and a lognormal model for positive catch rates, but fixing encounter probability=1 for any year where all samples encounter the species. The number of knots was 60 for the predicted surface and knot locations for regions identified using a k-means algorithm based on the location of survey observations across years. An extrapolation area of 75 km from the center of each knot allows for overlap in space among regions around knots. We specified 20000 extrapolation points in VAST per year. Model performance was examined with expected probability and observed frequency of encounter for encounter probability, quantile plots for residuals of the positive catch rates, and spatial trends in the Pearson residuals for encounter probability and positive catch rate components by knot.

To visualize the distribution of juvenile chum salmon with respect to spatial variation in GRP we plotted estimated GRP at each extrapolation point and overlaid with the station level log CPUE of juvenile chum salmon. To show uncertainty in the GRP estimates we plotted the standard errors of predicted densities of GRP at each extrapolation point. This plot was used to illustrate uncertainty in GRP especially offshore where we have little or no data.

Pearson correlation coefficients and p-values were estimated to test the relationships among sea temperature, mean body weight, log CPUE, and log GRP for the northern Bering Sea. For the southern Chukchi Sea, we included estimates of transport (mean May to August) through the Bering Strait (Woodgate et al.), sea temperature, mean body weight, log CPUE, and log GRP for the southern Chukchi Sea correlation analyses were used to examine relationships between annual GRP, CPUE, and physical and biological indices for the north eastern Bering and southern Chukchi seas. The VAST model did not converge for the southern Chukchi Sea, so we estimated densities for GRP and Catch for the two regions combined. Next, we separated the density estimates at each extrapolation by region. Finally, means and SEs of the means of the density estimates were calculated by region. GRP and CPUE were then log transformed. We also calculated means for GRP from the raw data for the correlation analysis and comparison of the SEs.

An analysis of variance (ANOVA, Fixed Effects) was performed to test for significant differences in estimates of GRP among years within each region and among regions and years. We used the area specific VAST density estimates at the extrapolation points (n=2000) that were then separated by region and year. If a significant difference ($P < 0.05$) occurred, a Sidak multiple comparison test was used to calculate the 95% ($\alpha = 0.05, 0.01, 0.001$) confidence intervals for all pairwise differences between the dependent variable means. The level of significance between the pairwise differences was determined by examining those confidence intervals that excluded zero for the three values of α.

Results

Juvenile Chum salmon diet

Within the northern Bering Sea, juvenile Chum salmon fed upon a variety of zooplankton prey as well as small age-0 fishes (Fig. 2). From 2003 to 2007, the percentage of Cnidaria in the juvenile Chum salmon SCI ranged from 16% to 43%. The percentage of Cnidaria in juvenile Chum salmon SCI increased

during 2016 through 2019, ranging from 25% through 93%. The percentage of Oikolpeura spp. in the juvenile Chum salmon SCI was highest during 2007 through 2015, ranging from 14% to 76% and was only a small percentage of their SCI during the other years ranging from 0% to 8%. Similarly, the percentage of Themisto libellula was highest during 2007 through 2015 ranging from 0.5% to 52%, but was absent from the juvenile Chum salmon SCI during the other years. The percentage of fishes in the juvenile Chum salmon SCI varied among the years with sand lance comprising the largest percentage of their SCI ranging from 3% during 2007 to 55% during 2006. Small capelin and age-0 walleye pollock were also found in juvenile Chum salmon stomach contents ranging from 0.5% during 2004 to 14% during 2005 and 1% during 2015 to 16.5% during 2004, respectively.

There were fewer prey items found in juvenile Chum salmon stomachs in the southern Chukchi Sea (Fig. 3). Oikopleura spp. dominated juvenile Chum salmon SCI 2013 and 2018, whereas Epilabidocera amphitrites was 100% of the SCI during 2019. Juvenile Chum salmon fed upon Themisto libellula with an SCI range of 2% during 2007 to 10% during 2013. Several prey species were present in juvenile Chum salmon SCI during only one or two years including Hyperia spp. (2012, 42%), Euphausiid (2012, 25%), and Thysanoessa raschii (2007, 38%; 2012, 32%). Fishes were only found in the Juvenile Chum salmon SCI during 2007 (Lumpenus fabricii, 25%).

Growth rate potential and catch by regions

VAST model estimates of the annual mean and standard error of growth rate potential for juvenile Chum salmon indicate variation in the GRP among years and regions in the Chukchi Sea and northern Bering Sea (Table 3). In general, GRP was lower in the Chukchi Sea than in the northern Bering Sea, except for during 2003, 2007 and 2017. Temporal trends in the GRP were increasing from 2003 to 2007, decreasing from 2007 to 2012, relatively stable through 2015, and from 2015 to 2019 increased in the northern Bering Sea and was variable and low in the Chukchi Sea.

Model estimates of the annual mean and standard error of juvenile Chum salmon biomass also illustrate variation among years within the Bering Sea and Chukchi Sea (Fig. 4). Juvenile Chum salmon biomass was higher in the Chukchi Sea during 2007 and 2018 than in 2003, 2012, and 2013. Within the northern Bering Sea tended to be as high, or higher from 2014 to 2019 than previous years with the exception of 2017. The years with the highest estimated mean biomass of juvenile Chum salmon were 2018 within the Chukchi Sea and 2014 in the northern Bering Sea.

Spatio-temporal variation in growth rate potential and catch

The VAST model indicated significant spatial and spatio-temporal variation in the estimated means and standard errors of GRP of juvenile chum salmon (Figs. 5 and 6). When overlaying the CPUE of juvenile chum salmon at each station (black squares) on the VAST estimates of the GRP we see higher CPUE in regions of lower GRP for the northern Bering Sea. Standard error of the mean estimates show significant error in the model estimate for regions where we lack data. In general, higher GRP occurred farther offshore and in the southern regions of the survey area. Years with the highest GRP included 2007, 2011, and 2006.

Plots of SEs of log GRP show more uncertainty in the offshore regions to the west, and closer to shore in the eastern Bering Sea. Years without data in the SCS and low sampling offshore show higher levels of error.

Correlation analysis of growth rate potential and catch with physical and biological data

Growth rate potential of juvenile chum salmon was more significantly correlated with physical and biological indicators in the Chukchi Sea than in the north eastern Bering Sea (Figs. 7 and 8). In the NBS, VAST estimates of GRP were positively correlated with sea surface temperature, but not CPUE or body weight of the juvenile chum salmon. In the Chukchi Sea, GRP was positively correlated with flux rates from the Bering Strait into the Chukchi Sea, body weight, and sea surface temperatures. CPUE and body weight were positively correlated with sea surface temperatures but not with flux rates.

ANOVA (in process)

The ANOVA model results indicate significant differences in GRP among years within the NBS and SCS regions.

Discussion (in development)

Using a growth rate *potential* model for juvenile Chum salmon within the northeastern Bering Sea and southern Chukchi Sea, we found that GRP varied significantly among years and regions. The strength of northward transport during summer months tended to coincide with years of higher juvenile Chum salmon GRP in the CS, indicating the possibility that northward advection of heat, nutrients, phytoplankton and zooplankton (see Polyakov et al., 2020) improves the potential for early marine growth of these juvenile salmon in this region. Within the NBS, juvenile Chum salmon GRP was highest during years with anomalous warming conditions on the shelf. higher during ?years and within ? LME's, and that transport plays an important role in increased GRP within the ?.

Our longer time series of juvenile Chum salmon GRP within the northern Bering Sea region revealed similar results to Farley and Moss (2009) that also showed a mismatch between areas of higher GRP on the eastern Bering Sea shelf and juvenile Chum salmon distribution.

- our model did not include sandlance, which are found in the area that j. chum salmon are distributed.
- Sandlance are good prey and this likely would increase GRP
- However, there are no good estimates of sandlance in coastal areas of the NBS
- Of note - j. chum salmon were not feeding on sandlance during (years) and instead were feeding primarily on lower quality prey.

Table 1: Equations and parameter description of the Chum salmon bioenergetics model. Note that subscripts i and s represent year (i =2003 to 2019; 2008 not sampled in the NBS) and station, and overbars denote mean quantities within the definitions of i.

Symbol	Equation and parameter description	Value	Source
Growth: $G_{i,s} = \tau \cdot I_{i,s} - (\mathrm{SMR}_{i,s} + \mathrm{ACT}_{i,s})$

CHAPTER 23 - Environmental drivers of productivity for two endemic Arctic forage fish, juvenile Arctic cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*), and an invading subpolar species, juvenile walleye pollock (*Gadus chalcogrammus*) in the Chukchi Sea

Objective 7: Develop spatially explicit bioenergetics models for Arctic cod and saffron cod as well as for juvenile pink and chum salmon and test the impact of warming summer temperatures on their growth and distribution

Vollenweider et al. (in preparation)

Abstract

The rapidly warming Arctic is creating newly accessible, ice-free areas, spurning interest in potential commercial fisheries. Arctic cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*) are endemic to the Chukchi Sea and have been identified for harvest, as well walleye pollock (*Gadus chalcogrammus*) that has recently invaded the region in growing numbers. To provide a foundation for fishery management, we quantified how productivity of each of these gadids fluctuates in response to environmental conditions. We modeled the impact of interannual environmental conditions on productivity over the course of four years, 2012, 2013, 2017 and 2019 in the U.S. region of the Chukchi Sea. Specifically, growth rate potential was calculated for each species using the Wisconsin Bioenergetics Model 4.0 with inputs of size-dependent fish energy, temperature, diet, and diet energy. Growth rate potential was scaled up from stations spaced 30 nautical miles apart and summed across the station grid for overall ecosystem productivity. Gadid productivity is likely correlated with temperature and food availability conferred by specific water masses and conducive to the growth of each species. Species-specific ecological and physiological requirements likely results in different water masses conferring maximum productivity to each species. Large interannual wind and pressure-driven fluctuations in the strength and extent of water masses structures interannual differences in gadid productivity. The link between these atmospheric processes and gadid productivity will inform fishery management and provide forecasting potential.

Keywords: spatially-explicit bioenergetics model, growth rate potential, Wisconsin Bioenergetics Model 4.0, water mass

Introduction

Declines in Arctic sea ice extent and duration have spurned interest in developing fisheries in newly ice-free, accessible regions. In federally managed US Arctic waters, comprised of the eastern Chukchi Sea and the western Beaufort Sea, all commercial harvests of fish are prohibited until sufficient information is available to support sustainable conservation and management (North Pacific Fishery Management Council, 2009). A core requirement for commercial harvest is an estimate of maximum sustained yield (MSY), which is calculated based on unfished biomass, age at maturity, natural mortality rate, and stock-recruitment parameters. None of these life history traits are known for even the most basic harvest model for two potential commercial fish species, Arctic cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*) (North Pacific Fishery Management Council, 2009). Another Gadidae that may garner future enthusiasm for harvest in the US Arctic is walleye pollock (*Gadus chalcogrammus*) (Hollowed et al., 2013). Walleye pollock is currently fished in adjacent waters of the Bering Sea (Ianelli et al., 2019) and has recently expanded into the Chukchi Sea with increasing abundance (Wildes et al., In Draft; De Robertis et al., In Draft). Complex models for commercial harvest are used for walleye pollock in the Bering Sea (Ianelli et al., 2019), but need to be evaluated for applicability in the Chukchi Sea (North Pacific Fishery Management Council, 2009). Once life history traits are quantified for the multiple

species of gadids in the Chukchi Sea, they need to be revisited periodically to adjust for changing environmental conditions that impact growth and productivity. This will be most pronounced in the Arctic, where oceanographic conditions are changing more rapidly than the rest of the globe (Koenigk et al., 2020; NSIDC, 2020).

Changing environmental conditions may have the highest impact on early life stages of fish. Small fish have high metabolic rates and a low capacity for storing energy, pushing them to their energetic limits (Sogard, 1997). Additional stresses imposed by unfavorable environmental conditions may likely exceed their ability to maintain their basic energetic needs. This is particularly true during their first year of life, a critical period (Howard et al., 2016; Farley et al., 2015; Heintz et al. 2013). Throughout summer, age-0 fish must grow quickly to evade predators and simultaneously store sufficient energy to sustain themselves through winter when food is limited. Consequently, the size and energy content of age-0 fishes in autumn reflects their summer growing conditions and indicates their preparedness to survive winter. This link has been made for walleye pollock in the Bering Sea, where total energy content in autumn correlates highly with their survival to recruitment two years later (Heintz et al., 2013). This concept should hold true for age-0 gadids in the Chukchi Sea, with their autumn body condition predictive of their future production.

Environmental fluctuations will impact the growth and production of age-0 gadids in the Chukchi Sea differentially based on their distinct ecological and physiological niches. Oceanographic conditions such as temperature and salinity that promote optimal growth are generally reflected by fish distribution. Age-0 Arctic cod and recently age-0 walleye pollock are distributed throughout salty (> 30.4 PSU) marine waters from the shoreline to the central Chukchi Sea, though Arctic cod are most prevalent in cooler water (2.6 — 6.7 °C) north of 69.5 °N while walleye pollock are more abundant in relatively warmer water (> 7 °C) south of that latitude (De Robertis et al., In Draft; De Robertis et al., 2017). Lab studies further substantiate Arctic cod and walleye pollock's thermal tolerances, with optimal growth for age 0 occurring at 7.3 °C and 13.0 °C, respectively (Laurel et al., 2015). In contrast, age-0 saffron cod are confined to shallow, coastal regions (> 7 °C, 28 - 31 PSU) in the Chukchi Sea and exhibit optimal growth at 14.8 °C in lab studies (Laurel et al., 2015). Spatial distributions are also driven in part by life history constraints such as ice-associated spawning and early feeding for Arctic cod (Graham and Hop, 1995; Craig et al., 1982) and estuarine spawning in brackish water for saffron cod (Pokrovskaya, 1960). Consequently, temperature and salinity impact growth and production of these gadids.

The Chukchi Sea is characterized by distinct ocean currents with unique temperature and salinity profiles that influence fish productivity. One of the most pervasive surface currents covering much of the Chukchi Sea is the Bering-Chukchi Summer Water, which originates from the Bering Sea and the Gulf of Anadyr (Danielson et al., 2017; Figure 2). This water mass is intermediate in temperature and salinity to other water masses. Along the Alaskan coastline of the Chukchi Sea, the Alaska Coastal Water flows northward from its inception in the Gulf of Alaska en route to the Arctic Basin. The Alaska Coastal Water is fresh and nutrient-rich from terrestrial freshwater runoff. Shallow coastal depths and high turbidity increase solar absorption, making the water mass up to 5 °C warmer than the Bering-Chukchi Summer Water (Danielson et al., 2017). The surface waters in the northern region of the Chukchi Sea, known as Ice Melt Water, which are left over from melted sea ice, are fresh and cold. The different oceanographic conditions of the dominant water masses provide different growing conditions for the three age-0 gadid species.

Another aspect that creates spatial heterogeneity in habitat quality for age-0 gadids in the Chukchi Sea is prey availability. Diets of age-0 Arctic cod and saffron cod in the Chukchi Sea are dominated by calanoid and harpacticoid copepods, as well as *Thysanoessa* sp. euphausids, and to a lesser degree mysids (Gray and Norcross, 2018; Sousa et al., 2018; Gray et al., 2015). Walleye pollock, in comparison, consume primarily euphausiids in the Chukchi and Northern Bering Seas (Cieciel et al., In Draft; Moss et al., 2009). The prominent water masses in the Chukchi Sea have distinct zooplankton assemblages, stemming

from the origination of currents (Pinchuk et al., 2017; Eisner et al., 2013). The Bering-Chukchi Summer Water is dominated by large zooplankton such as copepods (*Eucalanus bungii, Calanus glacialis/marshallae, Metridia pacifica)* and euphausiids (*Thysanoessa raschii*). These species are generally lipid-rich and high-quality prey (Vollenweider et al., Chapter 9). In contrast, the small zooplankton such as bivalve larvae and *Pseudocalanus* copepods characteristic of Alaska Coastal Water (Pinchuk et al., 2017; Eisner et al., 2013) have lower lipid content (Vollenweider et al., Chapter 9). Together, the spatial heterogeneity in oceanographic conditions and prey availability defines the habitat suitability for fish and consequently their growth potential.

Fish growth rate potential is a measure of individual fish growth and productivity and consequently overall ecosystem production. Growth rate potential incorporates fish size and energy content, density of prey by size and their energy content, and the physical environment to simulate fish growth. Both size- and temperature-specific bioenergetics models are needed for each gadid species to calculate growth rate potential. A bioenergetics model has been fully developed for walleye pollock (Buckley and Livingston, 1994), but not for Arctic cod or saffron cod. Growth rate potential is then scaled up by fish density to compute system productivity (Farley and Moss, 2009; Brandt et al., 1992). Growth rate potential should be evaluated on a fine spatial scale to account for heterogeneity in the environment and localized density-dependent processes (Brandt et al., 1992) associated with the different Chukchi water masses (Danielson et al., 2017). The location and extent of these water masses change from year to year primarily as a function of wind fields (Danielson et al., 2017; Pinchuk et al., 2017; Eisner et al., 2013) and are likely a major driver in the interannual productivity of gadids.

We evaluated the influence of spatial and interannual environmental variation on the productivity of three species of gadids in the US region of the Chukchi Sea (60.004° – 43.044° N, 170.000° – 153.179° W) to provide a foundation for emerging harvest strategies and ecosystem sustainability. We examined the age-0 stage of three potential commercial species, including two species endemic to the Arctic, Arctic cod and saffron cod, as well as expanding walleye pollock. Specifically, we used a spatially-explicit bioenergetics model to relate interannual differences in gadid productivity to variable oceanographic conditions observed in the US Chukchi Sea in 2012, 2013, 2017, and 2019 to test the following hypotheses:

- Arctic cod growth and productivity will be elevated in cool water masses, such as Ice Melt Water, and total production will be higher in colder years when these water masses are more pronounced;
- Saffron cod growth and productivity will continue to be restricted to warmer, nearshore Alaskan Coastal Water and will increase during warmer years; and
- Walleye pollock growth will flourish in warm years when Arctic cod production is diminished and constrained to smaller areas.

Methods

We used spatially-explicit bioenergetics models to quantify the influence of oceanographic conditions on the growth and productivity of three species of gadids, Arctic cod, saffron cod, and walleye pollock, with varying niches in the Chukchi Sea. Data for the modeling effort was collected from acoustic-trawl surveys conducted across the US Chukchi Sea in four of eight years, August – September of 2012, 2013, 2017, and 2019 (Figure 1). At each station, temperature and salinity were measured throughout the water column using a Seabird 19+ Conductivity Temperature Depth (CTD) instrument. Mean annual surface water temperature and salinity were calculated by averaging the values in the top 20 m at each station and then averaging over all stations. Zooplankton species assemblages and density were measured using a vertically-towed 60 cm, 505 µm mesh bongo net. Fish were sampled with a 200 m long CanTrawl 400/601 surface trawl with a 122 m headrope, a fished vertical opening of 19 m, and 162 – 1.2 cm mesh (De Robertis et al., 2015). While the vessel traveled between stations, a SIMRAD© hydroacoustic echosounder located fish deeper in the water column than the surface trawl could collect. If additional fish

were found, they were sampled with a modified Marinovich mid-water trawl with 12 m headrope, a fished vertical opening of 6 m, and 6.4 – 0.3 cm mesh (De Robertis et al., 2015).

Approximately 10 age-0 fish were subsampled from each haul and frozen at sea. In the laboratory, each fish was measured for total length (nearest mm) and wet mass (nearest 0.01 g). Stomach contents were extracted, weighed to the nearest 0.01 g, and species were identified to the lowest possible taxon to quantify diet. Diet energy was calculated using published values of lipid content of zooplankton from the Chukchi Sea (Vollenweider et al., In Draft). Individual fish were dried to a constant weight using Thermogravimetric Analysis and homogenized. Energy density (kJ/g dry mass) of each fish was measured using a Parr 6725 semi-micro bomb calorimeter following standard methods (Vollenweider et al., In Draft). Briefly, 30 – 200 mg of dried sample homogenate were pressed into pellets, combusted, and the emitted heat was measured and converted to energy.

We parameterized the Fish Bioenergetics 4.0 model (Deslauriers et al., 2017) for Arctic and saffron cod using published mass and temperature specific values of consumption (C), growth rate (G), respiration (R), specific dynamic action (SDA), and feces (F; Krieger et al., 2020). The core thermodynamic equation used was:

$$C_{ij} = G_{ij} - (R_{ij} + SDA_{ij} + U_{ij} + F_{ij}) \quad \text{(Equation 1)}$$

where consumption (C) is a measure of growth (G) minus losses for respiration (R), specific dynamic action (SDA), urine (U), and feces (F) for a given sized fish *i* at a given temperature *j*. Equation 1 requires size and temperature specific equations to derive each variable (Table 1). Equation parameters were collated from the literature and used to construct models for Arctic cod (Drost et al., 2016; Laurel et al., 2016; Hop et al., 1997; Hop and Graham, 1995; Jensen et al., 1991; Holeton, 1974) and saffron cod ((Laurel et al., 2016; Chen, 1989; Chen and Mishima, 1986).

For each of the four survey years, the Fish Bioenergetics 4.0 model (Deslauriers et al., 2017) was used to calculate the size-dependent growth-rate potential of individual fish for all three gadid species at each station following methods in Farley et al. (2009). Specifically, model inputs for field observations were station-specific values for water temperature, fish diet, and caloric density of individual fish. For each of the three species, annual ecosystem production was calculated across the US region of the Chukchi Sea. Fish production is a measure of the increase in fish biomass within a period of time and was calculated as:

$$\text{system-wide production} = \sum G_{ij} \ast\times N_{ij} \quad \text{(Equation 2)}$$

where G_{ij} is the calculated fish growth potential (g * d^{-1}) from the Wisconsin bioenergetics model at station *i* for a given size *j*, and N_{ij} is the number of fish at station *i* for a given size *j* in 10 mm length bins (Brandt et al. 1992). Sensitivity analyses were conducted to evaluate the robustness of the model and input parameters via Monte Carlo simulation using parameter error rates of 5%, 10%, 15%, and 20% following Bartell et al. (1986).

In progress

Discussion

Interannual variation in the production of the three prominent Arctic gadids in the Chukchi Sea is likely governed by the extent of the prominent water masses. Each of these water masses undergoes significant interannual differences in their strength and spatial extent, with greater deviations anticipated in the future. Ice Melt Water is derived from melting sea ice. Arctic sea ice extent has declined over the 41-year satellite record and is the second lowest on record, and was well below average in the Chukchi Sea in 2019 and 2017 (National Snow and Ice Data Center, accessed 4/22/2020). The Chukchi Sea has had increased persistence of open water in winter and earlier ice retreats in the spring, in large part from

increased ocean heat transport from the Bering Sea (Serreze et al., 2019). Arctic cod productivity is likely linked to characteristics of these water which effect growth, as well as the nutritionally-rich sea-ice diatoms that are passed up the food chain to juvenile fish (Falk-Petersen 1998). Continued reductions in Ice Melt Water likely influences gadid productivity.

Greater heat transport into the Chukchi Sea will diminish sea ice and may decrease productivity of endemic gadids while increasing production of walleye pollock. The dominant water mass in the Chukchi Sea is the Bering-Chukchi Summer Water which is derived from the Bering Sea and the Anadyr Currents. Transport through the Bering Strait is driven by differences in sea level pressure and wind (Serreze et al., 2019; Aagaard et al., 2006). Though sea level differentials and wind fields are hard to predict, general ocean warming in the Bering Sea in coming decades will likely increase ocean heat transport through the Bering Strait (Serreze et al., 2019). With greater influx of water from the Bering Sea, which supports one of the world's largest fisheries on walleye pollock (Ianelli et al., 2019), pollock production is anticipated to increase in the Chukchi Sea. Furthermore,

A second major water mass flowing north through the Bering Strait and into the Chukchi Sea is the Alaskan Coastal Water; for which the strength and spatial extent are driven by wind and freshwater input (Morris, 2019). Enormous quantities of freshwater river discharge along the eastern Bering Sea coast promote this current, including the Yukon, Kuskokwim, Nushagak and Kvichak rivers and to a lesser extent from riverine input from the Gulf of Alaska (Aagaard et al., 2006). River discharge is anticipated to increase as warming continues due to large contributions of freshwater from melting glaciers and permafrost (Chikita et al., 2007). Increasing prominence of the Alaskan Coastal Current in the Chukchi Sea may enhance saffron cod productivity, which are historically distributed along the Alaskan coast. Similar to the Bering-Chukchi Summer Water, the Alaskan Coastal Current transports a large heat flux to the Chukchi Sea, and is instrumental in sea ice melting by as much as 30% of the seasonal sea ice loss area (Woodgate et al., 2010). Consequently, increases in Alaskan Coastal Water prominence in the Chukchi Sea negatively influence the productivity of other gadid species.

Our findings will show that significant changes are occurring in the productivity of gadids in the Chukchi Sea in response to changing environmental conditions. Understanding the disparate trends in production among Arctic cod, saffron cod, and walleye pollock are foundational for developing commercial fisheries in a newly accessible region. Physical processes underlying the distribution and strength of the prominent ocean currents in the Chukchi could be a key indicator used in management strategy to understand and predict fish stocks, determine sustainable harvest levels, and maintain a sustainable ecosystem.

Collaborations

BOEM Arctic Integrated Ecosystem Survey (Arctic IES), Phase II – PI's Mueter, Kuletz, Farley, Ladd et al. (Alaska Fisheries Science Center (NOAA), M17PG00007; University of Alaska Fairbanks (UAF), M17AC00016; US Fish and Wildlife Service (USFWS), M17PG00017. $2,200,000). Support ship contract costs, data analysis and seabird observations/analyses for the Arctic Integrated Ecosystem Survey.

BOEM and Coastal Impact Assistance Program (CIAP) *Arctic Ecosystem Integrated Survey (EIS) Phase 1.* PIs - Farley, Mueter, Eisner et al., (NOAA-BOEM IAA-AK-11-08b, 1/1/12-5/31/16, $3,000,000). Summer surveys were conducted in the NBS and CS in 2012 and 2013. Observations included pelagic fish and groundfish, zooplankton, oceanography, and total and size fraction Chl-a. We will relate satellite derived estimates of phytoplankton community composition (outcome of our proposal) to *in-situ* total and size-fraction Chl-a. The validated satellite data can be compared to distributions of zooplankton and fish in this region.

DBO. The Distributed Biological Observatory (DBO) is a multidisciplinary Arctic ocean sampling program supported by the NOAA's Arctic Research Program (ARP). ARP supports an annual scientific cruise to the Pacific Arctic region during which U.S. scientists take a wide range of physical, chemical, and biological samplings. The DBO has designated eight "hot spots" areas across the Bering, Chukchi, and Beaufort seas where multidisciplinary sampling is focused. We have partnered with the DBO Program to collect a suite of physical and biological measurements in the Chukchi Sea over multiple years and to make these observations available to the AIERP Program. The DBO is a collaboration between multiple U.S. federal agencies and academic institutions as well as from other Arctic nations.

Harmful Algal Blooms. PIs Duffy-Anderson, Stabeno, Eisner, and Kimmel collaborated with WHOI researcher Don Anderson and NWFSC researcher Kathi Lefebre to collect samples for work on the detection of high levels of paralytic shellfish toxins in Northern Alaskan food webs.

International Partners

RUSSIA. PIs Eisner, Ladd, Duffy-Anderson collaborated with Russian oceanographers, Yury Zuenko and Eugene Basyuk at the Pacific Branch of Russian Research Institute of Fisheries and Oceanography (TINRO) to compile surface and bottom water temperature data and pollock abundance data (juveniles and adults) from the eastern and western Bering Sea. This effort resulted in a joint publication (see above) with communication ongoing.

Intergovernmental Consultation Committee: PI's Farley and Melnikov (TINRO Center Deputy Director) collaborated through the ICC to place Russian scientists on 2017 and 2019 surveys to compile on board fish diets, zooplankton biomass from a Juday net, and on board fish processing.

ITAE: To better study arctic marine ecosystems and the rapid changes that are occurring, we are collaborating with the Innovative Technology for Arctic Exploration (ITAE) program as it works to develop innovative technologies, including sensors and platforms, to meet the scientific demand in these regions. The mission of the ITAE program is to conceptualize and build effective research equipment for the assessment of the Arctic environment and ecosystem with the operation of high-resolution sensors on autonomous platforms near sea ice. The dynamic and fine-scale nature of these regions requires responsive, high-resolution data collection over large areas in real time — a logistical challenge ideally suited to fast, mobile autonomous platforms rather than traditional ship-based operations. Existing autonomous platforms are both small and slow, limiting the observational capacity, responsiveness, and deployment capabilities. ITAE is a collaborative research effort by University of Washington (JISAO) and NOAA engineers and scientists at the Pacific Marine Environmental Lab (PMEL).

National Oceanographic Partnership Program (NOPP). *Expanding exploration and using innovative technologies to assess the rapidly changing Bering and Chukchi Seas.* PIs - Stabeno, Mordy, Lomas, Eisner, Nielsen, et al. The US Arctic ecosystems are undergoing dramatic, unprecedented changes in response to ocean warming and declines in sea ice. In addition to the physical changes, biological shifts across all trophic levels have been observed (e.g., phytoplankton community composition and bloom timing; zooplankton dynamics; spatial shifts in fish distributions). This project expands ecosystem observations in NBS and southern CS using traditional and new technologies. Emergent technologies include profiling platforms, speciation techniques ('omics), *in-situ* visualization, and unmanned vehicles. This project will create new Ecosystem Observatories in the US Arctic.

NOAA Joint Polar Satellite System (JPSS) funded proposal: Satellite analysis of shifts in phytoplankton community composition and energy flow in the new Arctic. PIs: Eisner, Lange (Blue Marble Space Institute of Science), Lomas, Mordy, Nielsen, Stabeno; Collaborators Gann (AFSC), Lefebvre (NWFSC, HABs), Robinson (UC Santa Cruz, CoastWatch/PolarWatch), Wilson (SWFSC, CoastWatch/PolarWatch). 6/1/21-5/31/24, $515,966. The overall goals of this project are to: 1) analyze the variability of phytoplankton community size structure based on spectral slopes of absorption, backscattering, remote-sensing reflectance ($R_{rs}(\lambda)$), and empirical chlorophyll-a (Chl-a) -based algorithms from JPSS satellite data across time and space; 2) modify existing ocean color algorithms to exploit the unique $R_{rs}(\lambda)$ properties of *Synechococcus* in order to determine changes in this picoplankton group; 3) estimate diatom abundances from Chl-a-specific absorption; and 4) explore correlative methods to assess the probability of occurrence of harmful algae such as *Pseudo-nitzschia* spp. and *Alexandrium* spp. using Sentinel 3-A-OLCI satellite products to improve HAB predictions in the North Bering Sea (NBS) and Chukchi Sea (CS). Data from Arctic IERP will be used for ground-truthing satellite data.

NSF COLLABORATIVE RESEARCH: *What controls the transfer of diatom organic matter to age-0 pollock prey in the Bering Sea ecosystem?* PI - Lomas et al., (#OPP-1603460, 11/2016-10/2019; $108,908). This project explored both physiological responses of polar diatoms in culture, and the ecology (primary production and phytoplankton community) of phytoplankton in the BS and CS. The results from this and other collaborative projects listed below suggest that not only will the nutritional value of diatoms decrease as the BS and CS warm, but also the phytoplankton community, especially in the summer/fall period, will shift to small picoplankton (e.g., *Synechococcus*).

Ecosystems and Fisheries-Oceanography Coordinated Investigations (EcoFOCI) Program and Recruitment Process Alliance (RPA) at NOAA PMEL/AFSC. PIs - Stabeno, Duffy-Anderson, Eisner, Nielsen, Mordy, Farley et al. This is an integrated long-term base-funded NOAA program that conducts research in the US Arctic. It maintains long- term ecosystem moorings in the BS (since 1995) and CS (since 2010) and spends >100 days at sea each year. Field observations include: temperature, salinity, oxygen, currents, nutrients, phytoplankton (size-fractionated Chl-a, taxa, productivity), zooplankton/ichthyoplankton, pelagic fish and groundfish. EcoFOCI's goal is to improve understanding of ecosystem dynamics and apply that understanding to fisheries management. Field, laboratory and modeling studies are integrated to reach this goal. On average 19 (11-32) articles are published per year on all aspects of these ecosystems. Collaborators include: Pacific Marine Environmental Lab (PMEL)'s *Innovative Technology for Arctic Exploration* (ITAE, PIs - Mordy et al., $1.3M /year) which supports new technology to improve ocean observations; *AOOS* (PI - Stabeno, 2020-2022, $100K to EcoFOCI) which provides support to improve observations on northern BS (NBS) mooring observatory; and *NOAA's Arctic Research Program* (PIs - Stabeno, Mordy et al., ~$280K /year to EcoFOCI) which supports moorings and an ecosystem cruise (in collaboration with EcoFOCI) each year to the NBS and CS. Data collected under this consortium contributes to the Distributed Biological Observatory - an international effort to conduct opportunistic sampling at biological hotspots in the US Arctic.

North Pacific Research Board (NPRB) and Bureau of Ocean Energy Management (BOEM). Recent awards relevant to this project include the following:

Evaluating historical and future climate-driven changes to Pacific cod spawning habitat in the Bering Sea PIs - Rogers, Mordy, Stabeno, et al. (NPRB #2003, 7/2020 - 6/2023, $599,719). This project focuses on exploring the seasonal evolution of ocean temperature across the BS and its impact on spawning of Pacific cod. Specifics goals are to expand observations of seasonal oceanographic conditions in the eastern BS through deployment of an array of low-cost sensors to monitor bottom temperatures; use these data to validate and assess Regional Ocean Model System (ROMS) error and bias with respect to temperature dynamics; formally assimilate new data into ROMS; use ROMS and existing, experimentally-derived relationships between temperature and Pacific cod spawning success to characterize the extent, timing, and distribution of suitable spawning habitat; project the spatial distribution and timing of suitable spawning habitat under future climate scenarios; and introduce this information into the management process for Pacific cod. Changes in phytoplankton species and community structure, which will be directly assessed in the proposed research, impact ecosystem productivity with cascading effects on fish larval abundance and survival and spawning success.

Monitoring export fluxes to detect seasonal and interannual changes in the pelagic ecosystem of the St. Lawrence Island Polynya Region PIs - Stabeno, Mordy et al., (NPRB #1914, 2020 - 2024, 342,087). Climate change is rapidly affecting the NBS including the St. Lawrence Island Polynya (SLIP) where a large decline in sea-ice cover was observed in 2018, with potentially important consequences for the bird and marine mammal populations of the region. This project will deploy a sequential sediment trap to measure the magnitude and composition of the organic matter supplied to the benthic communities in the region. Sediment trap samples will provide continuous biological samples that will allow the monitoring of several aspects of the marine ecosystem from phytoplankton and zooplankton species to carbon supply to the benthos. This project will provide critical *in-situ* data for the proposed research, and addresses a pressing need for the long-term monitoring of the BS marine ecosystem to improve our ability to forecast and respond to the effects of climate change and provide deliverables to policy-makers.

PICES WG44: NBS and Chukchi IEA (Logerwell chair). We are collaborating with PICES WG44 on the Northern Bering-Chukchi Sea region to provide detailed assessment of the Pacific Arctic gateway, as well as detailed information that will inform understanding of connectivity of climate and ocean processes, species movements, shelf foodweb dynamics, fishing, trade, subsistence and food security, and human activities. The Northern Bering Sea-Chukchi Sea (NBS-CS) region is experiencing unprecedented ocean warming and loss of sea ice as a result of climate change. Seasonal sea ice declines and warming temperatures have been more prominent in the northern Bering and Chukchi seas as almost all other portions of the Arctic.

Synopsis

Why We Did it:

To understand how reductions in Arctic sea ice and the associated changes in the physical environment influence the flow of energy through the ecosystem in the Chukchi Sea.

What We Did

Researchers conducted Integrated Ecosystem Surveys (Arctic IES) aboard the R/V Ocean Starr (Figure 1) in late summer and early fall of 2017 and 2019. Fish observations from collaborative ship-based surveys were incorporated to provide a broader perspective (ASGARD). In addition to the vessel-based surveys, sub-surface moored sensors were deployed to gather biophysical information continuously from September 2016 to September 2019 and autonomous platforms were used to make observations to augment the ship-based surveys (e.g., gliders, saildrones, air-deployed profilers).

What We Learned

Subarctic walleye pollock were found in large numbers within the Chukchi Sea during our survey years, while Arctic cod were distributed further north than in previous survey years (2005, 2012, 2013).

Acoustic estimates of age-0 gadid abundance indicated that Age-0 walleye pollock, which were historically scarce in the region, were the most abundant species in many areas in 2017 and 2019. Small pollock and Arctic cod are difficult to distinguish in the field, and genetic techniques were used to identify age-0 gadids during these and previous surveys. This revealed that the species composition in the eastern Chukchi Sea shelf has shifted dramatically in recent years with the arrival of subarctic species (i.e. walleye pollock) in the region..

Warmer sea temperatures impacted fish fat storage and are predicted to decrease biodiversity

Juvenile Arctic cod at the end of the warm (2017) summer season had only half the fat storage and lower overall energy content than those collected during colder years (2012/2013). Similarly, saffron cod, capelin and Pacific sand lance had slightly lower energy content in warmer years. Reduced body condition of fish in the fall of warm years may reduce overwinter survival of fish. In addition, rising bottom temperatures in the Bering and Chukchi seas is predicted to reduce benthic invertebrate species diversity through loss of suitable temperature habitat. Taxa most impacted include gastropods and mussels, prey for adult gadids and other benthic feeders such as Pacific walrus. The taxa least impacted werebasketstars.

Warmer sea temperatures in the Chukchi Sea may improve overwinter survival of subarctic gadids.

Age-1 Pacific cod were observed in the western Chukchi Sea in 2018 and 2019, indicating possible overwinter survival of age-0 fish, although there was little evidence that they survive and/or remain in the Chukchi Sea to age-2. Adult Pacific cod were also observed in the Chukchi Sea during 2018 and 2019. Although densities in the western Chukchi Sea were very low compared to the Bering Sea, the adults are the first known (to us) in the Chukchi Sea.

Transport through the Bering Strait influences summer fish abundance and juvenile salmon habitat in the Chukchi Sea.

Observations from moorings, autonomous vehicles, and transport models indicate that the abundance of pelagic fish over the Chukchi shelf is tightly coupled to ocean current transport. Pelagic fish abundance is highly variable over the course of a year. Very few fish are present in winter. The abundance of pelagic fishes increases dramatically in summer and fall as they are advected to the area from the south, and are

ultimately transported northwards by fall. Increased transport through the Bering Strait is connected with improved early marine growth rate potential (a measure of habitat quality) for juvenile Chum salmon in the southern Chukchi Sea.

A biophysical transport model suggests that Arctic cod spawned in the northern Chukchi Sea may be an important source of larvae for the Beaufort Sea and Arctic Basin, while observed larval aggregations in the Chukchi Sea likely originated in the northern Bering and southern Chukchi seas.

Estimated hatch dates for Arctic cod in the northern Bering, Chukchi, and Beaufort seas ranged from November to July with peak hatching occurring from February to May. There was clear separation of hatch dates between Arctic cod caught in the spring and summer, suggesting different origins or strong size-dependent mortality.

Why It Matters

Unprecedented warming observed during the course of the Arctic IERP program may offer a window into the future Arctic (Figure 2). The biological indicators reported here suggest that increased warming could alter ecosystem structure and function with as yet unknown consequences for the people that depend on marine resources in the region.

Fig. 1 Chartered survey vessel, R/V Ocean Starr in Nome Alaska. Photo courtesy of Cathleen Vestfals

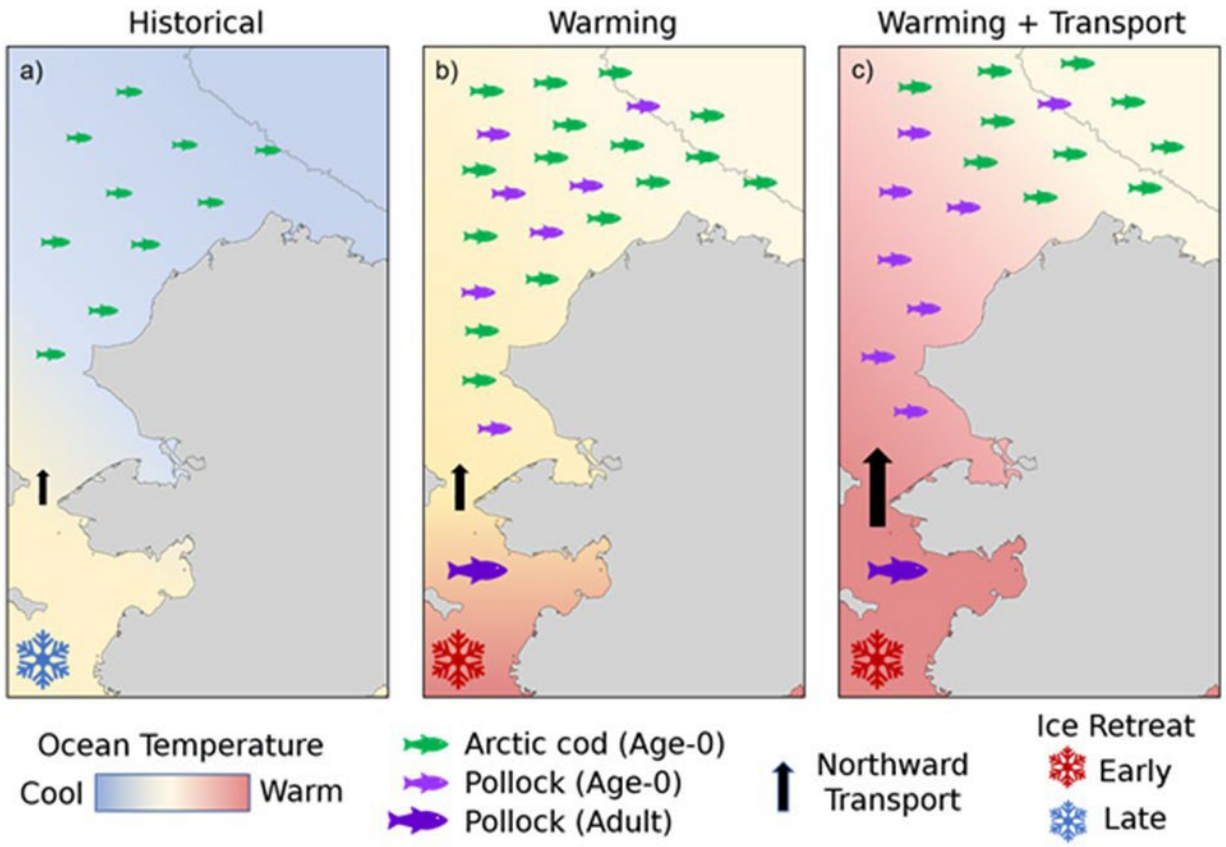

Fig. 2. Hypothesized scenarios based on observations of the Chukchi Sea gadid community. (a) Under historical conditions of later ice retreat, Arctic cod are observed in intermediate and cool waters across the Chukchi Shelf. (b) With increased warming and early ice retreat, age-0 Arctic cod increase in abundance and size across as a result of increasing temperatures. Increased presence of adult walleye pollock in the northern Bering Sea results in the transport of age-0 pollock into the Chukchi, where conditions are favorable for both gadid species. (c) With increased transport of warmer waters from the Bering Sea, Arctic cod are displaced further north along with the intermediate temperature waters. Age-0 pollock from the northern Bering Sea are transported with the warmer waters and become the dominant gadid in the southern portion of the shelf. The 1000-m depth contour is shown to indicate the Chukchi shelf break. (Levine et al. in preparation).

Final Report

November 30, 2021

Revised June 2022

Project title: A93 - Arctic Integrated Ecosystem Survey, Phase II; Upper Trophic Level (UTL)

Principal Investigator(s): Ed Farley, Kristin Cieciel, Dan Cooper, Louise Copeman, Alex De Robertis, Jeff Guyon, Ron Heintz, Kathy Kuletz, Elizabeth Labunski, Robert Levine, Libby Logerwell, Franz Mueter, Johanna Vollenweider, Jared Weems, Sharon Wildes, and Chris Wilson

Table of Contents

Executive Summary

The Chukchi Sea is undergoing dramatic sea-ice reductions and temperature increases, but resultant biological and trophic responses are poorly understood. The overall goal of this Upper Trophic Level (UTL; A93) project is to better understand the mechanisms and processes that structure the ecosystem and influence the distribution, abundance, and life history of lower (phytoplankton, zooplankton) and upper trophic species (fishes, seabirds, mammals), and their potential vulnerability to the rapidly changing environment of marine ecosystems in the Arctic. The Pacific Arctic Region (PAR) is experiencing significant warming and extremes in seasonal sea ice extent and thickness. To better understand the impact of warming on the PAR ecosystem, we linked this proposal with the Lower Trophic Level proposal (LTL; A92) and completed integrated ecosystem surveys, laboratory processing of samples and experimental projects to assess fish energetics and growth, along with analyses of data to address the following overarching hypothesis:

Reductions in Arctic sea ice and the associated physical changes to the environment influence the flow of energy through the pelagic ecosystem in the Chukchi Sea. Specifically, we expect lasting changes in the seasonal composition, distribution and production of phytoplankton; in the distribution and standing stocks of large crustacean zooplankton that serve as the prey base for upper trophic level fishes and seabirds; in the assemblages, distributions, and abundances of larval and early juvenile fishes that influence the recruitment success of later life stages, and in the distribution and abundance of adult fishes.

This report details the results of the UTL program. We conducted comprehensive ecosystem surveys of Chukchi Sea physics, chemistry, biogeochemistry and biology using an integrated network of moored arrays, autonomous vehicles, shipboard surveys, and laboratory experiments.

Specific hypotheses addressed by the UTL project include:

H1: Cods in the Arctic - *Loss of sea ice and continued warming of sea temperatures during summer in the Chukchi Sea will restructure the food web, decreasing the amount of fat available to higher tropic level predators.*

H2: Cod habitat in the Arctic: *The northern Chukchi serves as a nursery area for young-of-the-year Arctic cod, supplying juveniles to other areas of the Arctic.*

H3: Salmon expansion into a warming Arctic: *Summer surface waters in the northeastern Bering Sea will continue to warm and be a source of heat advected to the Pacific Arctic Region, providing new marine habitat for juvenile salmon.*

H4: Seabird community structure and seabird-prey dynamics: *The current predominance of planktivorous seabirds in the Arctic may shift back towards piscivorous seabirds, if warming sea temperatures restructure the food web*.

Emerging results from the UTL component were combined with historical data to demonstrate that:

1. Genetic techniques used to identify age-0 gadids during the 2017 and 2019 surveys, revealed the species composition in the eastern Chukchi Sea shelf has shifted dramatically in recent years with the arrival of subarctic species (i.e. walleye Pollock) in the region.

2. Acoustic estimates of age-0 gadid abundance indicated that Age-0 walleye pollock, which were historically scarce in the region, were the most abundant species in many areas in 2017 and 2019.

3. Observations from moorings, autonomous vehicles, and transport models indicate that the abundance of pelagic fish over the Chukchi shelf is tightly coupled to transport. Pelagic fish abundance is highly variable over the course of a year. Very few fish are present in winter. The abundance of pelagic fishes increases dramatically in summer and fall as they are advected to the area from the south.

4. Age-1 Pacific cod were observed in the western Chukchi Sea in 2018 and 2019, indicating possible overwinter survival of age-0 fish, although there was little evidence that they survive and/or remain in the Chukchi Sea to age-2. Adult Pacific cod were also observed in the Chukchi Sea during 2018 and 2019. Although densities in the western Chukchi Sea were very low compared to the Bering Sea, the adults are the first known (to us) records from the Chukchi Sea.

5. Analyses on juvenile Pink salmon ecology revealed that much of the variability in survival for northern Bering Sea stocks occurs during early life-history stages and that juvenile abundance is an informative leading indicator of Pink salmon runs to this region.

6. Juvenile Arctic cod at the end of the warm (2017) summer season had only half the fat storage and lower overall energy content than those collected during colder years (2012/2013). Similarly, saffron cod, capelin and sand lance had slightly lower energy content in warmer years.

7. Juvenile Chum salmon took advantage of high growth rate potential (GRP) in the southern Chukchi Sea during 2007; however, GRP was lower overall in the southern Chukchi Sea than within the northern Bering Sea even during the more recent warm years.

8. Rising bottom temperatures in the Bering and Chukchi seas is predicted to reduce benthic invertebrate species diversity through loss of suitable temperature habitat. Taxa most impacted include gastropods and mussels, prey for adult gadids and other benthic feeders such as Pacific walrus. Taxa least impacted include basketstars.

9. Estimated hatch dates for Arctic cod in the northern Bering, Chukchi, and Beaufort seas ranged from November to July with peak hatching occurring from February to May. There was clear separation of hatch dates between spring and summer caught Arctic cod, suggesting different origins or strong size-dependent mortality.

10. A biophysical transport model suggests that polar cod spawned in the northern Chukchi Sea may be an important source of larvae for the Beaufort Sea and Arctic Basin, while observed larval aggregations in the Chukchi Sea likely originated in the northern Bering and southern Chukchi seas.

Preamble

The Arctic Integrated Ecosystem Research Program

The Arctic Integrated Ecosystem Research Program (Arctic IERP, 2016-2021) was motivated by the rapid changes occurring in the waters of the northern Bering and Chukchi Seas. While much research has been done in the region, many important questions remain. As a cohesive research endeavor, the Arctic IERP was designed to address a single, overarching question:

How will reductions in Arctic sea ice and the associated changes in the physical environmental influence the flow of energy through the ecosystem in the Chukchi Sea?

The report you are reading now is one of five final reports from the fieldwork phase of the Arctic IERP (a synthesis phase was initiated in 2022 after the completion of the Arctic IERP field-based projects). This preamble provides a brief overview of the Arctic IERP, both to place each final report in the broader context of the whole program, and to encourage readers to examine the other final reports to learn more about the research that was done. More detailed information about the Arctic IERP can be found at https://www.nprb.org/arctic-program.

The spatial domain of interest for the Arctic IERP extended across the Chukchi Sea Large Marine Ecosystem (LME) as redefined by the Arctic Council's Protection of the Arctic Marine Environment (PAME) working group, and the northern Bering Sea (north of 61.5° N) as it strongly influences dynamics in the Chukchi Sea from the upstream direction. The main focus has been on the greater Bering Strait region and the Chukchi Sea. The program included the Arctic Basin and Beaufort Sea insofar as processes in the Chukchi Sea are influenced by these adjacent areas.

Development of the Arctic IERP

Before any Arctic IERP research proposals were written, the NPRB administered an assessment program, the Pacific Marine Arctic Regional Synthesis (PACMARS; https://www.nprb.org/assets/uploads/files/Arctic/PacMARS_Final_Report_forweb.pdf), that applied $1.5M provided by Shell and ConocoPhillips to compile and synthesize existing information about the ecosystem and inform research priorities. This assessment included community meetings in 2013 in Savoonga, Gambell, Kotzebue, Nome, and Barrow (now Utqiaġvik), in which representatives from 17 communities between St. Lawrence Island in the Bering Sea and Barter Island in the Beaufort Sea participated. One major area of emphasis that emerged from these community meetings was concern about food security for the region's residents in light of the rapid environmental changes taking place. Results from the scientific assessment and input provided via the community meetings informed the creation of the Arctic IERP. The PACMARS report informed both the IERP Request for Proposals (https://www.nprb.org/arctic-program/request-for-proposals/) and the submitted proposals.

Following a proposal review process, the Arctic IERP formally began in 2016 with funding from the North Pacific Research Board (NPRB), the Collaborative Alaskan Arctic Studies Program (formerly the North Slope Borough/Shell Baseline Studies Program), the Bureau of Ocean Energy Management (BOEM), and the Office of Naval Research (ONR) Marine Mammals and Biology Program. Generous in-kind support was contributed by the National Oceanic and Atmospheric Administration (NOAA), the University of Alaska Fairbanks (UAF), the U.S. Fish & Wildlife Service (USFWS), and the National Science Foundation (NSF). This coordinated program was developed in cooperation with the Interagency Arctic Research Policy Committee (IARPC) and the U.S. Arctic Research Commission.

The Research

The Arctic Integrated Ecosystem Research Program (IERP) invested approximately $18.6 million in studying marine processes in the northern Bering and Chukchi Seas in 2017-2021, beginning in the summer of 2017. The research was divided into three main, complementary projects. The Arctic Shelf Growth, Advection, Respiration, and Deposition Rate Experiments (ASGARD) project carried out research in late spring and early summer of 2017 and 2018 aboard R/V Sikuliaq. The Arctic Integrated Ecosystem Survey (Arctic IES) conducted fieldwork aboard R/V Ocean Starr in late summer and early fall 2017 and 2019. In addition to the vessel-based surveys, sub-surface moored sensors were deployed to gather biophysical information continuously from September 2016 to September 2019 and autonomous platforms were brought to bear (e.g., gliders, saildrones, air-deployed profilers).

In addition to the vessel-based work, a team of Arctic residents and social scientists, including members from eight communities in the North Slope and Northwest Arctic Boroughs and the Bering Strait region, met several times during the project to assess and analyze Indigenous observations and experiences with various types of change occurring in the region from Savoonga to Utqiaġvik. This group also compiled an annotated bibliography of Traditional Knowledge or Indigenous Knowledge (available through the data portal described below), to help researchers from other components of the Arctic IERP find information relevant to their studies.

Prior to the commencement of fieldwork, meetings were held in the three hub communities of Nome, Kotzebue, and Utqiaġvik. Scientists from the Arctic IERP and NPRB staff met with community members from each region to discuss the research purpose and plans. Research plans were also shared and discussed at meetings of the Alaska Eskimo Whaling Commission (AEWC), the Indigenous Peoples Council for Marine Mammals (IPCoMM), and with the Tribal Councils of Gambell and Savoonga on St. Lawrence Island. One result of these meetings was a shift in timing of the ASGARD cruises from May until June as well as a shift in timing and survey regions for the Arctic IES cruises, to avoid conflicts with subsistence hunting activities during what is traditionally the time for walrus hunting. Another result was the creation of communication protocols to avoid conflicts by alerting coastal communities to the presence of research vessels and adjusting the ships' routes to avoid areas where hunting was taking place. These communication protocols included regular radio broadcasts and daily emails to community members throughout the research area.

Results from the research are published in a growing list of peer-reviewed journal articles, as well as cruise reports that provide contemporary accounts of the cruises, and many social media postings that are available through the NPRB website. Data are publicly available as described below.

Collaborations

The NPRB collaborated and coordinated with several other U.S. agencies and organizations that fund Arctic marine research. NPRB staff worked closely with the U.S. Interagency Arctic Research Policy Committee (IARPC) and the U.S. Arctic Research Commission. As the Arctic IERP was developed, the NPRB secured commitments for collaboration from 22 existing research projects that were detailed in Appendix A of the request for proposals, and made connections with new projects as they were funded.

International researchers also collaborated with the Arctic IERP via the Pacific Arctic Group (PAG), the North Pacific Marine Science Organization (PICES), and the Intergovernmental Consultative Committee (US/Russia - bilateral) as well as collaborations developed by individual investigators. PAG participants, including researchers from Canada, China, Japan, Korea, Russia, and the United States, have coordinated their cruise plans to sample standard stations in the Chukchi and Beaufort Seas termed the Distributed Biological Observatory (DBO). The Arctic IERP contributed to this effort. US-Russian data sharing initiatives were hosted in San Diego in 2016 and Vladivostok in 2017 to promote collaboration and

exchange and to facilitate collaboration and synthesis of data and trends of patterns observed in the US and Russian waters in the northern Bering and Chukchi seas (PICES Press, Volume 26, Issue 1). ICC collaborations and other connections also brought scientists from the Russian Federal Research Institute of Fisheries and Oceanography (VNIRO), the Russian Pacific Scientific Fisheries Research Center (TINRO), and Hokkaido University to the US to participate in the Arctic IES cruises and co-author results. This collaboration is expected to connect research interests within respective EEZs (Russia/US) of the Chukchi Sea.

COVID-19

While the fieldwork of the Arctic IERP was completed before the outbreak of COVID-19, the final meeting of researchers in November 2020 was changed from an in-person event to an online format. Other plans for in-person events, such as meetings in hub communities within the US Arctic region (Nome, Kotzebue, and Utqiaġvik), were cancelled. Laboratory work and some collaborations were postponed or cancelled due to COVID-related restrictions and concerns. The NPRB made supplemental funds available to assist researchers with unanticipated expenses due to the pandemic. The overall productivity of the Arctic IERP was likely not greatly reduced, due both to good fortune in the fieldwork being completed and to the collaborative relationships that had been built or strengthened during the program.

Data Portal

Axiom Data Science, Inc. provided data management support to the Arctic IERP throughout the field program. Axiom staff assisted the scientists in authoring metadata and publishing the datasets to public archives. The data collected by the Arctic IERP are publicly accessible at https://arctic-ierp.dataportal.nprb.org/.

General Introduction

Boreogadus saida, known as the polar cod or as the Arctic cod, is a fish of the cod family Gadidae. The General Introduction and Discussion refer to *B. saida* as the Arctic cod. Individual chapters within the final report may refer to *B. saida* as polar cod or Arctic cod.

Background

The Pacific Arctic Region (PAR) is experiencing significant warming and extremes in seasonal sea ice extent and thickness (Frey et al. 2014). Over the past decade, record summer sea ice minima (2007, 2011, 2012) have occurred and climate models predict that the southern Chukchi Sea will be sea ice free for 5 months (July to November) within a decade or two (Overland et al. 2014). The impact of loss of summer sea ice on the PAR ecosystem is not fully understood, but a longer period of open water during summer is expected to increase primary production (Arrigo and van Dijken 2011) and, in addition to potential transport of additional heat from southern seas, is expected to increase summer sea temperatures by 4 to 8°C by the end of the century (Mahlstein and Knutti 2011). These shifts to the PAR ecosystem are likely to have large impacts on the ecology of upper trophic level species (UTL, fishes, birds, and mammals; see Sigler et al. 2011). For instance, the community structure of some UTL already show evidence of changes in the Chukchi Sea, such as the shift from predominantly piscivorous seabirds to planktivorous seabirds in recent decades (Gall et al. 2017). Other ecosystem consequences of continued warming have been described for the Barents Sea and include changes in zooplankton community structure as well as shifts in species distributions and relative abundance (Hop and Gjosaeter 2013; Orlova et al. 2013; Fossheim et al. 2015).

Arctic fishes such as Arctic cod (*Boreogadus saida*) and saffron cod (*Eleginus gracilis*) are key components of the PAR food web (Lowry and Frost 1981, Welch et al. 1992) and contribute to supporting large numbers of seabirds (Matley et al. 2012) and marine mammals (Bradstreet et al. 1986; Holst et al. 2001) which migrate to the Arctic to take advantage of high seasonal production. Arctic cod are particularly abundant in the PAR (see Moore et al. (2014) and references therein) and along with snow crab and saffron cod, are recognized as potential target species for new fisheries in this region (Arctic Fishery Management Plan 2009). We expect continued loss of sea ice and continued warming in the PAR to restructure the food web, negatively impacting Arctic cod growth and survival (Laurel et al. 2015), an important prey for seabirds and marine mammals (Welch et al. 1992; Holst et al. 2001; Matley et al. 2012). For instance, age-0 Arctic cod have a low thermal tolerance (< 7°C) for growth and survival; whereas saffron cod have a much wider tolerance and are expected to thrive at higher temperatures (Laurel et al. 2015). Age-0 Arctic cod have 2.7 times more lipid per unit body mass than Age-0 saffron cod (Ron Heintz, personal communication). We therefore hypothesize (H1) that within two to three decades, the Chukchi Sea shelf will experience a reduction in lipid-rich prey (Arctic cod) with negative consequences to other fishes and post-breeding seabirds, similar to that experienced by walleye pollock (Heintz et al. 2013) and Pacific cod (Farley et al. 2014) in the southeastern Bering Sea during a recent warming event (see Coyle et al. 2011).

Arctic Ecosystem Integrated Surveys (Arctic EIS) during late summer and fall 2012 and 2013 found high densities of age-0 Arctic cod in the northern Chukchi Sea (Fig. 1), but relatively few age 1+ fish (De Robertis et al. 2016, Goddard et al. 2014) suggesting this region may be an important nursery ground to examine climate impacts on the ecology of these age-0 fish. The distributions of age-0 Arctic cod were largely confined to the northern region of the Chukchi Sea in both years. Within the northern region of the Chukchi Sea, age-0 Arctic cod were three times more abundant and their distribution extended farther south in 2013 than during 2012 (Fig. 1, De Robertis et al. 2016). This observation was consistent with interannual differences in ocean currents and plankton populations during this period. For example, the Alaska Coastal Current was weaker and there was more "Chukchi winter and ice melt water" on the northern shelf in summer 2013, which was associated with less zooplankton of Pacific origin and lower

Chl *a* concentrations and a shift to larger cell sizes in 2013 (Danielson et al. 2016, Pinchuk and Eisner 2016). Additionally, drifters placed in areas of high age-0 Arctic cod abundance were advected off the shelf in 2012 but not in 2013 (Danielson et al. 2016), indicating potential fish transport to different areas. Together, these observations suggest there is much to be learned regarding mechanisms of dispersal to other areas of the Arctic and associated population dynamics of this species in this region of the Arctic (H2).

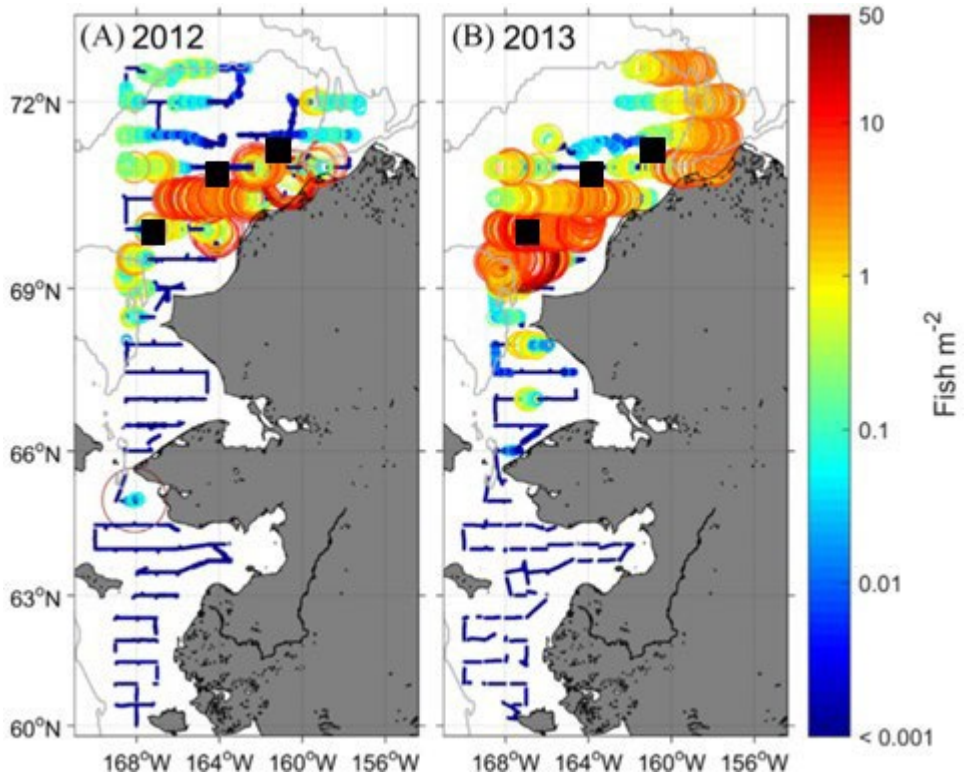

Figure 1. Density of Arctic cod blue to red represents increasing density) estimated by acoustic-trawl methods in A) 2012 and B) 2013. Fish are almost all age-0 except for an aggregation south of Bering Strait in 2012. The locations of the echosounder moorings deployed as part of the AIERP program are represented by the black squares.

In addition, we hypothesize that continued warming of surface temperatures will increase the likelihood of salmon production in the Arctic (H3). During 2007, summer sea temperatures in the Chukchi Sea were anomalously warm (Eisner et al. 2013). BASIS surveys conducted in the Arctic during 2007 documented relatively high abundances of juvenile pink and chum salmon in the Chukchi Sea (Moss et al. 2009). The abundant juvenile salmon returned as adults to the coastal regions of the PAR in relatively high numbers during 2008 (pink salmon) and 2009/10 (chum salmon) as reported by subsistence users in coastal communities (Carothers et al. 2013; Taquilik Hepa, personal communication). These events (anomalously warm summer sea temperatures, historic summer sea ice minima, and highly abundant juvenile pink and chum salmon in the Chukchi Sea) were all "surprises" in that they were large variations from predicted anthropogenic effects on temperatures and sea ice loss from climate models (Overland 2011). We hypothesize that these "surprises" will become the norm in the not too distant future and while the presence of maturing salmon in Arctic waters north of known salmon producing drainages likely reflects

straying and not colonization (Stephenson 2006), continued warming in marine, terrestrial and riverine environments may make it possible for these salmon to become permanently established in the Arctic.

It is also highly likely that climate warming in the Arctic will impact the abundance and distribution of seabird species. Seabird distribution is often influenced by oceanographic characteristics that promote productivity and concentrate prey (Piatt et al. 1991; Gall et al. 2013). In the Chukchi Sea, 'hotspots' of seabird abundance varied among foraging guilds (i.e., surface or diving foragers) and between summer (breeding season) and fall (post-breeding and migration), but were often associated with persistent topographic features such as shelf breaks and underwater canyons (Kuletz et al. 2015). During Arctic EIS, the distribution of planktivorous and piscivorous seabirds reflected the distribution of their prey at broad spatial scales (Arctic EIS reports: see https://web.sfos.uaf.edu/wordpress/arcticeis/). Gall et al. (2017) have also shown a decadal-scale shift from a predominantly piscivorous seabird community to one dominated by planktivores. If warming seas lead to longer ice-free conditions and generally higher productivity, this trend could continue (H4a). However, an alternative hypothesis (H4b) is that these conditions lead to smaller zooplankton and thus less suitable prey to support high densities of planktivorous seabirds, resulting in a shift back towards a predominantly piscivorous seabird community. Furthermore, lack of high-lipid prey (Arctic cod) near breeding colonies could result in low reproductive success and high nutritional stress (see Paredes et al. 2014).

Chapter Content

Each chapter addresses the objectives of the project in relation to the broader hypotheses.

Objective 1: *Quantify the distribution, abundance, and condition of demersal fishes and shellfishes*
Objective 2: *Quantify the distribution, abundance, and condition of pelagic marine fishes, in particular young-of-the-year Arctic gadids and other forage fishes*
Objective 3: *Combine results from previous Arctic surveys (Arctic EIS, Phase 1, BASIS) and planned surveys (Arctic IES Phase 2) to assess variability in pelagic and demersal fish ecology over time relative to ocean conditions.*
Objective 4: *Establish the relative abundance, size, and condition of juvenile salmonids that utilize the coastal regions of the PAR.*
Objective 5: *Further resolve early life history characteristics of Arctic cod and saffron cod and their behavior and connectivity between the Chukchi Sea and western Beaufort Sea.*
Objective 6: *Quantify the distribution, abundance, and prey association of seabirds in the PAR in relation to oceanographic conditions, prey abundance, and feeding guilds.*
Objective 7: *Develop spatially explicit bioenergetics models for Arctic cod and saffron cod as well as for juvenile pink and chum salmon and test the impact of warming summer temperatures on their growth and distribution*

Experimental Design and Methods

We conducted two 65-day integrated ecosystem surveys of the Chukchi and western Beaufort seas during August through early October in 2017 (Fig. 2; see 2017 Cruise Report) and 2019 (Fig. 3; see 2019 Cruise Report). The surveys followed the protocols developed for Arctic EIS (Arctic Ecosystem Integrated Survey 2014) and BASIS (Farley et al. 2005). Sampling was conducted on the R/V OCEAN STARR, capable of deploying bio/physical oceanographic gear (i.e. Arctic IES Phase II LTL), fish trawls (pelagic/surface) and demersal trawls (3-m plumb-staff beam trawl). Acoustic measurements along survey transects (gridded regions from east to west) along with modified Marinovich midwater trawl samples were used to estimate the distribution and abundance of midwater young-of-the-year cods and other forage fishes in the survey area. Surface trawls (Cantrawl 400/600) were used at nearshore stations to assess juvenile salmon. Demersal trawls (3-m plumb-staff beam trawl (PSBT)) were utilized along

gridded stations to assess older age classes of Arctic cod and crab. Oceanography and plankton sampling was coordinated with the Arctic Integrated Ecosystem Survey Phase II LTL team.

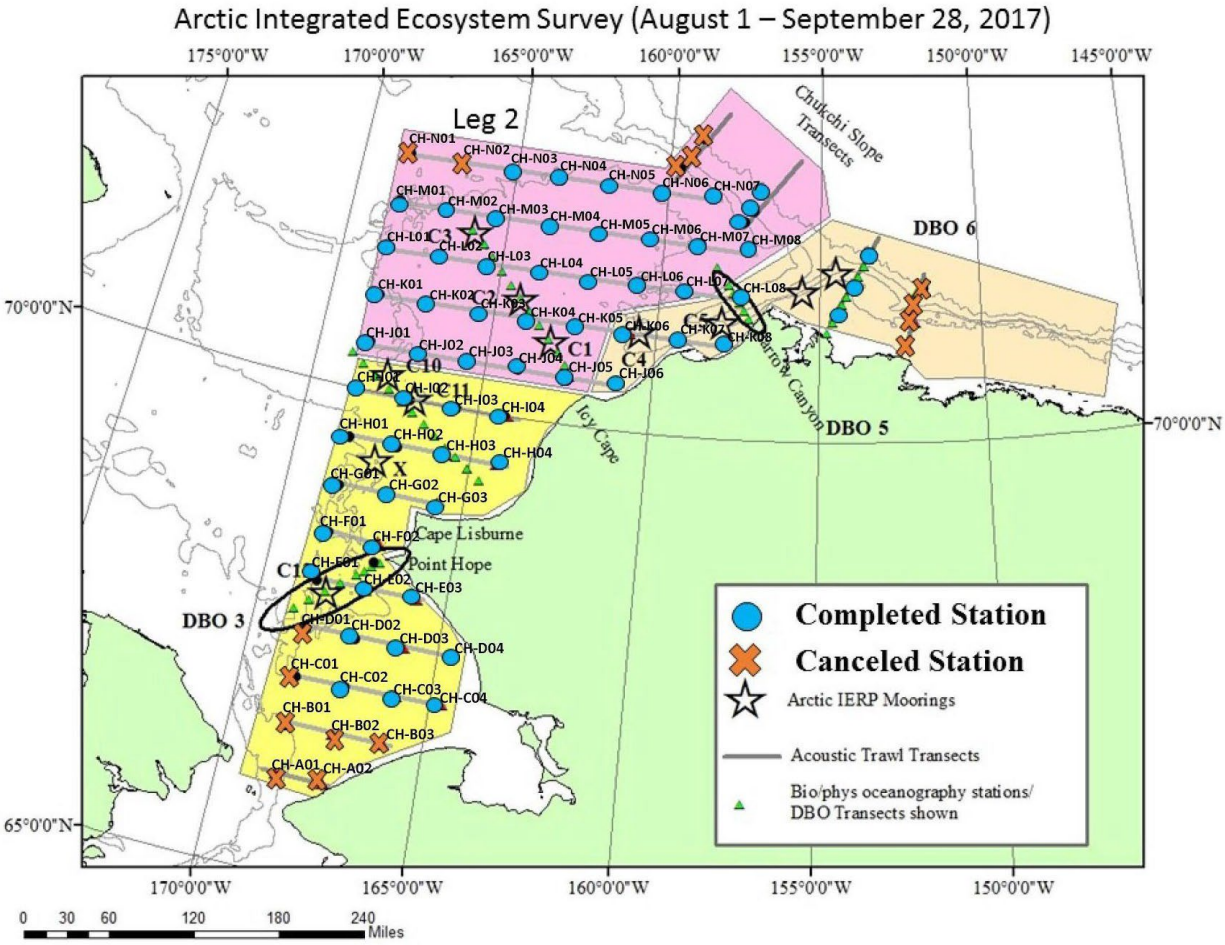

Figure 2. Research survey stations (blue dots -completed; orange crosses -canceled), acoustic transects (grey lines), oceanographic transects (green triangles), and moorings (black stars) for the Arctic Integrated Ecosystem Survey on board the Research Vessel, **OCEAN STARR** during August - October 2017.

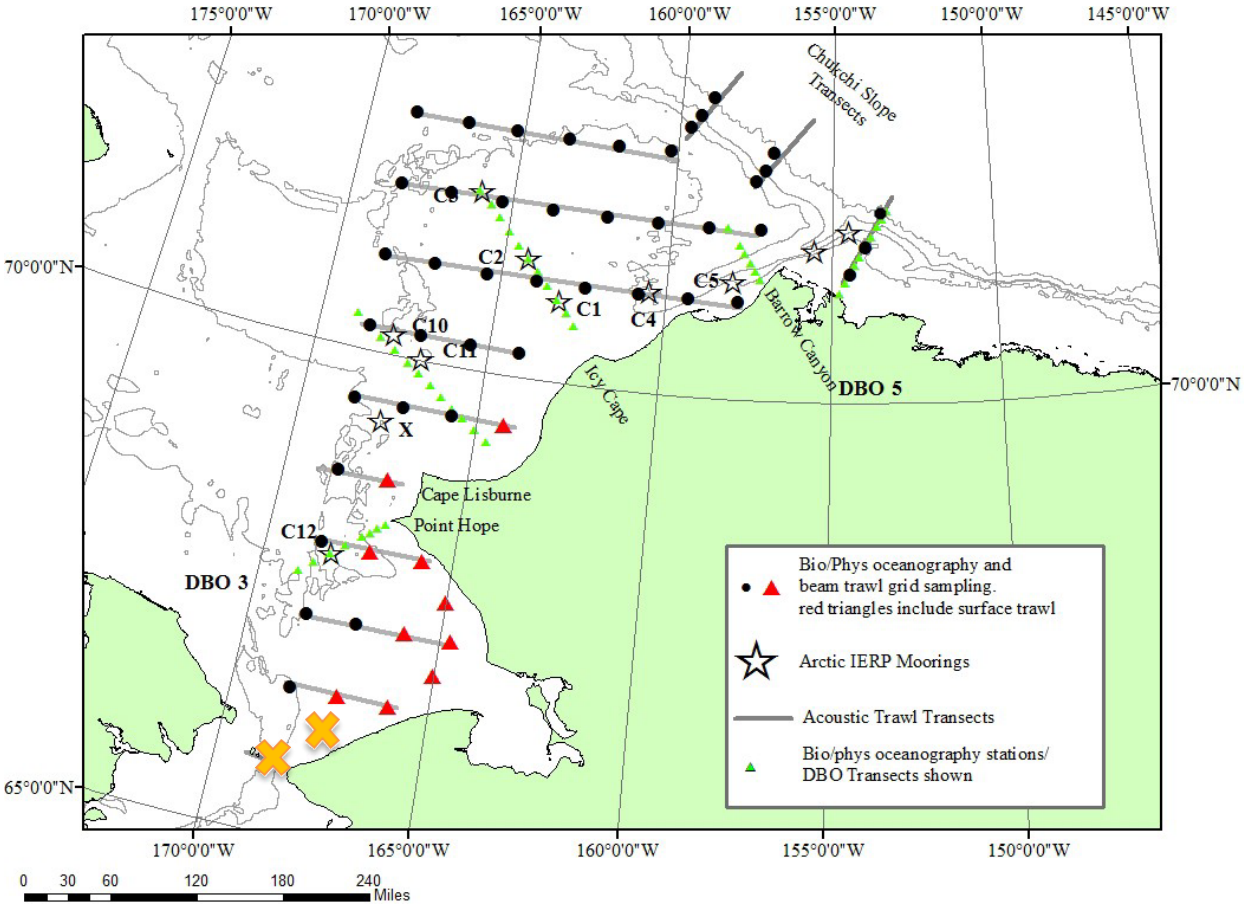

Figure 3. Research survey stations (black dots and red triangles), moorings (stars), oceanographic transects (green diamonds), and acoustic transects (grey lines) for the August 1 to October 4, 2019 Arctic Integrated Ecosystem Survey (Arctic IES) on board the Research Vessel, **OCEAN STARR**. Two stations were canceled (orange cross) due to weather.

General Discussion

The overall goal of this Upper Trophic Level (UTL) project was to better understand the mechanisms and processes that structure the ecosystem and influence the distribution, abundance, and life history of lower (phytoplankton, zooplankton) and upper trophic species (fishes, seabirds, mammals), and their potential vulnerability to rapidly changing marine Arctic environments. This approach was outlined in Moore et al. (2014) whereby fishes, seabirds, and mammals (UTL) respond to biological and physical changes in the ecosystem and thus serve as sentinels producing a continued record of ecosystem response to rapid climate change in the Pacific Arctic Region. The results of the UTL research were directly linked with results from the Lower Trophic Level (LTL) research that examined the climatological, physical, chemical and biological processes influencing the flow of energy from primary producers to zooplankton and ichthyoplankton in the Chukchi Sea and how a warming climate will influence these processes.

During current AIERP surveys, we tested how sampling gear types and survey designs affected the catchability and selectivity of different species and sizes to better understand sampling bias for small fishes and biodiversity measures (Chapters 7, 10 and 12). A correction to estimates of size and species selectivity of two survey trawls was determined necessary. The primary application of the new selectivity relationships was to estimate selectivity-corrected species and size distributions from trawl catches to decrease uncertainty in acoustic-trawl abundance estimates and allow for interannual comparisons. A case study to examine the power to detect changes in diversity of the demersal fish community found no apparent bias in diversity estimates for reduced survey designs, including those with spatially restricted sampling, but substantial increases in uncertainty was found as sample sizes decrease. In contrast, most of the sampling designs (such as Arctic IES) had substantial power for detecting changes in abundance of common species.

To address our overall goal and objectives, scientific analyses were structured around four major hypotheses, which are discussed separately below.

H1: Cods in the Arctic - *Loss of sea ice and continued warming of sea temperatures during summer in the Chukchi Sea will restructure the food web, decreasing the amount of fat and energy available to higher trophic level predators.*

Data from laboratory thermal experiments combined with evidence of declining lipid storage during warming ocean events in the central Chukchi Sea suggest that the southern and central Chukchi Sea regions are warming beyond the thermal limits of Arctic cod (Chapter 8 & 11). Age-0 cod survived the longest at -1 ℃ (~150 days) with reduced survival times measured with increasing temperatures up to the lowest survival duration at 5 ℃ (~90 days).

Increased ocean temperatures are affecting North Pacific fish both via direct thermal effects on their physiology as well as through indirect changes to available food quality and quantity (Chapter 11). During 2017 and 2019, the Chukchi Sea was nearly 4°C warmer than the previous 30-year average. The effect of anomalous warming on the energetic status of Arctic gadids was apparent. Juvenile Arctic cod at the end of the warm (2017) summer season had roughly half the fat storage and lower overall energy content than those collected during colder years (2012/2013). Similarly, saffron cod, capelin and sand lance had slightly lower energy content in warmer years. During 2017 both Arctic cod and saffron cod showed decreased lipid storage compared to fish from 2013 and 2012, respectively. This reduction in total lipid, triacylglycerols and diatom- and *Calanus*-sourced fatty acids was particularly significant in Arctic cod collected over the central Chukchi shelf in 2017.

This project documented a dramatic recent shift in the species composition of age-0 gadids, with age-0 pollock colonizing the Chukchi shelf in the most recent survey years (Chapters 4 and 6). Late summer surveys in the Chukchi Sea during 2012, 2013, 2017 and 2019 indicate that Age-0 Arctic cod were the

most abundant pelagic fish in all four survey years. However, age-0 walleye pollock (*Gadus chalcogrammus*) were present at high abundance throughout the Chukchi shelf in 2017 and 2019 and were the most abundant pelagic fishes in many areas (Chapter 6). In contrast, pollock were scarce and confined to the southern Chukchi Sea in the 2005, 2012 and 2013 surveys. Age-0 Arctic cod were substantially more abundant in 2017 than in any other year. This was possibly due to increased survivorship of larvae under warming conditions. However, given their poor body condition, these fish may have had poor over-winter survival following their first summer. Arctic cod and pollock were spatially separated in 2019, with Arctic cod primarily present in the northeastern portion of the survey area, which was characterized by cooler surface and bottom temperatures. The substantial increase in age-0 pollock in recent years suggests that environmental conditions now allow this species to extend its northern range into the central and southern Chukchi Sea, at least on a seasonal basis. The increased supply of juvenile pollock onto the Chukchi shelf may be linked to the high abundance of adult pollock in the northern Bering Sea in recent years, as well as increased flow through the Bering Strait. We hypothesize that the changes in abundance and species composition based on our 2012-2019 time series are tightly coupled to recent changes in temperature and the transport of Bering Sea waters onto the Chukchi shelf as reductions in sea ice and increases in warming and transport during 2017 and 2019 led to an increase in Pacific-origin waters on the Chukchi shelf in summer.

Survey data also indicated that Age-0 juvenile gadids showed interspecific differences in the spatial distribution of high condition individuals, with Arctic cod showing the highest lipid-based condition in the northern ice-associated region of Hanna Shoal (Chapter 11). In 2019, Arctic cod were only present in the northern Chukchi Sea but maintained a higher region-specific lipid storage than measured in 2017. Age-1 Pacific cod were observed in the western Chukchi Sea in 2018 and 2019, indicating possible overwinter survival of age-0 fish, although there was little evidence that they survive and/or remain in the Chukchi Sea to age-2 (Chapter 13). Low lipid storage of both walleye pollock and Pacific cod juveniles (Chapter 11 & 13) compared to published reports from the Gulf of Alaska and Bering Sea, make it implausible that 'boreal' gadids are successfully surviving winter on the Chukchi Shelf. If lower-fat fish such as walleye pollock or Pacific cod displace Arctic cod, Arctic predators will need to consume more fish to meet their energy requirements.

One of our objectives was to understand how warming sea temperatures and loss of seasonal sea ice may impact the epibenthic invertebrate community (Chapters 1 - 3). Survey data were used to determine "preferred" bottom temperatures for all taxa; modeled projections of bottom temperatures to mid-century and beyond in these regions were used to determine potential habitat gain or loss. The analysis indicated that by mid-century (2050) there will be a 50% decrease in suitable thermal habitat for many invertebrate species as the best thermal habitats contracted northward. By the end of the century (2100), projections indicate very little thermal habitat for almost all invertebrate species, except basketstars, assuming that most invertebrates cannot adapt to the pace of warming. Other data summaries and modeling suggest that larval snow crab are both advected from the northern Bering Sea and are also supplied by mature adults within the Chukchi or Beaufort seas. Warmer sea temperatures are accelerating either pelagic larval development or adult spawning and hatching times. However, sea temperature fluctuations (modeled) had limited influence on adolescent snow crab habitat suitability, whereas mature male snow crab were the most sensitive to changes in temperature.

H2: Cod habitat in the Arctic: *The northern Chukchi serves as a nursery area for young-of-the-year Arctic cod, supplying juveniles to other areas of the Arctic.*

Our project provided critical information on the early life history of Arctic cod through examination of their otoliths, modeling efforts, seasonal and time/space scale observations, and observations through late summer survey efforts. Trace elemental concentrations revealed at least two hatching populations based on significant differences in five of the eight trace elemental ratios from the eastern Beaufort Sea and

samples from the western regions (Chapter 19). Differences in trace elemental ratios indicated that Arctic cod from the eastern Beaufort Sea hatched in less saline waters than those from the western regions, possibly a result of hatching within the relatively fresh Mackenzie River plume (Chapter 20). Some samples from the northern Chukchi Sea had elevated levels of Zinc near the hatch mark, which could be due to hatching in Kotzebue Sound, where Zinc concentrations may be naturally elevated or as a result of mining. Estimated hatch dates ranged widely from November to July with peak hatching occurring from February through May depending on the region of capture (Chapter 19). We also identified a clear separation of hatch dates between spring- and summer-caught Arctic cod, suggesting different origins or strong size-dependent mortality. Finally, differences in hatch dates between pelagic and demersal juveniles support the settlement of older, larger juveniles to deeper shelf seafloor habitats in late summer.

A biophysical transport model coupled to a Pan-Arctic hydrodynamic ocean circulation model revealed potential spawning locations and regional connectivity between the northern Bering, Chukchi, and Beaufort Seas (Chapter 18). Analyses of simulated growth and transport models of newly hatched Arctic cod and saffron cod larvae identified species-specific differences in dispersal trajectories, despite similar hatch times and locations used in the model. Strong interannual variability in growth and dispersal was linked to several global-scale climate indices, suggesting that larval growth and transport may be sensitive to environmental perturbations. The model results show that Arctic cod spawned in the northern Chukchi Sea may be an important source of larvae for the Beaufort Sea and Arctic Basin, while observed larval aggregations in the Chukchi Sea likely originated in the northern Bering and southern Chukchi seas.

To determine seasonal movement and variability of age-0 gadids, bottom-moored multifrequency echosounders were deployed at three locations in the northeastern Chukchi Sea from 2017-2019 (Chapter 16). These observations indicate that the abundance and composition of the pelagic community on the Chukchi Sea shelf is highly variable over seasonal time scales. Fish abundance was very low in winter, increased in May, and reached peak abundance in late summer. Target strength and diel vertical migration of fishes increased in summer, indicating that this is a key period of growth for Arctic gadids. Tracking of acoustic targets indicates that age-0 gadids were displaced to the northeast, consistent with the dominant advection on the shelf. Fish speeds and headings were strongly correlated with local currents, providing evidence that these small age-0 fishes are primarily being passively transported and behavior plays a limited role in population distribution. Occasional reversals of fish transport were observed: when winds blow strongly towards the south, a reversal is seen in both current flow and fish tracks, with a higher proportion of fishes moving to the south and west.

Acoustic surveys with saildrone autonomous surface vehicles equipped with echosounders throughout summer 2018 provide further evidence that juvenile gadids are likely spawned in the south, are retained on the Chukchi shelf in summer, and are ultimately advected nortwards off the Chukchi shelf break in fall (Chapter 17). A subarea of the central Chukchi Sea was surveyed a total of four times in a single season; acoustic backscatter, a proxy for fish density, in this subarea increased by > 85% from late-July to mid-September. As summer progressed, fish developed more extensive diel vertical migrations and backscatter from individuals doubled. Both changes suggest that the observed increase in backscatter was driven primarily by increasing body size (i.e. individual growth) rather than changes in abundance. Across the survey area, backscatter was highest in regions with sea surface temperatures of 6-8 C, and lowest in areas influenced by recent ice melt. Particle tracking simulations indicated age-0 gadids were likely retained over the Chukchi shelf by extended periods of wind-driven southward flow during the survey period before strong northward flow in late fall transported them to the north. These findings suggest that in summer 2018, age-0 gadids were advected northward to the Chukchi shelf from the northern Bering Sea, where they were retained during a period of growth until late fall before being advected farther north toward the Chukchi and Beaufort shelf breaks.

Pelagic habitat requirements of Arctic larval fishes (including Arctic cod) and the effects of interannual variability of ocean conditions on their distribution was also investigated (Chapter 5). There was no significant difference in larval fish distribution among the two years examined (2012 and 2013), despite marked changes in annual water mass characteristics. In both years, larval Arctic cod were found in cold, high salinity water masses that contained higher biomass of large copepods. These large copepods are high in fat content (Chapter 9) providing high quality prey to larval Arctic cod and other larval fishes in the Chukchi Sea. In addition, a model for growth rate potential of Arctic cod indicated that temperature and food availability conferred by specific water masses was conducive to their growth (Chapter 23).

H3: Salmon expansion into a warming Arctic: *Summer surface waters in the northeastern Bering Sea will continue to warm and be a source of heat advected to the Pacific Arctic Region, providing new marine habitat for juvenile salmon.*

A multi-disciplinary research survey within the northern Bering Sea (NBS) has supported annual sampling (2002 to present) of the inner domain (bottom depths generally less than 55 m) during late summer (late August to late September) from 60°N to 66.5°N (Chapter 15). Oceanographic measurements within the NBS reveal that average annual sea surface temperature (SST, 11.5°C, upper 10 m) was warmest from 2014 to the present with 2019 being the warmest on record. In general, the catch per unit effort of juvenile pink, sockeye, and coho salmon were positively related to summer sea surface temperatures. This relationship likely reflects the influence of temperature on the distribution (e.g. Bristol Bay juvenile sockeye salmon (*O. nerka*), $\rho = 0.9$) and survival (e.g. juvenile coho salmon (*O. kisutch*), $\rho = 0.7$) of these juvenile salmon species.

Life-cycle models (adult return and escapement) of pink salmon (*Oncorhynchus gorbuscha*) reveal a lack of density-dependence for adult pink salmon spawners in the Yukon River and potential for some density-dependence for adult pink salmon spawners in the Norton Sound region (Chapter 14). Life-history (freshwater and early marine) models identify a positive and significant relationship between the abundance index for juvenile pink salmon and average Nome air temperature during their freshwater residency (August to June). This relationship supports the notion that warming air temperatures in this region (as a proxy for river and stream temperatures) are contributing to improved freshwater survival or increased capacity of freshwater habitats to support pink salmon production. Life-history models also show that the number of adult pink salmon returning to Norton Sound and the Yukon River is significantly related to the juvenile abundance in the northern Bering Sea. This result indicates that much of the variability in survival for northern Bering Sea pink salmon occurs during early life-history stages and that juvenile abundance is an informative leading indicator of pink salmon runs to this region.

A spatially explicit bioenergetics model was used to estimate the growth rate potential (GRP; %body weight per day) of juvenile chum salmon in the northern Bering and Chukchi seas (Chapter 22). Annual averages of GRP ranged from a low of 0.9 (2003) to a high of 12.3 (2007) in the northern Bering Sea and from 0.1 (2003) to 39.3 (2007) in the Chukchi Sea. Juvenile chum salmon were generally not distributed in regions of higher GRP with the exception being 2007 within the Chukchi Sea. There was a significant positive relationship between average seasonal transport through the Bering Strait and juvenile chum salmon GRP, suggesting summer transport of heat (and likely pelagic prey) improves early marine growth potential for juvenile chum salmon in the southern Chukchi Sea region. The year 2007 stands out as an anomaly within the 18 year time series with the highest GRP and catch per unit effort of juvenile chum salmon in both regions.

H4: Seabird community structure and seabird-prey dynamics: *The current predominance of planktivorous seabirds in the Arctic may shift back towards piscivorous seabirds, if warming sea temperatures restructure the food web*.

Recent loss of sea ice and warmer ocean temperatures could impact seabirds directly (due to lack of prey or lower quality prey) and indirectly (if low-quality zooplankton reduces forage fish availability; Chapter 21). In the northern Bering Sea and eastern Chukchi Sea, 2017-2019 were record-breaking years for warm ocean temperatures and lack of sea ice. The region supports millions of seabirds that could be affected by shifts in prey distribution and availability caused by changing environmental drivers. However, seabirds are highly mobile and often flexible in diet, and might alter their foraging distributions accordingly. To determine if there was evidence of long-term changes in abundance of seabirds, or if seabirds used the offshore habitat differently during recent warm years, we compared species richness, community composition, and distribution and abundance of selected species and all seabirds between two periods, 2007-2016 and 2017-2019. We also evaluated annual changes in abundance during 2007-2019. We used 79,426 km of transects from vessel-based surveys conducted July through September.

Total seabird density for the entire study area increased by ~20% during 2017-2019, but changes were not consistent across the study area, nor among species, and species richness declined except for a slight increase in the northern Chukchi Sea (Chapter 21). Total seabird density declined most in the northern Bering Sea (-27%), although it increased in the Chirikov Basin. During 2017-2019, abundance of piscivorous murres (*Uria* spp.) decreased everywhere, whereas planktivorous *Aethia* auklet density increased by 70% in Chirikov Basin; auklets apparently abandoned their post-breeding migration to the Chukchi Sea. Short-tailed shearwaters (*Ardenna tenuirostris*) expanded farther into the northern Chukchi Sea, with nearly twice the density of the previous decade. We identified five seabird community types, three of which (all dominated by an alcid species) contracted spatially in the later period, and shifted south or near colonies. In contrast, a short-tailed shearwater-dominated community expanded northward, and a community defined by low seabird density expanded throughout the eastern portion of both the northern Bering and Chukchi Seas, suggesting higher-density communities had shifted westward.

The retraction of the auklet community from the Chukchi Sea to the northern Bering Sea during the warm years of 2017-2019 was consistent with the hypothesized shift back to a piscivorous seabird community, although further monitoring would be required to determine if that trend continues. However, the increase in abundance and northward movement of short-tailed shearwaters, which often consume primarily euphausiids, appears to contradict the hypothesis. This shearwater is an omnivore and consumes small fish, fish larvae, and cephalopods, thus its diet is more plastic than that of the least and crested auklets. In addition, the Lisburne seabird colony monitored by the Alaska Maritime National Wildlife Refuge continues to show increases in numbers of nesting murres and kittiwakes, which are piscivores. Thus the shift southwards of auklets (strictly planktivorous), continuous presence of omnivorous shearwaters, and growing colonies of piscivorous seabirds, together provide correlative support for the hypothesis that continued warming could shift the seabird community of the Chukchi Sea back to a predominance of piscivorous, or at least omnivorous species.

Application to Resource Management and Alaska Communities

Recognizing the potential for commercial fishing activities to expand into the northern Bering Sea and the Arctic, and the lack of baseline information from these areas, the North Pacific Fishery Management Council (NPFMC) has taken several proactive measures to prevent the northward expansion of commercial fishing without prior assessment of fisheries resources. These measures include a ban on non-pelagic trawling in the Northern Bering Sea Research Area until a research plan can be developed and a ban on all commercial fishing in the US Exclusive Economic Zone of the Arctic under the Arctic Fishery Management Plan (FMP, https://www.npfmc.org/arctic-fishery-management/). Implementation of the FMP requires baseline surveys to assess the status of fisheries resources in the Arctic. Information on fish populations collected by this and other projects are critical to informing the NPFMC about the status of fish stocks in the Chukchi Sea and environmental mechanisms underpinning variation in their populations. The Arctic FMP identifies Arctic cod (*Boreogadus saida*), saffron cod (*Eleginus gracilis*) and snow crab (*Chionoecetes opilio*) as potential target species in the Chukchi Sea. An important and required element of any FMP is a description of Essential Fish Habitat (EFH) for each target species in the FMP. Data collected during our surveys already contribute to updating EFH descriptions for the three species named in the Arctic FMP using the best available scientific information.

Together, the LTL and UTL components provide a comprehensive view of the ecosystem and provide clarity on the changing ecosystem for resource managers and Alaskan communities. The LTL program found that there is an increased transport and heat flux into the Arctic basin, substantial interannual variability in the amount of nutrients available to sustain spring production, and that warming will increase the spatial extent of picocyanobacteria Synechococcus, a smaller less energy-rich phytoplankton that will negatively impact the flow of energy to higher trophic levels. There appear to be concomitant reductions in larger sized zooplankton, reducing the amount of prey available for larger, pelagic predators such as bowhead whales and seabirds. There will be winners and losers in the Arctic fishes as climate-driven distribution shifts are restructuring larval fish community composition and bioenergetic pathways that will influence the flow of energy to higher trophic levels. This will have cascading consequences for upper trophic level production that provides the basis for commercial fishing communities, and for local communities in the Arctic that rely on fishes, seabirds and marine mammals for food.

The UTL Arctic Integrated Ecosystem Surveys provide further information on the impact of climate variability on ecosystem function and fitness of fishes and invertebrates. During the research period (2016 to 2021), adult subarctic gadids moved into the northern Bering Sea in large numbers. Commercial fishing for Pacific cod (using longline) commenced within the northern Bering Sea and in Russia's exclusive economic zone in the Chukchi Sea. However, we did not find large numbers of adults of either subarctic or Arctic gadids (Arctic cod and saffron cod) within the Chukchi Sea survey region. We did find large numbers of age-0 Arctic cod and saffron cod as well as age-0 subarctic gadids (walleye pollock) within the southern Chukchi Sea region. Pollock were largely absent in previous surveys of the same area in 2005, 2012 and 2013, but were the most abundant pelagic fishes in many areas in 2017 and 2019. In 2019, age-0 Arctic cod were found further north in the survey region than was reported during earlier surveys (Arctic EIS 2012 and 2013). In addition, we found that warming ocean temperatures and increased transport during summer months through the Bering Strait improves habitat quality for juvenile salmon within the southern Chukchi Sea. These changes are related to faster early marine growth and survival of young salmon, potentially leading to higher numbers of adult salmon returns to the Arctic.

Prey quality is likely an important consideration: for example, age-0 Arctic cod are more lipid-rich and energy-dense than walleye pollock. Additionally, environmental factors are likely to play an important role in food quality: although juvenile Arctic cod were very abundant at the end of the warm (2017) summer season, they had only half the fat storage and lower overall energy content than those collected during colder years (2012/2013). Similarly, saffron cod, capelin and sand lance had slightly lower energy content in warmer years. These changes in the distribution of abundant age-0 pelagic fishes are consistent with expectations under continued warming, and will likely continue as the Alaska Arctic continues to

warm. These changes in the abundance, distribution and lipid content of small fishes are likely to impact food availability and quality for higher trophic level predators (piscivorous fishes, marine mammals, and birds) and for communities who depend on these food sources. For example, piscivorous seabirds require forage fish of high energy density to raise chicks to fledging during the short Arctic summer. Low quality prey can significantly increase the number of fish needed to raise chicks, increasing foraging effort and extending the chick-rearing period. Late fledging dates and low fledgling weight can reduce overwinter survival. Low recruitment in harvestable seabirds can impact the ability of local communities to gather eggs and adult birds.

In response to changes in prey, some seabirds, such as short-tailed shearwaters and thick-billed murres, have shifted their distribution farther north, and are remaining in the Arctic later into summer or fall, but they must still return south through the Bering Strait. Other marine birds, such as eiders, maintain the timing of their post-breeding southward migration through the Bering Strait region. Due to lack of sea ice, these southward migration patterns now overlap with increased vessel traffic during months of nighttime darkness, potentially resulting in higher risk of vessel-bird collisions. The new overlap of human activities during fall migration of marine birds could pose challenges to bird conservation and to management of vessel traffic lanes throughout the region.

Our results from the Arctic Integrated Ecosystem Survey indicate that our overarching hypothesis:

Reductions in Arctic sea ice and the associated physical changes to the environment influence the flow of energy through the pelagic ecosystem in the Chukchi Sea. Specifically, we expect lasting changes in the seasonal composition, distribution and production of phytoplankton; in the distribution and standing stocks of large crustacean zooplankton that serve as the prey base for upper trophic level fishes and seabirds; in the assemblages, distributions, abundances, and body condition of larval and early juvenile fishes that influence the recruitment success of later life stages, and in the distribution and abundance of adult fishes

is being realized.

Directions for Future Research

Through the combined LTL-UTL AIERP programs, key elements were identified for future research including maintaining long-term observations, incorporating new measurements into the observational programs, enhanced modeling of the region, and operationalizing new technologies. To further advance our understanding of ecosystem variability and climate-induced trends, we recommend the following elements for future research.

Monitoring - To establish baselines that will enable the assessment of trends and variability, we recommend the following activities be continued:

- Maintain moored observatories at key physical (e.g., Icy Cape, M8, C12,) and biological (e.g., C12) hot spots;
- Maintain hydrographic and zooplankton sampling transects (e.g., DBO, Icy Cape) and surveys (e.g., Northern Bering Sea Assessment);
- Continue planktonic monitoring to track ecosystem changes of phytoplankton, zooplankton and ichthyoplankton;
- Continue acoustics surveys and time series of fish as subarctic gadids begin moving into the Chukchi Sea.
- Maintain seabird observations on platforms of opportunity.
- Continue benthic sampling for fishes and invertebrates.

Expanding Observations - To address gaps exposed through this research and other program, we recommend the following:

- Expand the M8, M14, and C12 observatories with traditional (e.g., sediment traps, nitrate sensors, water samplers, eDNA samplers) and new (e.g., RISe profilers, imaging systems) technologies;
- Expand CTD, zooplankton, and fish (ichthyoplankton, juvenile, and adult stages) surveys to the Chukchi and Beaufort shelf break and western Beaufort Shelf;
- Measure taxon-specific grazing (e.g., grazing on *Synechococcus*) to determine if seasonal variability in growth is due to bottom-up (e.g., warming) or top-down control;
- Measure contributions of the pico fraction, nano-fraction and microplankton fraction to phytoplankton biomass (Chla) and productivity;
- Expand otolith-derived aging and microchemistry of early-stage fish species to enhance our understanding of habitat use, model parameterization, and energy allocation.

Modeling - To provide insights into biophysical processes and ecosystem trends and variability on spatiotemporal scales that cannot be realized through observational programs, we recommend the following:

- Enhance the ROMS based biophysical modeling suite while transitioning to regional MOM6;
- Validate and improve existing models using observational data from the Arctic IES;
- Assimilate observational data through targeted modeling sensitivity experiments;
- Use the modeling suite to understand mechanistic linkages within the biophysical system and align with the Synthesis, Analysis and Products listed below (e.g., quantify the transport of heat/salt, quantify drivers of nutrient flux, quantify extreme events);
- Integrate ROMS/MOM6 LTL modeling (up through zooplankton) with the AFSC Alaska Climate Integrated Modeling Project (ACLIM) that addresses marine ecosystem and fishery dynamics, and incorporates fishery economics.

Synthesis, Analysis and Products

- Quantify the transport of heat and salts;
- Quantify the physical and biological drivers of nutrient flux into the Chukchi Sea;

- Synthesize phytoplankton and zooplankton data to connect to other trophic level work including lipids in phyto- and zooplankton, fish distributions in comparison to plankton, kton, and zooplankton relation to seabird distributions;
- Conduct analysis of adult spawning stock biomass and fish egg data to determine if shifts in the distribution of species are due to increased larval transport and/or changes in spawning locations with warming;
- Conduct analyses of benthic-pelagic coupling to understand if a reorganization of the ecosystem in the Northern Bering-Chukchi Seas ecosystem has occurred and what the impact will be on managed and subsistence resources;
- Develop metrics for Arctic ecosystem assessment.

Collaborations - To provide insights on the status of the Arctic ecosystem to stakeholders and the public partnerships and collaborations must be enhanced. We recommend fostering existing collaborations identified in the collaborations section of this report, and enhance collaborations with local communities and international partners (e.g., Canada, Russia).

New technology - To address observational gaps (e.g., seasonal transitions, phytoplankton and zooplankton speciation, under-ice production), we recommend expanded use of new and emerging technologies:

Imaging and Artificial Intelligence (AI)

- Employ phytoplankton imaging/AI on surface vehicles and moorings to derive speciation and identify and quantify species associated with Harmful Algal Blooms;
- Continue picophytoplankton counts to fill the phytoplankton size spectra and align with imaging methods;
- Monitor zooplankton communities using *in-situ* imaging/AI;
- Utilize towed and moored cameras with AI to assess decadal changes in the benthic community (e.g., epifauna, fish).

Platforms

- *RISe* (**R**efloating **I**ce **Se**nsing) is a profiling mooring that submerges when ice arrives and refloats in the spring after ice retreat. The system includes a *Prawler* that moves up and down the mooring line measuring temperature, salinity, chlorophyll, and dissolved oxygen. RISe provides real-time information of the full water column during the entire open water season;
- *Pop-up* floats are deployed in the late summer/fall and rise to the surface under the ice the following spring. It can measure temperature, salinity, oxygen, fluorescence, PAR, and provide images on the seafloor and under ice;
- The MRV Systems *ALAMO* (Air Launched Autonomous Micro-Observer) is an autonomous vertically profiling float that is ice-reinforced for sampling through the winter;
- Benthic platforms (e.g., benthic rover, respirometers, microbial incubator, automated samplers) that can be used to assess shifts in the benthic community, nutrient cycling, and production;
- Optimize the use of *Saildrones* and other uncrewed systems equipped with active acoustics to understand age -0 pelagic fish distributions and biomass.

CHAPTER 1 – Winners and Losers in a Warming Arctic: Potential Habitat Gain and Loss for Epibenthic Invertebrates of the Chukchi and Bering Seas

Objective 1: Quantify the distribution, abundance, and condition of demersal fishes and shellfishes

Elizabeth Logerwell (NOAA), Muyin Wang (PMEL), Lis Jorgensen (IMR), Kimberly Rand (NOAA Affiliate)

Abstract

Our goal was to examine how the epibenthic invertebrate community in the Pacific Arctic Region might be affected by continued increases in ocean temperatures. We used epibenthic invertebrate catch and bottom temperature data collected on groundfish assessment and ecosystem surveys from 2009-2018 in the Bering and Chukchi seas to determine the "preferred" temperature of all taxa. We grouped taxa into five clusters according to their similarity in median temperature and temperature range. We then used an ensemble of eight climate models to project bottom temperature to mid-century and end of the century. Based on these projections, we show how the amount and distribution of cluster-specific thermal habitat might change with ocean warming. We found that by mid-century (2050) there was a 50% decrease in thermal habitat for all clusters except for the most eurythermic cluster, and that thermal habitat contracted to the north. By the end of the century (2100) there was very little thermal habitat for all clusters, except the most eurythermic cluster, and habitat was further contracted to the north. The cold-water and stenothermic cluster, hypothesized to be the most vulnerable to ocean warming, had virtually no projected thermal habitat by the end of the century. These "losers" were primarily gastropods and the mussel *Musculus* sp. These taxa are prey to endangered Pacific walrus (*Odobenus rosmarus*), which is harvested as a food resource in native Alaskan communities; and are prey for commercial groundfishes such as Pacific cod (*Gadus macrocephalus*) and Alaska pollock (*Gadus chalcogrammus*). By 2100 the most eurythermic cluster, hypothesized to be the least vulnerable to warming, had projected suitable thermal habitat throughout most of the Bering and Chukchi Seas, except nearshore coastal regions. The most abundant species of these "winners" was the basketstar *Gorgonocephalus cf. arcticus*. The loss of thermal habitat for all but the "winners" could impact species diversity of the Bering and Chukchi Seas because the "winner" cluster accounted for only 26 taxa or 8% of all taxa observed. Temperature is one determinant of habitat, so a full habitat and ecosystem model is needed to provide more detailed predictions. In addition, more laboratory studies of thermal acclimation potential of Arctic benthic invertebrates are needed. Nonetheless, our results provide the first indications that the epibenthic invertebrate community in the Bering and Chukchi seas, which supports marine mammals, seabirds and human communities, may be seriously impacted by future ocean warming.

Keywords: epibenthic invertebrate community, thermal habitat, climate change, climate projections

Introduction

Loss of sea ice and rise of ocean temperature are impacting Arctic ecosystems around the globe (Huntington et al., 2020; Polyakov et al., 2020; Renaud et al., 2015). Ocean warming has been shown to impact Arctic plankton (Dalpadado et al., 2020; Eisner et al., 2014), fish (Aune et al., 2018; Mueter and Litzow, 2008; Wisz et al., 2015), infaunal invertebrates (Grebmeier, 2012; Solan et al., 2020), seabirds (Gall et al., 2016) and marine mammals (Davis et al., 2020; Laidre et al., 2015). In contrast, the potential impacts of ocean temperature increase on the epibenthic invertebrate community have not been extensively examined. This is a critical knowledge gap because the epibenthic invertebrate community, along with the infauna, supports a number of key upper trophic level predators including commercial groundfish, marine mammals, and seabirds (Bluhm and Gradinger, 2008; Packer et al., 1994; Whitehouse et al., 2017). Arctic native communities depend heavily on many of these predators (cetaceans, pinnipeds,

and sea ducks) for nutrition and for cultural and spiritual fulfillment (Hovelsrud et al., 2008; Huntington et al., 2020).

Despite the critical need to understand the impacts of temperature on epibenthic invertebrates, very few temperature-dependent rate measurements of benthic macrofauna have been made. The physiological capacity of benthic organisms to acclimate or adapt to warming or otherwise changing conditions is also understudied (Pörtner, 2010). A macrophysiological approach can be useful in this situation. Macrophysiology is the study of interpopulation, interspecific and high taxonomic variation in physiological traits over large geographical and temporal timescales. The overall goal of the approach is to understand the reasons for variation in physiological traits and the subsequent ecological implications, particularly in the face of substantial environmental change (Chown et al., 2004).

We took a macrophysiological approach, as described above, to study the potential impacts of ocean warming by using the range of temperatures at which all sampled epibenthic invertebrate taxa over the US Pacific Arctic have been observed over the past decade. We posit that cold-water and stenothermic taxa would be highly susceptible to ocean warming (a.k.a the "losers"), whereas warm-water and eurythermic taxa would be relatively tolerant of warming (a.k.a. the "winners"). Instead of defining taxa *a priori* to be Arctic or boreal, as other investigators have done (Renaud et al., 2015), we used cluster analysis to group taxa by the median and the range of temperatures at which they have been observed. We took advantage of a decade's worth of epibenthic invertebrate catch and temperature data from groundfish assessment surveys (Lauth et al., 2019) and ecosystem surveys of the Bering and Chukchi seas (including the Arctic Ecosystem Integrated Survey and the Arctic Integrated Ecosystem Research Program (Baker et al., 2020; Mueter et al., 2017)). We used an ensemble of eight coupled climate models that participated in the Coupled Model Intercomparison Project Phase 5 (CMIP5) to predict the mean increase in bottom temperature from present to mid-century as well as to the end of the century and calculated the amount and distribution of seafloor thermal habitat (that is, the area within the temperature range of each cluster of taxa). We then discuss the impacts of projected changes in thermal habitat on epibenthic community diversity and Arctic foodwebs.

Methods

The study area for this work encompassed the Bering and Chukchi seas which are seasonally ice-covered shelves (<200 m depth) with currents typically flowing northward due to the difference in sea level between the Pacific and the Arctic (Aagaard et al., 1981). South and north of the shelf breaks are the Aleutian Basin and Central Arctic Ocean, respectively, and the two seas are separated by Bering Strait which is 88 km wide (Fig. 1a). The water masses of the Bering Sea include the nutrient-rich Anadyr Water, Bering Shelf Water, and the comparatively fresh and nutrient-poor Alaska Coastal Water (Coachman, 1986; Danielson et al., 2016). These water masses bring freshwater, nutrients, and organix matter into the Chukchi Sea through Bering Strait (Danielson et al., 2016; Walsh et al., 1989). Near-bottom resident cold and salty water in both the Bering and Chukchi seas is also present, the result of previous winter cooling (Danielson et al., 2016). The Bering Sea is home to some of the most productive and lucrative demersal fisheries in the world. Alaska fisheries as a whole accounted for 57% of the weight and 3% of the ex-vessel value of total U.S. domestic landings in 2020 (Hiatt et al., 2021). In comparison, the Chukchi Sea currently lacks large stocks of commercial groundfish and it is closed to commercial fishing in the US EEZ (North Pacific Fishery Management Council, 2009). There are several human communities that relay on the northern Bering and Chukchi seas for food security through subsistence harvest of marine mammals, fish and seabirds. In addition, the Arctic ecosystem provides these communities with a means for social and cultural expression (Huntington, 2000).

The epibenthic communities of the Bering Sea and Chukchi Sea were sampled during groundfish assessment and ecosystem surveys conducted by National Oceanic and Atmospheric Administration

(NOAA) National Marine Fisheries Service, Alaska Fisheries Science Center (AFSC) (Baker et al., 2020; Lauth, 2011; Lauth et al., 2019; Mueter et al., 2017; Rand et al., 2018). While the Southeast Bering Sea has been surveyed annually for epibenthos since 1975, the other areas were surveyed less often and only since the 2000s. To minimize the effect of long-term trends, catch data were used from surveys from 2009-2018 in the Southeast Bering Sea; 2010 and 2017 in the North Bering Sea; 2012 and 2017 in the Chukchi Sea shelf; and 2013 in the Northeast Chukchi Sea around Barrow Canyon (Fig. 1b). The 83-112 Eastern bottom trawl was used for sampling in all years (Stauffer, 2004), with the exception of the 2017 Chukchi Sea survey which employed a 3-meter plumb staff beam trawl (Abookire and Rose, 2005). For both nets, net mensuration equipment coupled with a GPS feed was used to calculate area swept and catch-per-unit effort (CPUE (kg km^{-2})). Net width was not measured for the beam trawl because the beam keeps the net width constant. Catch was enumerated, weighed, and identified to the lowest taxonomic level feasible on board or from voucher specimens and photographs after the surveys, on land. Catch data of fish were removed before further analysis.

Bottom water temperature data were collected at each trawl station using a Sea-Bird bathythermograph continuous data recorder attached to the headrope of the net. In addition, temperature and salinity with depth were measured with CTDs during the 2012 and 2017 Chukchi Sea surveys. The median temperature at all stations where each invertebrate species (or lowest taxa identified) occurred in the data set was calculated. The temperature range of each taxa was calculated as the 10th and 90th percentiles of temperatures at all stations where it occurred. K-means clustering was used to group taxa by median temperature and range. K-means clustering is a method of vector quantization that partitions n observations into k clusters in which each observation belongs to the cluster with the nearest mean (Bock, 2008). K-means clustering minimizes the within-cluster variances (i. e., the squared Euclidean distances). The number of clusters (k) was chosen as a balance between the number of groups and the variance within groups. Bigger k results in a lower variance to the extreme case of k=n which results in variance of 0. The final k was selected by plotting the variance (sum of squares) within groups by the number of groups and observing the ‘elbow’, or where the slope of the decrease in variance changes from steep to shallow.

The diversity represented by each cluster was assessed by calculating the number of taxa and the percent of all taxa (a.k.a., alpha-diversity). The relative abundance of megabenthic invertebrates in each cluster was calcuated as the mean of the percent CPUE (kg km^{-2}) at all stations, where percent CPUE at each station was calculated as CPUE for each species at that station dividied by total CPUE at that station over all years.

To select climate models for bottom temperature projections, model summer ocean temperature data from Representative Concentration Pathway (RCP) 8.5 scenarios were interpolated on to the survey stations (by latitude, longitude and bottom depth). RCP8.5 combines assumptions about high population and relatively slow income growth with modest rates of technological change, leading in the long term to high energy demand and high greenhouse gas emissions in the absence of climate change policies (IPCC, 2014). This high emissions scenario is frequently referred to as “business as usual”, suggesting that it is a likely outcome if society does not make concerted efforts to cut greenhouse gas emissions. Among the 22 models downloaded, 8 showed relatively good agreement with observations. The data points were combined and separated into a north (>= 66° N), and a south (< 66° N) domain because the whole domain spans a large latitudinal range (54° N - 74°N) which may contain large meridional gradients. Model projections for July and August were averaged because those months were when the surveys occurred. Decadal average bottom temperatures were calculated for 2008-2017 (“present”), 2045-2054 (“mid-century”), and 2091-2100 (“end-of-century”).

Maps of the bottom temperature projections were generated by averaging model output within 100 km^2 grid cells. The 8 projection models had varying spatial resolutions (from 0.18° Longitude to 1.71° Longitude), and the 100 km^2 grid cell sized captured at least one data point for each model.
The amount of thermal habitat available for each cluster of species was calculated as the proportion of the total study area projected to be within the temperature range for that cluster. Thermal habitat was calculated for each cluster for present, mid-century and end-of-century projections of bottom temperature. Maps of the distribution of thermal habitat for all clusters and decadal projections were also produced. ArcGIS Desktop 10.6, version: 10.6.0.8321 (www.esri.com) was used to create maps.

Results

Variance within k-means cluster groups declined rapidly as group number increased from 1 to 5 in all regions (Fig. 2). For group numbers larger than 5 variance decreased less rapidly. So group size (k) was chosen to be 5 for further analysis.

The five k-means clusters were given qualitative descriptors arbitrarily based on average median and range of temperature for taxa in the cluster. Clusters for which median temperatures were 0.6° or less were designated as representing "cold-water" taxa. Clusters for which median temperatures were 2.5° or greater were designated as "warm-water". "Stenothermic" clusters were those with a range of 2.8° or less and "eurythermic" clusters were those with a range of 5.5° to 6°; "highly eurythermic" was a range of 9.0° (Table 1).

Cluster A, the "cold, stenothermic" cluster and Cluster E, the "warm, high eurythermic" cluster contained the lowest proportion of taxa (12% and 8%, respectively). Cluster D, "warm, eurythermic", contained the greatest proportion of taxa (38%). Cluster B, "cold, eurythermic" and Cluster C "warm, stenothermic" contained intermediate proportions of taxa (21% and 19%, respectively). Clusters B and D had the greatest proportional catch density (49% and 38%). The other clusters had catch densities less than 10% of total catch (Table 1).

The most abundant taxa (in terms of biomass density) in Cluster A, "cold, stenothermic", were Gastropoda and *Musculus* sp., at 3.8% and 3% of total catch density, respectively. Other taxa, occurring at less than 1% of catch density but greater than 0.1%, included echinoderms, sipunculids, and arthropods (Table 2). The most abundant taxa in Cluster B, "cold, eurythermic", were *Ophiura sarsii* and *Ophiura* sp. at 39% of total catch density. Other taxa in this cluster included echinoderms, mollusks, chordates, gastropods, cnidarians, arthropods, and annelids. The most abundant taxon in Cluster C, "warm, stenothermic", was *Nuculana radiata*. The other taxa caught at densities greater than 0.1% were a gastropod and a bryozoan. The most abundant taxon in Cluster D "warm, eurythermic", was *Chionoecetes opilio*, at 9% of total catch density. Other taxa in this cluster included echinoderms, cnidarians, bryozoans, sponges (Porifera), arthropods, gastropods, mollusks, cnidarians, chordates, and annelids. The most abundant taxon in Cluster E "warm, highly eurythermic" was *Gorgonocephalus cf. arcticus*. Other taxa in this cluster included arthropods, cnidarians and echinoderms.

Observed temperatures from CTD data collected in 2017 and 2019 fell within the range of model projections for both domains and were very close to the ensemble mean of the model in the north domain (Fig. 3). However, in general, these eight models overestimated the mean bottom temperature in the southern domain. The spread in the projected temperature is larger in the Northern domain compared with Southern domain. This is more obvious in the latter half of the 21st century. Looking forward to the future decadal changes, model projections indicated an increase in average bottom temperature in the north domain from 0.98 °C at present to 2.25 °C by mid-century (an increase of 1.27 °C) and to 5.60 °C by the end of century (an increase of 4.62 °C). Model projections of the South domain indicate an increase from

3.83 °C at present to 5.15 °C by mid-century (an increase of 1.32 °C); and to 8.10 °C by the end of the century (an increase of 4.27 °C) (Table 3).

The spatial distribution of model projections of bottom temperature shows coldest water in the north and warmest to the south and nearshore, as expected (Fig. 4). The range of the coldest water shrinks to the north from present to mid-century to end-of-century; and waters to the south warm. Bottom waters less than 0 °C virtually disappear by the end of the century.

The proportion of the study area within the temperature range of each cluster, based on model projections of bottom temperature at present, indicated that there was proportionally the least thermal habitat for Cluster A "cold, stenothermic" (31%) and the most for Cluster E "warm, highly eurythermic" (96%) (Table 4). The other two eurythermic clusters, Clusters B and D, also had a relatively large proportion of thermal habitat available to them, 88% for both. There was an intermediate proportion of thermal habitat available for Cluster C, "warm, stenothermic" (61%).

The amount of thermal habitat decreased for all clusters from present to mid-century, except for Cluster E for which there as an increase of 2%. The amount of thermal habitat available at mid-century ranged from a low of 13% for Cluster A and a high of 98% for Cluster E. The decrease in thermal habitat from mid-century to end-of-century was even greater than from present to mid-century. Thermal habitat for Cluster A virtually vanished by the end of the century, at 2%. There was 10% or less thermal habitat available for Clusters B and C; and there was 13% available for Cluster D. 72% of thermal habitat was available for Cluster E at the end of the century.

Available thermal habitat, based on present-day model projections, was similar for all clusters, except Cluster A, "cold, stenothermic", for which thermal habitat was confined to the north and west; and Cluster C, "warm, stenothermic", whose thermal habitat did not extend as far north as the others (Fig. 5). Projected available thermal habitat contracts to the north for all clusters from present to mid-century, except for Cluster E, the most eurythermic (Fig. 6). By the end of the century the contraction to the north is so great that there is projected to be suitable thermal habitat for Clusters A-D only north of 65° N, in the northern Chukchi Sea; and thermal habitat for Cluster A is only found at the slope between the Chukchi Sea and Central Arctic Ocean (Fig. 7). The distribution of thermal habitat for Cluster E at mid-century contracts very slightly to the north, and more noticeably to the west.

Discussion

An ensemble of eight coupled climate models projected a mean increase in summer bottom temperature in the Bering to Chukchi Sea region of around 1.3 °C by mid-century and an even greater increase of around 4.5 °C by the end of the century. Warmer waters were projected to expand north, as expected; and the nearshore area, the location of the typically warm and low salinity Alaska Coastal Current (Coachman et al., 1975), was projected to be the warmest by the end of the century, up to 10 °C and greater. These projections are consistent with the reduction of sea ice cover, and earlier sea ice retreat in the region (Wang et al., 2018).

Cold-water and stenothermic taxa, which we suggest would be the most vulnerable to ocean warming, were projected to experience the greatest decline in the proportion of thermal habitat available. Thermal habitat for these taxa, "the losers", decreased by more than 50% by mid-century; and by the end of the century only 2% of the total Bering-Chukchi Sea region was projected to be within their temperature range. The scant thermal habitat that was projected to be available was distributed at the far north on the shelf break and slope between the northern Chukchi Sea and the deep Central Arctic Ocean basin. Temperature projections of the Arctic slope and basin were not examined for this study, but we suggest that even if bottom temperatures were projected to be suitable, the depth of slope and basin would not

match the habitat requirements of these shelf-occupying taxa. In other words, retreat of shelf benthos can only continue until they reach the northern shelf break and slope, with local extinctions a likely consequence. Similar to our predictions, Parada et al. (2010) have documented range contractions to the north of the commercially important snow crab (*Chionoecetes opilio*), driven by ocean warming and the shrinking of the Bering Sea cold pool.

Warm-water and highly eurythermic taxa, hypothesized to be the least vulnerable to ocean warming, were projected to experience the least decline in the proportion of thermal habitat available. Thermal habitat for these taxa, the "winners", increased slightly from present to mid-century and then decreased from 98% to 72% of the study area by the end of the century. There was virtually no latitudinal shift in the available thermal habitat for these taxa, the reduction in available habitat was the result of a slight westward contraction away from the area of the Alaska Coastal Current.

A similar examination of thermal thresholds of Arctic epibenthic invertebrates and predicted changes in bottom temperature was published by (Renaud et al., 2015). They combined geographical observations with model projections of bottom temperature through the end of the century to define temperature thresholds and project future spatial distributions as we did, except that they defined species as "Arctic" or "boreal" *a priori* based on published literature and expert opinion. They also limited their study to 65 benthic taxa. In addition, the geographical scope of their study was different than ours, encompassing all of the Arctic.

Of the species Renaud et al. (2015) analyzed only seven of the Arctic species had clear upper temperature thresholds, and these ranged between 2 °C and 6 °C. These species are analogous to our Clusters A through D which had upper temperature thresholds ranging from 2 °C to 5.1 °C. Similar to our conclusion that these clusters may experience a northward contraction of suitable thermal habitat, Renaud et al. (2015) concluded that the northward progression of low-temperature isotherms suggest shrinking distribution ranges for these taxa in the future. Fourteen of the boreal species that Renaud et al. (2015) studied showed clear lower temperature thresholds, ranging from 4 °C to 10 °C. By this definition, our data did not include any boreal species, the lower temperature thresholds of the taxa we examined ranged from -1.5 °C to 1.8 °C. Renaud et al. (2015) concluded that the boreal species with the lowest thresholds are expected to be the first to expand into the Arctic. In contrast, we did not project northward expansions of thermal habitat, only contractions of habitat to the north. This could be due to the fact that most of our taxa were cold-water "Arctic" taxa, as defined by Renaud et al. (2015). In addition, as we suggest above, even if we had expanded our study area south and included more "boreal" taxa, the Bering Sea slope may represent a habitat boundary between the shallow Bering Sea shelf and the deep Aleutian Basin.

The conclusions of the Renauld et al. (2015) study, although it did include the Bering and Chukchi seas in bottom temperature projections, were driven by taxa occurring outside our study area. 68% of the Arctic taxa and all but two of the boreal species are found only in the Barents, Norwegian, North Atlantic and/or Beaufort seas, (EOL.org). The Barents Sea and surrounding waters are warmer than the Pacific Arctic at a given latitude due to warm Atlantic and coastal waters which flow into the southwestern part and keep the southern Barents Sea relatively warm and ice free, compared to the Chukchi Sea which receives winter-cooled waters from the Bering Sea (Hunt et al., 2013). In addition, the taxonomic composition of the Arctic and boreal species in the Renaud et al. (2015) study was limited compared to our study: 67% of the 28 Arctic species they examined were annelids and 72% of the boreal species were annelids.
In contrast to Renaud et al.'s (2015) study of benthic invertebrates and other studies on the distribution of fishes, our projections of thermal habitat did not predict range expansions to the north, only contractions of habitat to the north and offshore. Mueter and Litzow (2008) and Alabia et al. (2018) have documented changes in the distributions and trophic levels of Bering Sea epibenthic communities from 1982-2016 with ocean warming. They observed a northward expansion of sub-Arctic fish and crustacean species and an increase in community trophic level (more large groundfish) over time. In contrast to our analysis,

which was of the entire epibenthic invertebrate community (at least as reflected in our catch data), their analysis was limited to catch data on 36 fish and 10 crustacean (crab and shrimp) species. There is also evidence for northward range expansions of demersal fish and shrimp species in the Barents Sea and Western Eurasion Basin (Polyakov et al., 2020). These previous studies documenting distributional shifts northward with ocean warming focused on fishes and a few crustaceans, not the epibenthic invertebrate community we examined. A comparative analysis of the temperature tolerances of fishes and invertebrates is beyond the scope of this paper. The reasons that the response of fish distributions to ocean warming may have a different geographic manifestation than that of the invertebrate community require future study.

Our projections of changes in the distribution and extent of thermal habitat do not address the potential for changes in benthic invertebrate biomass over time. Grebmeier (2012) and Grebmeier et al. (2018, 2006) have documented decreases over the past three decades in biomass of benthic infauna (mostly bivalves, amphipods, polychaetes, and sipunculids) in the Northern Bering Sea and increases in the southeast and northeast Chukchi Sea. They attribute decreases in the Bering Sea to the loss of sea ice and a breakdown in the benthic-pelagic coupling that provides pelagic carbon to the benthos. They attribute increases in the Chukchi Sea to higher export of pelagic production to the benthos resulting from a longer open water season. Bluhm et al (2009) have documented increases in epibenthic biomass (mostly ophiuroids, snow crab *Chionoecetes opilio*, holothurians, and urchins) in the southeast Chukchi Sea, Norton Sound and the southeast Bering Sea (Bluhm et al., 2009). In particular, snow crab abundance increased from the late 1970s to the 2000s in the Chukchi Sea. Recent surveys, however, show that snow crab stocks in the Bering Sea are in decline. Biomass of crab was the lowest on record in 2021, continuing a declining trend that began in 2015 (Zacher et al., 2021). To address changes in biomass, an ecosystem model that incorporates projections of primary production, pelagic consumption, supply of pelagic carbon to the benthos, benthic biomass and bottom temperature; and that includes both the infaunal and epifaunal benthic community would be enlightening likely next step.

These predicted changes in amount of thermal habitat available to epibenthic invertebrates could have reverberating impacts on whole Arctic food webs. The most abundant taxa (in terms of biomass) in the cold-water and stenothermic cluster, a.k.a. the “losers”, were gastropods and the mussels *Musculus* sp. These taxa are prey to endangered Pacific walrus (*Odobenus rosmarus*), which is harvested as a food resource in native Alaskan communities (Hovelsrud et al., 2008; Sheffield et al., 2001; Sheffield and Grebmeier, 2009). They are also among the most frequently occurring prey taxa in the stomachs of commercial groundfish such as Pacific cod (*Gadus macrocephalus*) and Alaska pollock (*Gadus chalcogrammus*) in the Northern Bering Sea (A. Whitehouse, pers. com.; Alaska Fish Stomach Database https://www.fisheries.noaa.gov/resource/data/alaska-fish-stomach-database) and flatfish (yellowfin sole) in the Chukchi Sea (Whitehouse et al., 2017). The most abundant species in the warm-water and highly eurythermic cluster, a.k.a. the “winners”, was *Gorgonocephalus cf. arcticus*. They prey on zooplanktonic prey, such as euphausiids using their sticky tube feet and a sophisticated system of spines and hooks (Rosenberg et al., 2005). They have little nutritional value so likely have few predators.

The predicted changes in thermal habitat could also impact species diversity of the region. Thermal habitat for all taxa (except those with the broadest temperature range) contracted to the north, such that by the end of the century the projection was that south of 65 °N (Point Hope) there would only be suitable thermal habitat for the “winners”. This could have an impact on taxonomic diversity of the Bering-Chukchi Sea region because this cluster accounted for only 26 taxa or 8% of all taxa observed. Our diversity calculations are based on data with varying levels of taxonomic resolution, so this estimate may be biased low because of the inclusion of catch data at resolutions higher than species.

We did not examine whether North Pacific epibenthic invertebrate taxa, found south of the Bering Sea might find suitable habitat in a warming Bering Sea. However, the relatively shallow depths of the Bering

Sea shelf, compared to the depth of the slope and basin, might make the "new" habitat unsuitable for southern taxa. Analogous to the situation to the north, we suggest that the possibility of new species invading from the south with warming ocean temperatures might be constrained by the southern shelf break and slope. We also did not examine whether epibenthic invertebrates in the Gulf of Alaska could expand into the Bering Sea with ocean warming; this deserves further study.

A key assumption of our approach was that observed temperature ranges were representative of species physiological tolerances. Laboratory studies of thermal acclimation potential of Arctic epibenthic invertebrate megafauna are scarce. Richard et al. (2012) conducted laboratory experiments to determine the temperature limit of 4 species from Kongsfjorden in Svalbard: a sea urchin (*Strongylocentrotus droebachiensis*), a gastropod mollusk (*Margarites helicinus*), a bivalve mollusk (*Serripes groenlandicus*), and an amphipod of the genus Onisimus. They found that the sea urchin and the gastropod could acclimate to the highest experimental temperature, 10.3 °C. These two species were in the "warm, broad range" cluster in our analysis, although their temperature range (as defined by the 5th and 95th percentiles) was up to only 5.1 °C. Richard et al. (2012) conclude that their results that Arctic species could acclimate to high temperatures "appear anomalous", most likely because the Gulf Stream increases sea temperatures in Svalbard in summer to an average of 4 °C to 6.5 °C, more similar to temperate regions than to other polar regions. Indeed, these temperatures are higher than most of our study area. The climate variability hypothesis predicts that high seasonal variation in ocean temperature, such as observed in temperate regions (and in Svalbard), will result in greater ability to acclimate to increased temperature compared to environments with less seasonal temperature variability such as the tropics and polar regions (Stevens, 1989). Supporting this hypothesis, a number of thermal tolerance experiments have been conducted with Antarctic species and most have demonstrated a narrow thermal tolerance range (Morley et al., 2011; Peck et al., 2010, 2009b, 2009a). Laboratory acclimation experiments of Arctic taxa occurring in less variable and colder temperatures than Richard et al studied are needed. It's also important to note that temperature increases within physiological tolerance extremes, but outside the 'normal operating temperature range' of an organism can result in lower growth and reproduction (Pörtner and Knust, 2007; Wang and Overgaard, 2007).

Another key assumption of our work is that there will be no significant evolutionary adaptation to warming temperatures. Climate change in the Arctic has been rapid. Sea temperatures have risen 1-3 degrees in 40 years (Timmermans and Labe, 2020), and our projections are that sea temperatures are predicted to rise 4 degrees over the next 80 years. This increase is more rapid than has been observed over the past million years or on record over the last glacial cycle (PAGES 2k Consortium et al., 2019) and is faster than normal evolutionary timescales (Peck et al., 2009b). So we suggest that it is unlikely that Arctic benthic macrofauna will be able to evolutionarily adapt to such a rapid increase in ocean temperature.

Model projections of ocean bottom temperature suggest that by the end of the century there will be suitable thermal habitat available for only a small number of Arctic epibenthic invertebrate taxa. Temperature is one determinant of habitat, a full habitat model incorporating other parameters such as sediment type and export production coupled with an ecosystem model that captures trophic and competitive interactions would provide a more detailed picture of the possible future of Arctic benthic communities. In addition, more laboratory studies of thermal acclimation potentials of Arctic benthic invertebrates are clearly needed. Finally, continued monitoring of the distribution, abundance and species composition is needed to track changes and refine predictions about the future of this diverse and productive community that supports a number of upper trophic taxa including Arctic human communities.

Acknowledgements

The authors would like to acknowledge the efforts of all field-going personnel from the Alaska Fisheries Science Center Resource Assessment and Conservation Engineering Program. The ideas for this project were generated at workshops supported by the Nordic Council, AG-FISK (Project number: (159)-2017-Arctic biodiversity). Louise Copemen and Mike Litzow (NOAA AFSC) provided valuable comments that improved to quality of the manuscript. This manuscript is a product of the NPRB Arctic Integrated Ecosystem Research Program [NPRB publication number: ArcticIERP-XX]; and is FOCI Publication #XXXX.

Table 1. Median temperature and range for each cluster and percent of species in each cluster. “Cold” clusters are those which median temperatures 0.6° C or less and “warm” clusters are those with median temperatures 2.5° C or greater (arbitrarily defined). “Stenothermic” clusters are those with a range (5^{th} to 95^{th} percentile) of 3.5° C or less; “eurythermic” clusters are those with a range of 5.5° to 6° C and the “highly eurythermic” cluster has a range of 9.0° C (arbitrarily defined). Number and percent of taxa and percent catch biomass density are also shown

Cluster	Median temperature	Temperature range (°C)	Magnitude of range	Qualitative descriptors	# of taxa	% kg km_2
A	-0.3	-1.5° – 2.0°	3.5°	cold, stenothermic	40 (12%)	9%
B	0.6	-1.4° – 4.6°	6.0°	cold, eurythermic	65 (21%)	49%
C	3.4	1.8° – 4.6°	2.8°	warm, stenothermic	60 (19%)	2%
D	2.5	-0.5° – 5.1°	5.5°	warm, eurythermic	119 (38%)	38%
E	2.8	-0.7° – 8.3°	9.0°	warm, highly eurythermic	26 (8%)	3%

Table 2. Percent catch by species (or lowest taxon) in each cluster. Taxa with percent catch greater than or equal to 0.1% are shown, the rest of the catch is summed and shown as 'Other'.

CHAPTER 2 - Late summer distribution and abundance of pelagic larval crab communities, including blue king crab and snow crab, in the Pacific Arctic Gateway

Objective 1: Quantify the distribution, abundance, and condition of demersal fishes and shellfishes

Jared Weems[1], Alexei Pinchuk[1], David Kimmel[2], and Franz Mueter[1]

[2] NOAA, Alaska Fisheries Science Center, Seattle, WA

Abstract

This multiyear study establishes a critical baseline of late summer larval crab abundance and distribution across the northern Bering and Chukchi seas. We present a snapshot of larval crab community dynamics over space and time for three environmentally contrasting years: 2012 (cold), 2013 (average), and 2017 (warm). Preliminary data summaries suggest spaciotemporal differences in larval crab communities across years are driven by both survey design (sampling date) and variable environmental conditions (temperature, salinity, and water mass distribution). Snow crab larval stages, the most abundant and ubiquitously distributed species in our datasets, provide evidence that mature female crab inhabiting the northern Bering Sea, Chukchi Shelf, and deeper waters in Barrow Canyon and on the Chukchi and Beaufort slopes all potentially supply larvae to the Chukchi Shelf in late summer through hypothesized south-north advection and north-south upwelling processes. Additionally, the Chirikov Basin appears to be an important megalopae settlement area for snow crab larvae advected into the region with southern Bering Sea Shelf Waters (BSSW) or western Anadyr Water. Rare observations of blue king crab larvae were associated with colder BSSW in the southern and central Chukchi Sea in 2012, suggesting that they originated in northern Bering Sea nearshore island habitats known to harbor adult spawners. Larval community distributions remained relatively consistent across years and regions, though abundances were variable. Comparison of stage groups by region suggests possible advanced development in warmer years (2013 & 2017) relative to the colder year (2012). Warming conditions may accelerate either pelagic larval development or benthic adult spawning and hatch release timing. These results provide the most comprehensive assessment of pelagic crab in the northern Bering Sea and Chukchi Sea to date. Future analyses of these data could provide information on early life history survivorship in changing pelagic environments and potentially identify nursery areas for settling post-larval and early instar crabs in the benthos.

Introduction

Planktonic crab larvae are common constituents of zooplankton communities over the Pacific Arctic shelf during summer (Eisner et al., 2013; Landeira et al., 2017). Few studies have examined the distribution and abundance of pelagic larval and settling crabs in Pacific Arctic large marine ecosystems (e.g. Ershova et al., 2019; Landeira et al., 2017). The paucity of crab early life history data severely limits our understanding of crab settlement dynamics and benthic recruitment throughout the region. Current impediments include under-reported or Family aggregated larval abundance estimates, lack of taxonomic and stage-specific resolution in species of non-commercial interest, and poor understanding of larval crab biology in Arctic environments. Recently described larval crab planktonic communities at select areas in the Bering and Chukchi seas show distinct species-specific spatial distributions between two sampling years (Landeira et al., 2017). While Landeira et al. provided the first taxonomically complete description of crab larvae in the Chukchi Sea, comprehensive species and stage-specific distributions and abundances have not been described and associations with adult populations and environmental conditions remain vague.

Pacific subarctic crabs are important subsistence and socioeconomic resources in the region. Adult and juvenile snow crabs are ubiquitous and abundant throughout the Bering Sea and Chukchi Sea (Bluhm et al., 2009; Zheng and Kruse, 2006). Mechanisms for advection of larvae and recruitment of post-larval settlers to the benthos have been hypothesized, such as the Environmental Ratchet Hypothesis for southeastern Bering Sea snow crab (Orensanz et al., 2004; Parada et al., 2010) and variable larval transport of Bristol Bay red king crab with climate change (Daly et al., 2020). To the north in the Chirikov Basin, a hot spot for settling megalopae has been hypothesized based on an over-abundance of early juvenile instars observed in bottom trawls (Kolts et al., 2015). These studies describe oceanographic advection and the location of adult female spawners as primary factors contributing to successful settlement of crab in the Bering Sea. These results rely heavily on model-estimated larval transport; however, model validation is difficult and the parameterization of larval behaviors are largely based on laboratory studies. Without integration of field-observed larval data, we cannot verify model assumptions about early life history dynamics for important crab species. Additional environmental unknowns and complex oceanographic conditions in the marginal ice zone throughout the Bering and Chukchi Seas provide uncertainty. Zooplankton and fish communities are structured by oceanographic domains with contrasting water masses. For example, cold temperatures limit the distribution of temperate species while providing ideal habitat and a thermal refuge for Arctic species (Danielson et al., 2020; Eisner et al., 2013; Hollowed et al., 2013; Pinchuk and Eisner, 2017). It is unknown if the distribution of crab larvae is similarly structured by environmental conditions or if their distribution primarily reflects adult preferences.

To better understand larval crab biology and their seasonal abundance and spatial distribution, we examined the species and stage composition of crab larvae relative to environmental variation using late summer samples from three sampling years. Objectives for this report include quantifying crab species and stage group catch-per-unit-effort (CPUE) to compare distributions across years relative to surface and bottom seawater water mass designations (summarized oceanographic and pelagic production indices) and infer the possible origin for larvae observed. Future analyses based on this report will test community assemblage relationships and commercial crab species abundance and distribution responses to environmental gradients.

Methods

Survey area and regions

Samples were collected in the Chukchi Sea and northern Bering Sea in August through September of 2012 and 2013 as part of the Arctic Ecosystem Integrated Survey (Arctic EIS) Program (Mueter et al., 2017) and August through September of 2017 as part of the Arctic Integrated Ecosystem Survey Phase II (Arctic IES Phase II) Program (Baker et al., 2020). Surveys were conducted using a square grid-based design of equidistant sampling stations approximately 30 nautical miles apart across all years between 60-73.5°N latitude and 155-170°W longitude. Additional oceanographic and plankton sampling every 15 nautical miles occurred in the Chukchi Sea in both 2012 and 2013. Sequential gear deployments at each station collected data on oceanography, zooplankton, and pelagic and benthic macroinvertebrates and fishes; from which all data presented here were acquired.

For seasonal and regional comparisons, we subdivided the study region into three areas: northern Bering Sea (NBS) south of the Bering Strait at 66°N, southern Chukchi Sea (SCS) between 66°N and 69.5°N, and northern Chukchi Sea (NCS) north of 70°N based on sampling design. Surveys conducted in 2012 and 2013 on board the F/V Bristol Explorer were nearly identical in timing and station coverage. Sampling began the first week of August in the southern Chukchi Sea and proceeded northward to approximately 73°N along the Chukchi Sea slope, concluding by early September. Thereafter, surveys of

the northern Bering Sea occurred north to south from Bering Strait to 60°N and concluded by late September. In contrast, the 2017 survey on board the R/V Ocean Starr started in the northern Chukchi Sea and proceeded south with the majority of grid-based sampling events occurring between the last week of August to late September. The 2017 northern Bering Sea survey was conducted on board the F/V Northwest Explorer concurrently from late August through late September using identical methods, however proceeded south to north from 60°N to Bering Strait.

Field sampling and processing

Conductivity-temperature-depth (CTD) profiles of the water column were collected with Sea-Bird Electronics Inc. SBE 911 or SBE 25 units attached to a Niskin bottle rosette steel frame or with a SBE 49 unit in-line with zooplankton net tows. Raw oceanographic data was processed by the Alaska Fisheries Science Center (NOAA) FOCI Program (Danielson et al., 2017). For this study, surface (0-10 m depth) and near-bottom (deepest 10 m) layer mean temperatures (ST / BT, °C), mean salinities (SS / BS, psu), and mean integrated water column chlorophyll a (mChla, mg m^{-3}) were computed. Surface and bottom water mass designations / origin were determined according to Danielson et al. (2020) using the above T/S values.

Zooplankton samples were collected with a 60 cm MARMAP-style bongo frame with 505µm mesh net. Calibrated General Oceanics Inc. mechanical flowmeters were used to estimate seawater filtrate volume. Net rinsed and sieved codend samples were fixed in 1 L glass jars with 5% buffered formalin 150 µm filtered sea water solution. Laboratory zooplankton community processing employed sequential Folsom sampling splitting methods to quantify community composition (Pinchuk and Eisner, 2017). Mean zooplankton abundances (ind. m^{-3}) at each station were aggregated into three groups for analysis: total zooplankton (Z), a 'Pacific' zooplankton indicator group (PZ), and an 'Arctic' zooplankton indicator group (AZ) based on Eisner et al. (2013). PZ and AZ species groupings have previously been used to track water masses of Pacific and Arctic origin, respectively (Eisner et al., 2013; Pinchuk and Eisner, 2017). All oceanographic, chlorophyll a (primary production index) and zooplankton community (secondary production index) estimates were calculated by station to compare to larval crab communities in future analyses.

Crab larvae were processed and removed from complete, non-Folsom split zooplankton samples (Weems and Pinchuk, 2015). Larvae were identified to species and classified into life stage (molt stage) based on best available taxonomic descriptions. Crab life stages were aggregated for each species for cross-species comparisons due to different numbers of larval molts needed to compete the larval cycle across species. Hereafter aggregated life stages are termed 'stage groups'. Biologically, stage groups reflect increasing size, mobility (swimming ability), and pelagic larval duration (PLD, planktonic time) as larvae grow from hatching to benthic settlement and carcinization (development of crab-like form). Stage groups used for analysis include small early stage zoeae (EZ, approximate age 0-4 weeks), larger late stage zoeae (LZ, 4-8 weeks), and relatively large megalopa/glaucothoe decapodite stages (MG, > 8 weeks) which most resemble adult crab morphology. All individuals in each stage group were counted and catch-per-unit-effort (CPUE, individuals per unit volume seawater filtrate) was calculated for each group by station.

Analysis

In this report, we provide maps and qualitative descriptions for larval community and species / stage group abundance and distribution by year and region relative to basic environmental conditions. A future manuscript and dissertation chapter, Weems et al. (in prep), will provide further analysis correlating larval community structure and species-specific distribution to regional environmental covariates and water masses, as well as test blue king crab and snow crab larval response to environmental conditions using a generalized additive modeling framework.

Database preparation and quality control were maintained with Microsoft® Excel®. Maps of CPUE were produced using ArcGIS® (ESRI, 2014) software. Water mass figures and all data summaries and statistical analyses were conducted using R Version 3.5.2 (R Core Team 2021).

Results

Larval crab abundance and distribution

A total of 23,550 crab larvae were observed, categorized by species / stage, and counted across 347 stations spanning all study years. Specimens of uncertain taxonomy and poor condition were excluded from analyses (n = 1,417 individual Pagurid hermit crabs). Standardized abundances (CPUE in ind. $1000m^{-3}$) by species and region are summarized in Table 1. Visual assessments of CPUE by species / stage group (ind. m^{-3}) and proportional contribution of stage groups are mapped by year and station for the total larval community and separately for *P. platypus* and *C. opilio* (Figure 1). Additional maps for all species including *P. ochotensis*, *P. trigonochirus* (cf), *L. splendescens*, *H. grebnitzkii*, *T. cheiragonus*, *O. gracilis*, *H. coarctatus*, *P. camtschaticus*, and *C. bairdi* are included in Supplementary Figures. Very rare commercial species *P. camtschaticus* (n = 1) and *C. bairdi* (n = 7) were mapped in years where present but not further summarized.

Crab larvae were found at nearly all stations sampled. Larval abundance, distribution, and stage composition reveal a few species / stage groups are found regionally in relatively high abundance. Interannual comparison of total community abundance and distribution by region was relatively consistent, except for the southern Chukchi Sea in 2017 due to lower numbers associated with later sampling (Figures 1A-F). Blue king crab, *P. platypus*, occurred as late stage zoea and glaucothoe in low abundances in the Chukchi Sea in 2012 and 2013 but were entirely absent in 2017. Abundances were 3-10 times larger in 2012 compared to 2013 (Figures 1G-L). In contrast, snow crab, *C. opilio,* was the most ubiquitous species across all sampling regions and years. Estimated abundances and proportional contributions by stage group varied by region (Figures 1M-R). Early stage zoeae *C. opilio* occurred nearly exclusively in the North Chukchi Sea region but in relatively low abundances. Late stage zoeae *C. opilio* were the dominate larval group across the entire Chukchi Sea shelf in late summer. Near-settling stage megalopae *C. opilio* were most abundant in the offshore waters of the North Bering Sea in September, though they also occur throughout the Chukchi Sea. Two additional commercial crab larval species were rarely observed. One red king crab, *P. camtschaticus,* was caught in the eastern Chirikov Basin, Bering Sea in 2012. The second ever recorded observation of Southern Tanner crab, *C. bairdi*, larvae in the Chukchi Sea occurred at CH-D03 on Aug 13, 2013 (Landeira et al., 2018), while a few individuals were also seen in the southern region of the North Bering Sea.

Other crab species were important constituents of the larval community, typically observed either in high abundances over constricted ranges or in lower abundances across larger regions (Table 1, Supplementary Figures 3-68). Four Infraorder Anomuran species, taxonomically related to king crab, were significant contributors to the overall community. The Alaskan hermit, *P. ochotensis,* was highly abundant as early stage zoeae in the northern Bering Sea in mainland nearshore areas of Norton Sound across all years. Larger late stage zoeae and glaucothoe stages of the fuzzy hermit (*P. trigonochirus* (cf) and splendid hermit (*L. splendescens*) were moderately abundant and ubiquitous across the Bering and Chukchi Seas offshore regions. The northern hairy king crab, *H. grebnitzkii,* occurred only in the Chukchi Sea in early sampling years with trends similar to blue king crab only in higher abundance. Three Infraorder Brachyuran species, taxonomically related to snow and Southern Tanner crab, were observed in three distinct patterns. The Arctic lyre crab, *H. coarctatus,* mirrored *C. opilio* in observed distribution but had lower abundances. The helmet crab, *T. cheiragonus,* had a consistently high abundance of megalopa stage decapodites in the northern Chukchi Sea region across years. In contrast, the megalopae of the Pacific decorator crab, *O. gracilis,* were primarily found in the southern, nearshore areas of the North Bering Sea region.

Environmental and oceanographic conditions

Sampling was largely restricted to the shallow northern Bering Sea and Chukchi Sea shelves with a mean sea floor depth of 38.6 m (± 13.6) (plus standard deviation, SD) Two stations were sampled off the shelf near Barrow Canyon in 2017 with a sea floor depth greater than 200 m, thus oceanographic data was only analyzed to 150 m depth to match the maximum zooplankton net tow depth.

Water mass characteristics and measures of primary and secondary production are summarized by year and region in Table 2 and water masses were defined and mapped for each year (Figure 2A, B). Anadyr Water (AnW) originates in Russia and is typically colder, more dense water overlain by Alaska origin water masses in more western stations across all regions. The Bering Sea Shelf water includes three distinct water masses that flow onto the Chukchi Shelf, including 1) warm Shelf Water (wSW) warmed by summer seasonal heat, 2) cool Shelf Water (cSW) warmed to a lesser extent due to sub thermo- and halocline entrapment, and 3) Winter Water (WW/MWW) consisting of subzero, cold waters originating under the previous winter's annual sea ice. Alaska Coastal water (wCW, cCW) was relatively warm and less saline due to terrestrial freshwater runoff. Finally, Melt Water (MW) is indistinguishable from cool Alaska Coastal water but originates from recently melted sea ice.

All water masses are distinct and consistently present across all years and provide evidence supporting vertical and horizontal segregation of water masses on regional scales (Figure 2A). In 2012, late summer cold air and ocean conditions prevailed and were driven by southwesterly winds pinning the Alaska Coastal Water along shore flowing northward into the Arctic. Cool summer Bering Sea Shelf Water propagated in the surface waters across the Bering and Chukchi corridors. Cold conditions in 2012 contributed to a relatively strong (extent, thickness) ice cover in spring 2013. However, by late summer 2013 warmer conditions and northeasterly wind fields were consistent, a reversal in contrast to 2012. These southwesterly flowing winds both 'shut-down' the north Chukchi ACC nearshore flow through Barrow Canyon and drove warmer, less saline coastal surface waters offshore across all regions. In 2017, warm conditions were pronounced. More recent years have been characterized by anomalously low winter sea ice concentration coupled with warm to hot air and water temperatures, decreased salinity, and southerly winds driving more heat north into the Arctic.

Discussion

Larval community trends relative to environmental conditions

Larval community catch was variable and generally a low proportion of total zooplankton abundance in zooplankton samples). Species identification and stage descriptions were ascertained and confirmed in this analysis through available literature sources (Table 1). Species *P. trigonochirus* and *H. grebnitzkii* do not have complete larval descriptions, however we are confident in species identifications based on available literature and adult distributions identified in associated benthic bottom trawls.

We hypothesized that seasonality in biological processes and water masses are the primary drivers of larval community structure. Observed species and stage distributions are linked to crab biology by larval hatch area and timing, pelagic larval duration, and preferred settlement habitat. Meroplanktonic crab larvae are seasonally produced from a bottom-dwelling female's egg brood whereby they are hatched and released to disperse into the pelagic water column to growth, feed, swim, disperse from the natal habitat, and reduce predation pressure (Possingham and Roughgarden, 1990; Strathmann, 1985). Over several weeks or months, multiple shell molting cycles take place before larvae settle to a preferred benthic substrate. Survival during early pelagic stages ultimately may determine successful recruitment to adult populations (Strathmann et al., 2002). Consistent adult stock range or spawning habitat (i.e. larval origin) in the Pacific Arctic, as detailed in Loggerwell et al. (this issue, AIERP-UTL Report), Mueter et al. (2017), and historically observed in the NOAA Eastern Bering Sea Bottom Trawl Survey, would be

important information to consider relative to species-specific inferred migration triangle migration pathways (Harden Jones, 1968).

Larval crabs found as one or few stages in a spatially constricted space could reflect a specific adult spawning stock of origin and/or larval advection mechanism. Larvae originating from a specific adult population would likely have similar release time and location and therefore develop under similar pelagic conditions and transport processes. We observed spatially consistent aggregations of several species and stage groups between years with evidence of possible upstream spawning stocks. These included: 1) snow crab early zoea in the northern Chukchi sea, which likely originated from potential spawning stocks in deeper waters of Barrow Canyon and along the Beaufort Sea Slope. 2) Snow crab megalopae in the northern Bering Sea (Chirikov Basin), which likely originate from spawning stocks on the northeastern Bering Sea and Anadyr shelves. 3) Blue king crab late stage larvae and post-larvae in offshore waters of the southern Chukchi Sea with possible spawning stocks to the south in the northern Bering Sea and Bering Strait region associated with nearshore rocky island habitats. 4) Alaskan hermit crab early stage larvae with likely origins in near-coastal areas of the northern Bering Sea and Norton Sound. Across species, we suggest mature female crab chose preferred spawning grounds with consistent, directional oceanographic flow to promote larval advection to optimal nursery habitat for settlement. If predictable transport mechanisms and settlement habitats are maintained, annual environmental conditions would more directly impact yearly benthic recruitment through larval survivorship.

Larval crab that were ubiquitous across all regions could suggest expansive adult stocks employing slow bet-hedging larval release strategies. By spreading larvae over space and time, females selectively limit larval death under poor conditions and reduce competition under optimal conditions. Therefore, the possibility of failure of an entire larval cohort is reduced (Laaksonen, 2004; Pineda et al., 2010). We suggest the following larval species and stage groups reflect non-specific adult spawner habitat selection and prolonged hatching periods. 1) Highly abundant snow crab late stage zoea and megalopae throughout the Chukchi Sea present in all years across the majority of stations, and similarly 2) Arctic lyre crab late stage zoea and megalopae. 3) The fuzzy and splendid hermit crabs of the Chukchi Sea were observed in multiple stages per sampling event, suggesting an even more prolonged spawning period. Overall, we suggest expansive hatching or settlement of larvae is reflective of generalist species occupying a large niche space. Thus, high losses of larvae in one area may be compensated for in another area to maintain high abundances and distributional ranges.

Larval species and stage distributions are linked to local, seasonal, and climatically driven environmental conditions. Stability of water masses in the Pacific Arctic is driven by presence or absence of sea ice, as impacted by atmospheric forcing (Danielson et al., 2017, 2014). We observed all water masses in all years though distribution of those water masses were dramatically different across years. Danielson et al. (2017; 2020). Community level analysis does show some species appear to inhabit only certain water masses, such as shelf waters or coastal waters (Pinchuk and Eisner, 2017; Kimmel et al., AIERP-LTL Report). Typically, cold water species such as snow crab, Arctic lyre crab, blue king crab, and northern hairy king crab were major larval community constituents in colder, offshore shelf waters. Blue and hairy king crab in particular fit this pattern as adults are thought to occur and spawn in rocky and shell island habitats of the north Bering Sea, which were not overlain with Alaska Coastal Water. This suggests they occupy and are advected in the bottom water layer below or near the pycnocline. However, abundant and ubiquitous species like snow crab, Arctic lyre crab, fuzzy hermits, and splendid hermits occur in both offshore and coastal waters, which is consistent with adult distributions across the northern Bering Sea and Chukchi Sea epibenthic communities (Divine et al., 2019; Mueter et al., 2017; Jewett & Feder, 1981). All species exhibited interannual variation as reflected by presence/absence and stage of occurrence and may be influenced by temperature conditions and water mass flow. We suggest with increased warming and regional climate shifts, long term population fluctuation will be a species-specific dynamic response integrating annual larval survivorship and settlement dynamics.

Future Analyses

Trends identified above will be further explored in Weems et al. (in prep) by modeling community and species-specific response to environmental covariates. We will attempt to identify community-level environmental drivers, determine species-specific relationships to important covariates, then test blue king crab and snow crab stages specific response to environmental drivers over space and time.

Multivariate community structure analysis

To characterize the composition of the larval crab community (by species and stage group) during late summer over multiple years relative to environmental conditions, we used 1) non-metric multidimensional scaling (nMDS) ordination to visualize annual community dissimilarities relative to best ranked subset of explanatory environmental covariates. 2) PERMANOVA to statistically test for differences in community composition by region and water masses, and 3) indicator species analysis to identify species with strong affinities for specific water masses or regions.

Blue king crab and snow crab community modeling

To further examine regional patterns in abundance and distribution of our primary target species, snow crab and blue king crab, we will use generalized additive models (GAM) to examine individual counts relative to location and environmental parameters. General hot spot models will assess inter-annual consistency in spatio-temporal peaks of abundance in snow crab larvae distribution in the northern Chukchi Sea by early zoeae stages and in the northern Bering Sea / Chirikov Basin by megalopae stage larvae. Interannual assessment of potential differences in development rate in larvae relative to environmental drivers will focus on late zoea to megalopae transition in snow crab and presence or absence of late stage zoea and glaucothoe in blue king crab within the Chukchi Sea from 2012 and 2013.

Conclusions

Larval crab analysis across a cold, average and warm year in the North Bering Sea and Chukchi Sea sampled during the Arctic EIS and IES II Programs show relatively high consistency in community composition across years by region and water mass. Abundance was variable, but spatiotemporally consistent within regions where sampling occurred at the same time of year. Variation in species distribution was suspected to be driven by water mass position, while variation in stage groups by species could be driven by physiological responses to increasing temperatures or sampling season. In 2012, late summer cold air and ocean conditions prevailed and were driven by southwesterly winds pinning the ACC along shore and northward into the Arctic. Cool summer BSSW propagated in the surface waters across the Bering and Chukchi corridors. This cold year appears to have delayed either crab spawning or physiology (molt frequency, pelagic larval duration) in several species, likely contributing to the presence of blue king crab at the time of sampling. Cold conditions in 2012 contributed to a more extensive and thicker ice cover in spring 2013. However, in late summer 2013 warmer conditions and northeasterly wind fields were consistent and warmed most surface waters relative to 2012. These Arctic winds 'shut-down' the north Chukchi Alaska Coastal Water flow into the Arctic and promoted offshore winds driving warmer, less saline coastal surface waters offshore across all regions leading to strong vertical stratification. Larval communities appeared to be more spread out and overlapping, but strong stratification would likely have limited mixing of communities and excluded cold bottom water larvae from surface waters. In 2017, warming conditions were pronounced in both surface and bottom waters across all regions. More recent years (2014-2020) have been characterized by anomalously low winter sea ice concentration coupled with average to hot air and water temperatures, decreased salinity, and southerly winds driving more heat north. Larval community response is difficult to assess due to survey design discrepancies between programs, however decreased abundances in the Chukchi Sea could be explained by faster development, higher molt frequency, and earlier settlement. However, we cannot rule

out poor larval recruitment or survival. With continued warming and further northward movement of temperate species into the Chukchi Sea, we might expect increased variability in larval community production due to changes in water mass stratification and advection, local food production or prey mismatch, and predation pressure from temperate fishes (e.g., Walleye pollock, Pacific cod).

- Total larvae count (N observed) = 23,550. Larvae excluded in analyses = 1,417 including red king crab (*P. camtschaticus* , N = 1), Tanner crab (*C. bairdi* , N = 7), and unknown Pagurid larvae.

Table 2: Arctic Eis and Arctic JES Phase II sampling information, number of zooplankton samples processed for larval counts, and mean environmental parameter values by region. Sampling years 2012 and 2013 have consistent overlap in dates across regions, while only Chirikov Basin and northern N. Chukchi in 2017 overlap consistently enough to include in interannual analyses. Physical and biological oceanographic mean values are restricted to matching larval stations only, where data was available.

CHAPTER 3 - Model-based Fish Distributions and Habitat Descriptions for Arctic Cod (*Boreogadus saida*), Saffron Cod (*Eleginus gracilis*) and Snow Crab (*Chionoecetes opilio*) in the Alaskan Arctic

Objective 1: Quantify the distribution, abundance, and condition of demersal fishes and shellfishes

Marsh, J.M., Mueter, F.J., Pirtle, J.

Abstract

In the 2009 Arctic Fisheries Management Plan (FMP) the North Pacific Fishery Management Council (NPFMC) identified Arctic cod (*Boreogadus saida*), saffron cod (*Eleginus gracilis*) and snow crab (*Chionocetes opilio*) as the three potential target species in the Arctic Management Area (AMA) (NPFMC 2009). For the FMP and for an update to the definition of Essential Fish Habitat (EFH) in 2017, qualitative assessments of these species based on presence-absence survey data were done for late juvenile and mature life stages. To improve on these EFH assessments, we used a quantitative approach based on Maximum Entropy (MaxEnt) species distribution models to link habitat characteristics to species occurrence data from surveys for larval, juvenile and mature life stages. In addition, we used the best-fit models for each species and life stage to predict the distribution of suitable habitat separately for warm and cold years. In this summary, we present the probability of suitable habitat for each life stage of these species in the AMA (US Chukchi and Beaufort Seas). Shifts in the predicted probability of suitable habitat during warm and cold conditions varied by species and life stage. These predicted differences in response to changing temperatures provide insight into future shifts in distribution with climate change.

Introduction

The climate and oceans are rapidly warming in the Alaskan Arctic and will likely have far reaching impacts on marine ecosystems, including the distribution of fishes. Currently, Essential Fish Habitat (EFH) definitions for Arctic species identified as potential target species in the Arctic FMP are qualitative based on presence-absence data. We refined EFH for Arctic cod, saffron cod and snow crab in the Beaufort and Chukchi Seas within the AMA (Fig. 1) using the most recent and best available science. Specifically, we use species distribution models to link habitat characteristics to species occurrence data from numerous surveys. Preliminary maximum entropy (MaxEnt) models were developed by the lead author with support from Alaska Sea Grant and NOAA's Habitat Conservation Division. These models were applied to combined juvenile and adult life stages to produce maps of potentially suitable habitat for each species. Here, we further refined these models by incorporating new survey data from the Beaufort Sea, Barrow Canyon, and nearshore surveys dividing the survey catch data by life stage, as well comparing predicted distributions in warm and cold conditions. The ultimate goal is to refine the EFH text and maps for juvenile, adult and possibly larval life stages of Arctic cod, saffron cod and snow crab for the next 5 year EFH revision.

Objectives

1. Identify core habitat characteristics most important to the distribution and habitat suitability of larval (where data are available), juvenile and adult Arctic cod, saffron cod and snow crab.
2. Refine text descriptions of what constitutes EFH for all life stages (larval, juvenile, and adult) of Arctic cod, saffron cod and snow crab in the Beaufort and Chukchi Seas.

3. Refine maps depicting spatial habitat distributions, by life stage (larval, juvenile, and adult), for Arctic cod, saffron cod, and snow crab in the Beaufort and Chukchi Seas.
4. Develop separate maps of distribution and habitat linkages for life stages of saffron cod, Arctic cod and snow crabs during warm and cold periods.
5. Develop maps indicating distribution shifts between warm and cold periods
6. Develop maps of growth potential for juvenile Arctic cod overall, and separately for warm and cold periods.

Methods

We used environmental and biological survey data from 2000 - 2018 within the AMA to model the probability of suitable habitat for larval, juvenile and mature Arctic cod, saffron cod and snow crab using MaxEnt models. First, we compiled available survey data from 2000 - present and divided occurrences by species and life stage (based on body length and carapace width). We created rasters of potential habitat explanatory variables and selected a suite of independent variables (Table 1). Using explanatory habitat variable rasters and presence data from surveys we modeled the probability of suitable habitat by species and life stage and identified key habitat characteristics in each model. A given species and life stage was considered absent in grid cells that had a probability of suitable habitat less than 5%. Habitat suitability maps were created showing the smallest possible habitat area encompassing a given percentile of the cumulative habitat suitability over all grid cells. Cells where the probability of suitable habitat for a given species and life stage was greater than or equal to 5% were sorted in decreasing order and areas containing the upper 95%, 75%, 50%, and 25% of habitat suitability values were mapped (Figs. 2-4). We consider areas representing the top 25% to be hotspots with the highest probability of suitable habitat and the top 50% to be the "core habitat". The 95% level of areas where the species is present corresponds to the definition of EFH area in Alaska (Sigler et al. 2012). We also used the best-fit models to predict habitat suitability under warm and cold conditions by fitting the models to habitat raster sets from cold and warm years, respectively. Finally, we created potential growth rate maps for age 0 and juvenile Arctic cod and juvenile saffron cod using published, temperature-dependent, laboratory-based grow rate models (Laurel et al. 2016; 2017) and temperature rasters.

Results

For each species and life stage, distribution maps show key habitat areas including the core habitat area defined as the top 50% of suitable area (Figs. 2-4). Temperature was an important habitat covariate for predicting the probability of suitable habitat for many of the life-stage species combinations. Early life stages of Arctic cod were more sensitive to temperature changes and had larger fluctuations in suitable habitat between warm and cold years. The area of suitable habitat decreased for Arctic cod in warm years and increased in cold years indicating climate warming may limit their distribution in the Chukchi Sea. Like early life stages of Arctic cod, larval saffron cod were limited to cooler temperatures. For all older life stages of saffron cod, habitat suitability increased with temperature. Suitable habitat was greatest during warm periods for age-0 saffron cod, but was similar for older life stages. For adolescent snow crab, temperature fluctuations had limited influence on changes in habitat suitability. Mature males snow crabs were the most sensitive to changes in temperatures.

Conclusions

Increases in data availability from numerous surveys conducted since 2009 and advances in species distribution modeling allowed us to update and substantially refine habitat descriptions for three species by life stage in the Alaskan Chukchi Sea and Beaufort Sea. Model performance was acceptable or good in most cases, suggesting that our models provide an adequate basis for updated EFH descriptions for the target species. Moreover, the available data support the development of separate habitat models for warm

and cold conditions as an essential step towards dynamic EFH descriptions. Finally, we showed that estimates of growth potential based on temperature-dependent growth rates from laboratory studies, where available, can be combined with abundance estimates to further improve habitat descriptions by estimating the potential productivity.

Abstract

We used genetic techniques to identify gadids (cods) to species in the Pacific Arctic during a time of substantial physical changes in the marine ecosystem, between 2012 and 2019. The dominant fish species in the upper trophic level of the Chukchi Sea is Arctic Cod (*Boreogadus saida*); however other cods such as Saffron Cod (*Eleginus gracilis*), Pacific Cod (*Gadus macrocephalus*) and Walleye Pollock (*Gadus chalcogrammus*) have been observed. Two aims in this study were to evaluate the accuracy of at sea morphological identification with genetic species identification and to document the change in species composition and distribution of gadids in the Pacific Arctic. The morphologically cryptic nature of these gadids, particularly among young-of-the-year fish can lead to misidentification. Microsatellite and mtDNA genetic results revealed that most *B. saida* collected in the Chukchi Sea in 2012 and 2013 were correctly identified at sea. Conversely, results from samples collected in 2017 and 2019 revealed a large number of *G. chalcogrammus* and some *G. macrocephalus* and *E. gracilis* that were initially identified at sea as *B. saida*. The majority of misidentification occurred between *B. saida* and *G. chalcogrammus*. This study indicates a northward shift of *G. chalcogrammus* and *B. saida*. In addition, juvenile Polar Cod (*A. glacialis*), which is not typically found in the Chukchi Sea and was not identified at sea, was genetically detected at 3 hauls on the northern Chukchi shelf, outside of its documented distribution. Accurate species identification, especially during a time of changing marine landscapes, is not only important for survey abundance estimates but for downstream analyses as well. This emphasizes the value of implementing strategies for correct identification of the gadid species in order to better capture and monitor this change. Our results provide strong evidence of distributional shifts and range expansions of gadid species in the Arctic, which may be the result of changing climactic conditions.

Introduction

As changes in the ocean environment unfold in the Arctic, resident species will need to adjust, relocate or perish. Elevated water temperatures, melting sea ice, and other physical changes (Baker et al., 2020; Huntington et al., 2020; Danielson et al., 2020), will usher in an ecologically altered food web (Meuter and Litzow, 2008; Bluhm and Gradinger, 2008) as species seek their optimal habitat. In the past decade, geographic range expansions of species in areas of environmental change around the globe have been reported, such as the movement of *Dosidicus gigas* (Humboldt Squid) toward both poles in the Pacific Ocean (Zeidberg & Robison, 2007), advancement of *Gadus morhua* (Atlantic Cod) and *Mallotus villosus* (Capelin) into the Barents Sea (Howell and Filin, 2014), and shifts in distribution of the cods in the northern Bering Sea (Baker, 2021). Hundreds of species have already exhibited range shifts (Molinos et al., 2017; Pinsky, 2020; Poloczanska et al, 2013, 2016) and future shifts are projected for more species (Cheung et al., 2013; Molinos et al., 2015; Morley et al., 2018; Grebmeier, 2006). An altered ecosystem

in the Arctic will inevitably lead to winners and losers (Sigler, 2011; Fossheim, 2015; Bouchard, 2017; Moore and Stabeno, 2015; Kleisner et al., 2017). Restructuring of the ecosystem will benefit some species but will be detrimental to others. It is yet uncertain which species can take advantage of increased growth potential from warmer temperatures and freshwater input from coastal shelf areas (Copeman, 2016). For some of the northernmost cold-loving species like *Boreogadus saida* (Arctic Cod[1]) and *Arctogadus glacialis* (Polar Cod), there may ultimately be no refuge in a warming Arctic.

Here we focus on species of gadids in two marginal seas of the Pacific Arctic. The Chukchi Sea and the Bering Sea to the south are connected by the narrow Bering Strait. This is one of the world's most productive ocean ecosystems and is characterized by large continental shelves (Grebmeier et al., 2015) with high benthic biomass resulting from persistent nutrient, carbon, and heat flow through the Bering Strait (Woodgate et al., 2005; 2018; Carmack and Wassmann, 2006; Danielson et al., 2020). This flow from the Bering Sea into the Chukchi fuels high primary productivity (Huntington et al., 2020). Recent estimates of net community production (NCP) identify the northern Bering and Chukchi shelves as the single most productive region across the entire Arctic marine system (Codispoti et al., 2013). However, it is a system currently undergoing rapid change (Danielson et al., 2020; Huntington et al., 2020).

In the Bering Sea, the climate over the past 40 years has shifted from high inter-annual variability to multi-year regimes of warmer and colder years (Stabeno, et al., 2012; 2017; Stevenson and Lauth, 2012; Duffy-Anderson, et al., 2017). The Bering Sea cold pool, an area of bottom shelf waters cooler than 2° C resulting from ice melt (Wyllie-Echeverria and Wooster, 1998), has diminished in size in the recent warm years (Conner and Lauth, 2017), particularly in the summers of 2017–2019 (Stevenson and Lauth, 2019). The cold pool has long served as a thermal barrier preventing northward migration of subarctic groundfish (Stevenson and Lauth 2019; Baker, 2020). Ice formation was delayed in the winter of 2017/2018 and even later in 2018/2019, resulting in low abundance of ice algae which lead to low abundances of lipid-rich copepods and a high number of small, lipid-poor copepods, and subsequent cascading impacts on higher trophic levels in the northern Bering Sea marine ecosystem (Siddon et al., 2020). Temperature changes in the Bering Sea have led to an increase in water flow north into the Chukchi Sea (Woodgate et al., 2018), which has experienced similar environmental shifts with increased temperatures, earlier ice melts, and longer ice-free seasons (Frey, 2015; Wood, 2015).

The dominant fish species of the Chukchi Sea has historically been *Boreogadus saida* (Arctic Cod) (De Robertis, et al., 2017; Logerwell et al., 2015), followed by *Eleginus gracilis* (Saffron Cod) (Datsky, 2016; Whitehouse et al., 2014; Goddard et al., 2014; Logerwell et al., 2015). *B. saida* is a circumpolar species, and is usually associated with ice covered waters (Gradinger and Bluhm, 2004). In the Chukchi, *B. saida* is found in a temperature range of 2 to 6.7 °C (Ponomarenko, 1968, Wyllie-Echeverria, 1995, De Robertis et al., 2017), although age-0 fish have been found to grow optimally in the laboratory at 9°C (Laurel et al., 2018). Eggs of *B. saida* are typically associated with ice and develop normally in -1.0°C to 3.5°C, but not >5°C (Drost et al., 2016; Kent et al, 2016). *E. gracilis* has an Arctic-boreal Pacific distribution and occupy nearshore regions from the Korea Peninsula to southeast Alaska and to Dease strait in the Canadian Arctic (Mecklenburg et al., 2002; Vestfals et al., 2019). *E. gracilis* tolerates higher temperatures (>7.5°C), than *B. saida* (Copeman et al., 2016; Laurel et al., 2016), and tolerates areas of lower salinity (Wolotira, 1985) than *B. saida* (De Robertis et al., 2017). In colder years, both *B. saida* and *E. gracilis* are also found in the Bering Sea (Baker et al., 2021; Lauth, 2011).

[1] The common names, Arctic Cod and Polar Cod, are used interchangeably for *Boreogadus saida* and *Arctogadus glacialis* in the literature. In this article we use latin names or follow the most current list of common names published by the American Fisheries Society (Page et al., 2013), and capitalize all common names per ASIH and AFS policy.

Two abundant gadids in the Bering Sea are *Gadus chalcogrammus* (Walleye Pollock) and *Gadus macrocephalus* (Pacific Cod). The geographic distribution of *G. chalcogrammus* is primarily boreal Pacific, with records south to California and Korea and also in the N. Atlantic (Mecklenberg et al., 2011). It is among the top fished species in the world, with the major fishing grounds in the Bering Sea and Sea of Okhotsk (Bulatov, 2014). *G. macrocephalus* occur on continental shelves and slopes from 34-63 N latitude on both sides of the North Pacific from the Yellow Sea to the Okhotsk an Bering Seas, and across the northeastern Pacific to Oregon (Allen & Smith, 1988; Canino et al., 2010). Both *G. chalcogrammus* and *G. macrocephalus* prefer waters above 0°C (Wyllie-Echeverria and Wooster, 1998; Kotwicki and Lauth, 2013) but otherwise tolerate a large temperature range (Baker and Hollowed, 2014).

Gadids in the Pacific Arctic are morphologically similar, and species can be difficult to distinguish. *G. chalcogrammus* and *B. saida* larvae (<60 mm) are particularly cryptic. A few characteristics are reported in Matarese et al., (1989) involving mostly pigmentation differences. Additional distinguishing characteristics emerge with larger fish, but in general, larval gadids, particularly *G. chalcogrammus* and *B. saida*, are difficult to identify in the field.

In this study, we genetically examine these four gadid species in the Pacific Arctic during a time of substantial physical changes in the marine ecosystem, 2012–2019. We have two aims: 1.) To evaluate the accuracy of at sea morphological identifications with genetic species identification and 2.) To document the change in species composition and distribution of gadids sampled in the North Pacific Arctic in 2012, 2013, 2017 and 2019.

Methods

Sample collection

Gadids were collected by vessels operating in the eastern Chukchi Sea in 2012, 2013, 2017, and 2019 (Table 1). Samples were collected through a combination of bottom trawl (a 3-m plumb-staff beam trawl) and a mid-water/surface trawl (a modified Marinovich midwater trawl). An additional collection of *B saida* was opportunistically collected in the Bering Sea in 2010 when present in bottom trawls. In 2012, 2013, 2017, and 2019, *B. saida* was targeted for genetic sampling in the Chukchi Sea to examine its population structure. In 2012, *B. saida* samples were collected by bottom trawl and up to 36 fish were randomly sampled from each haul. Conversely, in 2013 and 2017, *B. saida* were collected by mid-water/surface trawl. In 2013, larger sample sizes (150+) were retained from each haul. The 2017 *B. saida* collections included some individually barcoded samples and some bulk samples (n=50).

Initial genetic screening of the 2017 samples of *B. saida* detected large numbers of *G. chalcogrammus* in the southern Chukchi Sea that had not been identified in the field. This prompted a decision to collect a larger subsample of cods in 2019 for genetic identification, as well as some additional 2017 samples. Sampling in 2019 was also conducted primarily by midwater/surface trawls. Lengths and weights of up to 60 specimens of each cod species were subsampled from each trawl. Fish were frozen whole at sea at -80°C.

Additional fish identified as *B. saida* from the N. Bering Sea collected in 2010 by surface/mid-water trawl, were added for comparison of samples to an earlier, cooler, year, and to illustrate the southern reaches of this species during some years.

Laboratory

DNA was extracted from 7,009 cod tissue samples using Qiagen DNeasy[2] Tissue kit protocols. We took a two-phase approach to distinguishing among candidate gadiid species (*B. saida, E. gracilis, G. chalcogrammus, G. macrocephalus, and Arctogadus glacialis* [Polar Cod]). Because the initial objective was to examine population structure of *B. saida*, all samples were first examined with microsatellite markers. After analysis of the 2017 collections, it was determined that species other than *B. saida* were present in the sample. One microsatellite marker was highly diagnostic, *Sai25*, in distinguishing *B. saida* from the other gadids. Next, for all non-*B. saida*, we sequenced a partial cytochrome oxidase c, subunit I (COI) fragment to distinguish the remaining cods.

Microsatellites

We developed a microsatellite marker, *Sai25*, using methods derived from Glenn and Schable (2005) that was diagnostic for *B. saida*. Adult *B. saida*, *G. chalcogrammus*, *E. gracilis*, and *G. macrocephalus* were morphologically identified by a skilled taxonomist, and tissue samples were used as reference samples in the initial microsatellite investigations of samples collected in 2012. Reactions were prepared according to manufacturers' instructions with primers (*Sai25*F: 3'CAGTTGACCACATCCCACCA and *Sai25*R:3'ATTTCACGTCCCATACCCCG), Qiagen master mix and RNase-free water. Thermal cycling was performed under the following conditions: 95°C for 15 min, 28 cycles of amplification (94°C for 30 sec, 60°C annealing temperature for 90 sec, and 72°C for 60 sec), and a final extension cycle of 72°C for 30 min. Fragments were analyzed on a 16 capillary ABI 3130xl DNA Analyzer (Applied Biosystems [AB]), and genotypes were determined with Genemapper 5.0® (AB) software. Samples which exhibited a size range of 280-283 base pairs (bp) at microsatellite marker *Sai 25* were clearly identified as *B. saida*. All other gadids exhibited fragment sizes larger than 300 bp and overlapping in size: *E. gracilis*, 302-324*, G. chalcogrammus*, 308-400*,* and *G. macrocephalus,* 304-382.
mtDNA.

To identify the species of individuals with *Sai25* alleles outside the allele size range for *B. saida*, a partial region of the mtDNA gene cytochrome oxidase I (COI) was sequenced. This ~170 bp segment of COI was amplified using the coi.175f and coi.345r primers described in Collins et al. (2019). We confirmed that this region contained SNPs that could differentiate each of the 5 possible gadid species (*B. saida*, *G. chalcogrammus*, *E. gracilis*, *G. macrocephalus*, and *A. glacialis*) using sequence data downloaded from the National Center for Biotechnology Information. Specifically, we downloaded COI sequences from the following species: 7 sequences from *A. glacialis*, 31 sequences from *B. saida,* 75 sequences from *E. gracilis,* 64 sequences from *G. macrocephalus*, and 233 sequences from *G. chalcogrammus*. Most of the sequences were vouchered specimens; this was especially true for species with less available sequences. We then used the software Geneious (https://www.geneious.com/) to align and compare reference sequences. Visual comparisons revealed at least one diagnostic SNP between each species, with many more for most comparisons. Additionally, we did not notice any potentially misidentified specimens in the database, as diagnostic SNPs were consistent across specimens.

Amplicon libraries were prepared for COI sequencing using a slightly modified genotyping-in-thousands by sequencing protocol (Campbell, et al., 2014; described in Gehri eta al., 2020). Libraries were sequenced on an Illumina MiSeq using 2x75 bp chemistry. R1 and R2 sequences were processed separately and grouped into unique variants using the R package Dada2 (Callahan et al., 2016). Sequences were then compared to existing COI sequences for gadids (described above) using nBLAST, and species were identified based on the best alignment for each sequence. Samples were only assigned a species ID if the best aligning sequence contained > 100 reads, species identification for the R1 and R2 sequences matched, and at least one of the reads (R1 or R2) produced an unambiguous alignment (i.e., best match to

[2] Mention of trade names or commercial companies is for identification only.

a single species). Some samples were not able to be resolved due to poor sample quality (127 of the 2,139 samples from 2017 and 133 samples of the 3,611 samples from 2019) and were removed from analyses.

Analyses

Field species identification was evaluated for accuracy with a confusion matrix using the caret package in R (Kuhn et al., 2016). The matrix allows for examination of the classification of each of the five gadid species. It provides a visual of how many fish were correctly identified at sea (true positives and true negatives), and how many were incorrectly identified at sea (false positives: *B. saida* at sea but non-*B. saida* in the lab and false negatives: non-*B. saida* at sea, but *B. saida* in the lab). From the confusion matrix we calculated the sensitivity (SE) for a given species *s*,

$$SEs = \frac{TPs}{TPs + |\ FNs}$$

where TP is the number of true positives and FN is the number of false negatives. The specificity (SP) for each species was calculated as

$$SPs = \frac{TNs}{TNs + |\ FPs}$$

where TN is the number of true negatives and FP is the number of false positives. The average of SE and SP provides the balanced accuracy (BA) and gives an estimate of the overall accuracy of at sea species identification. Analyses were conducted separately for small and large size classes of fish from 2017 and 2019. Fish sizes of 60 mm or smaller were classified as age-0 (Helser et al., 2017) and fish larger than 60 mm were classified as age 1+.

Results

Analysis of microsatellite marker *Sai25* was completed for all gadids (N=7,014) collected in the Bering Sea in 2010 (N=89) and the Chukchi Sea in 2012 (N=575), 2013 (N=860), 2017 (N=2,012), and 2019 (N=3,478) (Table 1). A subset of these samples (N=2,949) were also sequenced at a partial COI fragment (2010, N=54; 2012, N=175; 2013, N=122; 2017, N=744; 2019, N=1854 (Appendix 1)). A summary of the results was created by amalgamating the number of each species detected in 2° latitudinal increments for each year (Table 2). Genetic analysis of the 2010, 2012 and 2013 samples exhibited mostly *B. saida*, with a few *G. chalcogrammus* (0/89 individuals in 2010, 3/575 individuals in 2012 and 1/860 individuals in 2013) (Table 2; Fig. 1a). Fish caught in 2017 and 2019 revealed the presence of 4 species of gadids: *B. saida*, *G. chalcogrammus*, *G. macrocephalus*, and *E. gracilis*, and the presence of a fifth species, *Arctogadus glacialis*, in the 2019 collection. The 2017 collection contained 1,492/2,012 *B. saida*, 428/2,012 *G. chalcogrammus*, 66/2,012 *G. macrocephalus*, and 26/2,012 *E. gracilis* (Table 2, Fig. 1b). The 2019 collection was comprised of 1,753/3,478 *B. saida*, 1,474/3,478 *G. chalcogrammus*, 46/3,478 *G. macrocephalus*, 182/3,478 *E. gracilis*, and 13/3,478 *Arctogadus glacialis* (Table 2, Fig. 1c).

Sampling efforts in 2010, 2012, 2013, and 2017 targeted collection of *B. saida*, and the 2010, 2012, 2013 collections exhibited 99.99% correct identification of *B. saida* at sea. Conversely, genetic identification of 2,012 fish caught in 2017 revealed that 21.6% were misidentified at sea. Because of this misidentification, a subsample of all species of cods was retained for genetic identification of the 2019 collection. Genetic identification of the 3,478 fish caught in 2019 revealed that 19.8% were misidentified at sea.

In the 2017 collection, 1,924 fish were identified at sea as *B. saida*; however 433 of those were genetically identified to be 420 *G. chalcogrammus*, 8 *G. macrocephalus*, and 5 *E. gracilis* (Table 3a-b). Additionally, 3 of the 62 *G. macrocephalus* identified at sea were genetically identified as *G.*

chalcogrammus. In both size classes, 0 specimens were identified at sea as *G. chalcogrammus* in 2017 (Fig. 2a & b). *G. chalcogrammus* at sea species IDs that were not identified as *G. chalcogrammus* (specificity, SP), for both small and large size classes, was 0.00. A zero SP means zero *G. chalcogrammus* were correctly identified at sea. The balanced accuracy (BA) = 0.50, is the same as correct identification by random chance (Table 3a-b). The high sensitivity for *B. saida* (SE = 1.0) indicates all genetically identified *B. saida* were correctly identified as *B. saida* at sea, but the low specificity (SP = 0.01) indicates many fish identified at sea as *B. saida*, were genetically identified as something else (Table 3a-b). The balanced accuracy of evaluating *B. saida* is slightly better for larger fish (BA = 0.51 in small fish and 0.75 in larger fish) (Table 3a-b). Smaller *G. macrocephalus* and *E. gracilis* were correctly identified at sea more often than at random (in 2017, BA = 0.62 and 0.69) while, larger *G. macrocephalus* and *E. gracilis* had a high accuracy of at sea identification (BA = 0.96 and 1.0; Table 3a-b).

In the 2019 collection, 2,398 fish were identified at sea as *B. saida*. Of those specimens, 676 were genetically identified as: 654 *G. chalcogrammus*, 13 *A. glacialis*, 7 *E. gracilis*, and 2 *G. macrocephalus* (Table 3c-d). Additionally, 21 of the 853 *G. chalcogrammus* identified at sea, were genetically determined to be *B. saida*. Most samples of *G. macrocephalus* and *E. gracilis* were correctly identified at sea. Of 45 *G. macrocephalus*, 2 were genetically identified as *B. saida* and of 182 *E. gracilis*, 7 were misidentifed as: 5 *B. saida*, one *G. chalcogrammus* and one *G. macrocephalus* (Table 3c-d). The accuracy of species identification at sea for both large and small size classes improved in 2019. The accuracy of both *B. saida* and *G. chalcogrammus* produced a BA of 0.74 for small fish sizes and 0.86 and 0.87 for larger fishes. The accuracy for *G. macrocephalus* and *E. gracilis* identification was high for smaller fishes (BA = 0.83 and 0.91) and very high for larger fish (BA=0.99; Table 3c-d). Juvenile *A. glacialis* was not identified at sea, but genetic identification detected this species at 3 hauls in the northernmost areas of the cruise. In 2019, 13 age-0 *Arctogadus glacialis* (Polar Cod) were detected in the northernmost area of the survey (Fig. 3a & b)

Discussion

Monitoring the compositions of marine species in a changing Arctic is not only important for understanding the overall effects on the ecosystem, but for understanding of local food sources, commercial fishery management, and resource protection. This study provides evidence of a distributional shift to the north of *G. chalcogrammus* and *B. saida*. In the colder years of 2012 and 2013, *B. saida* was the primary cod species in the Chukchi Sea, with little observation of the other cods except for *E. gracilis* which was also present in the Chukchi Sea as noted by De Robertis (et al., 2017). The warmer years of 2017 and 2019 revealed a progressive infusion of *G. chalcogrammus* and to a lesser extent, *G. macrocephalus*. *G. chalcogrammus*, while detected in small numbers (< 1% of the catch) in the Chukchi and Beaufort seas in the cooler years of 2008-2013 (Goddard et al., 2014; Logerwell et al., 2015) accounted for 42% overall of the gadid specimens collected for genetic analysis in 2019, and was present in high densities in the southern Chukchi Sea and Kotzebue Sound (Levine et al, 2021).

B. saida is also moving north, whether due to competition with *G. chalcogrammus* or physical marine changes is unknown. *B. saida*, was detected at lower latitudes in the cooler years, as far south as latitude 60° N in the Northern Bering Sea in 2010 (this study). By 2019, only 14 *B. saida* individuals were genetically detected in gadid samples collected south of latitude 70° N. This is corroborated by observations by the AFSC groundfish survey: Arctic cod had a 99% decline in biomass in the northern Bering Sea between 2017 (4,000 mt) and 2019 (47 mt) (AFSC survey, 2019). Fishes that prefer colder water conditions, such as Arctic Cod (*B. saida*), showed declines in abundance in the northern Bering Sea from previous survey years (Baker, 2021). While age-0 *B. saida* is thought to be able to maximize growth at the elevated temperatures seen during 2017 and 2019 (Laurel et al., 2018), we speculate the reasons for the movement north may be more related to increased water flow from the Bering Sea (Woodgate 2018),

bringing a shift in *B. saida* prey and competition from the incoming *G. chalcogrammus*. Along with warmer boreal waters from the south come more boreal lipid poor copepods which displace the Arctic lipid rich copepods (Siddon et al., 2020). Early ice breakup and warmer growing conditions enhance the survival of *B. saida* because of early hatching, an extended growth season, and optimal growth temperatures, however, competition and predation from invading subarctic species will likely negate these positive effects (Bouchard et al., 2017). Scenarios of lower salinity are also predicted for coastal and shelf areas as warming temperatures increase river runoff (Bluhm and Gradinger, 2008), which would favor *E. gracilis* over *B. saida*.

Another gadid species which was unexpectedly detected in our sample is *Arctogadus glacialis*. *A. glacialis* is common in the Canadian, Russian, and northeast Atlantic Arctic, however documentation for occurrence in the Pacific Arctic is scarce (Mecklenburg et al., 2014). Only 3 records of its presence has been previously noted in the literature in the northern Chukchi Sea area. Andriashev (et al., 1980) reports *A. glacialis* in Siberia on the deeper border waters of the Chukchi Sea to 81°N, 178° W and two records (age 1+, 98 mm and 221mm) in the Chukchi Borderlands: 76° N, 164° W (Mecklenburg, 2014). We identified 13 specimens of age-0 *A. glacialis* (37-50 mm) from three different trawl sites in our 2019 collection. These specimens were all collected in waters at approximately latitude 72° N and longitude 161° W.

Arrival in a new region does not guarantee establishment and subsequent positive population growth (Burgess et al. 2012, Sadowski et al. 2018). A range expansion may occur if the species are able to adapt to a broad range of environmental conditions. A successful invasion or colonization requires a species to disperse to a new location and maintain positive growth through either self-persistence or ongoing immigration (Bridle and Vines 2007). A leading edge of both *G. chalcogrammus* and to a lesser extent, *G. macrocephalus* were noted in the Chukchi Sea in 2017 and 2019, but it is unknown if these fish are able to over winter in the freezing temperatures and ice formation in the Arctic winter (Woodgate et al., 2005). Northward expansion of Atlantic croaker (*Micropogonias undulatus*) along the east coast of the United States in the 1990s has been linked to sequential warm winters that allowed cold-sensitive juveniles to survive through the winter and subsequently establish north of the species' historical range (Hare and Able, 2007). Lionfish juveniles, by contrast, have appeared as far north as New York (implying no lack of dispersal abilities) but have not become established above Cape Hatteras because they fail to survive through the winter (Grieve et al., 2016). In the Barents Sea, recent warming has led to a change in spatial distribution of fish communities (Fossheim et al., 2015). Along the western coast of Svalbard, an influx of warm Atlantic water produced a northward expansion of boreal Atlantic cod (*Gadus morhua*) and haddock (*Melanogrammus aeglefinius*) into areas dominated by the native *Boreogadus saida* (Renaud et al., 2012). Continued warming is likely to enable Atlantic croaker, lionfish, and other species to survive year-round at higher latitudes (Grieve et al. 2016, Hare and Able, 2007).

Pertaining to the Chukchi Sea, perspectives during the cooler sea surface temperatures of 2008-2013 were that bottom water temperatures in the Arctic were too cold to support spawning *G. chalcogrammus*, and that the sub-adult fish caught at high latitudes may have been advected by currents from spawning locations in the Bering Sea (Hollowed, et al., 2013). Few adult pelagic fish were detected in the hydroacoustic survey or captured in the midwater trawl in 2017 and 2019 in the survey area (Levine et al., 2021). We speculate that the warmer waters and ice reduction of the warmer years of 2017-2019 have continued to reduce barriers to subarctic fish (Bering cold pool; Eisner et al., 2020) and have increased water transport from the Bering Sea, carrying sub-adult gadids into the Chukchi (Levine et al., 2021). It is yet unknown whether these age-0 invaders are able to overwinter in these arctic waters and spawn, and whether this constitutes a true range expansion.

Due to the reported distributions of previous surveys, the presence of *G. chalcogrammus* was not anticipated by collectors in 2017. Previous surveys indicated the primary pelagic fish species in the

Chukchi Sea were *B. saida* and *E. gracilis*. After reviewing the 2017 field collection misidentifications, shipboard scientists were able to more accurately identify these age-0 cods at sea with the help of a microscope. Counts of pyloric caeca were conducted on a subsample of specimens from each trawl and for individuals which could not be easily identified as *B. saida* or *G. chalcogrammus*. Specimens with <40 pyloric caeca were classified at sea as *B. saida* (W. Strausburger & N. Kuznetsova, personal communication September 2017). Without additional investment of time, species ID of these small (< 60 mm) fish are difficult. Next generation genetic techniques are able to provide high throughput, reliable species identification at affordable costs in a reasonable period of time. Future surveys may benefit from identifying to genus at sea, and retaining fish (or a small piece of tissue) for post survey genetic species identification.

Correct species identification may also have implications for historic data. *G. chalcogrammus* and *G. macrocephalus* have previously been noted in low abundances in the Chukchi Sea (Goddard et. al., 2014; Logerwell et al., 2015). Surveys in the Chukchi and Beaufort Seas in 2008 detected low abundance for both *G. chalcogrammus* and *G. macrocephalus* (< 1% for both) of the catch (Logerwell et al., 2015). The catch of these species in both seas were of sizes greater than 90 mm (age 1+). Species identification of fish in 2017 and 2019 seemed to improve with size, and supports the idea that the larger size class from the 2008 surveys were correctly identified. Additionally, ichthyoplankton tows in the Beaufort Sea in 2008 revealed a small presence of *G. chalcogrammus* larvae, although adults were not observed in the Chukchi or Beaufort Sea (Logerwell et al., 2015). Surveys of the Chukchi in 2012 also reported low abundance of both *G. chalcogrammus* and *G. macrocephalus* (Goddard et al., 2014). Genetic identification revealed that at sea species identification was mostly accurate in 2012 and 2013 with < 1% misidentification of specifically targeted *B. saida* and very few *G. chalcogrammus* were identified in pelagic trawls in the Chukchi Sea in 2012 (18 age 1+ and 10 age-0 specimens, De Robertis et al., 2017). Even with the unlikely potentiality of misidentification of juvenile cods in the 2008 (Logerwell et al., 2015) and 2012 (Goddard et al., 2014) Chukchi surveys, the increase in juvenile *G. chalcogrammus* in summer waters of the Chukchi Sea in 2017 and 2019 is noteworthy: 21% of the genetic sample in 2017, and 42% in 2019.

Accurate species identification, especially during a time of changing marine landscapes, is not only important for survey abundance estimates (Levine et. al., 2020; 2021), but for downstream analyses as well. Laboratory analyses such as ageing, diet, stable isotopic composition, and energetics, rely on accurate species identification. Age-0 cods, particularly *G. chalcogrammus* and *B. saida* have been recognized as difficult to differentiate in the field. One study suggests that *G. chalcogrammus* may be a genealogically recent hybrid of *B. saida* and *G. morhua* (Arnason and Halldorsdottir, 2019). The two species at early life stages are identical at most exterior characteristics (Matarese et al., 1989; Mecklenberg et al., 2018). The presence of *G. chalcogrammus* and *G. macrocephalus* in the southern Chukchi Sea in 2017 highlights the importance of genetics in identifying morphologically similar species and comparing with at sea identifications.

Our results provide strong evidence of a change of gadids in the Pacific Arctic (at least in summer). The change in species composition of juvenile cods in the Chukchi Sea between the summer of 2012 and 2019 is dramatic. Because of the difficulty in distinguishing between external morphologies of these species, major increases in the abundance of age-0 *G. chalcogrammus* in the Chukchi, and the northern shift of the distribution of *B. saida* would not have been detected without genetic sampling of the survey catch. This emphasizes the importance of implementing strategies for correct identification of the cod species in the Arctic in order to better capture and monitor the ecology of this rapidly changing region.

CHAPTER 5 - The effect of oceanographic variability on the distribution of larval fishes of the northern Bering and Chukchi seas

Objective 2: Quantify the distribution, abundance, and condition of pelagic marine fishes, in particular young-of-the-year Arctic gadids and other forage fishes

Logerwell, E.A., Busby, M., Mier, K.L., Tabisola, H., Duffy-Anderson, J., 2020. The effect of oceanographic variability on the distribution of larval fishes of the northern Bering and Chukchi seas. Deep Sea Res. Part II Top. Stud. Oceanogr. 104784. https://doi.org/10.1016/j.dsr2.2020.104784

Abstract

We investigated the pelagic habitat requirements of Arctic larval fish and the effects of interannual variability of ocean conditions on their distribution. We examined the distribution of larval Arctic cod, Bering flounder, yellowfin sole and capelin in the Chukchi and northern Bering seas during two years with different oceanographic conditions. We found that despite marked changes in water mass distribution, the distributions of larval fishes were not significantly different between the two years. In both years, Arctic cod and Bering flounder were found in cold, high salinity shelf waters advected from the south and influenced by winter cooling (Chukchi Winter Water and Anadyr Water mix). Yellowfin sole and capelin distributions were also similar from year-to-year but they were only found in warm, low salinity Alaska Coastal Water. The cold, high salinity water masses had elevated large copepod biomass, and the Alaska Coastal Water had elevated small copepod biomass. Thus, we propose that these water masses provided different but nonetheless potentially profitable foraging habitat for the four species of larval fishes. We conclude by suggesting that the timing and location of spawning of these species has evolved such that larval offspring are distributed in suitable foraging habitat despite interannual variability in ocean conditions. This study provides a baseline of Arctic larval fish distribution and insight into the degree of climate variability that might be expected to impact early life history stages of larval fish. Our results also increase the knowledge of the mechanistic links between oceanography and the early life history of fish. Because growth and survival of early life stages of fish often drives population change, our results contribute to the understanding of the impacts of climate change on Arctic fish populations.

Keywords: USA, Alaska, Chukchi Sea, Fish larvae, Climate changes, Polar waters, Habitat

Introduction

The Arctic climate is rapidly changing. Ocean temperatures have been warming at over two times the global rate since the mid-20th century (Huang et al., 2017). Sea ice extent, duration and thickness have been declining at an increasing pace (Kwok and Rothrock, 2009; Meier et al., 2012; Wang and Overland, 2015). Embedded within these long-term trends is a high degree of interannual variability in sea ice timing, duration, extent and thickness, as well as ocean temperature and currents (Day et al., 2013; Wang and Overland, 2015; Woodgate et al., 2015). It is not known with certainty how changes in Arctic climate will impact fish, although impacts are expected. Increased water temperatures may affect growth rates negatively or positively depending on the fish's optimum growth temperature and food availability (Björnsson et al., 2001; Laurel et al., 2015). Reductions in sea-ice extent may negatively impact fish that depend on sea ice for spawning, such as Arctic cod (Rass, 1968). On the other hand, an increase in the open water period due to loss of sea ice may result in increased primary production which could benefit fish feeding (Arrigo et al., 2008). The timing of spring season sea ice retreat is also an important factor. Earlier sea-ice retreat with ocean warming may change the timing

and intensity of the spring bloom of phytoplankton resulting in a reduction in productivity and/or a mismatch between the timing of larval first feeding and the availability of prey (Grebmeier, 2012). The survival of early life history stages of fish is generally thought to be an important determinant of variability in the abundance of subsequent older age classes (Hjort, 1914; Lasker, 1981). Furthermore, early life stages of fish are particularly sensitive to changes in their environment such as variability in transport to nursery habitat, exposure to predators and changes in food availability (e.g. Siddon et al., 2011). Thus, an understanding of the impacts of interannual variability and long-term climate trends on Arctic fish populations benefits from information on Arctic fish early life history.

Our work was part of the Arctic Ecosystem Integrated Survey (Arctic EIS), a University of Alaska College of Fisheries and Ocean Sciences program conducted in 2012 and 2013 to document physical and biological oceanography, zooplankton, ichthyoplankton, demersal fish and pelagic fish. The overarching goals of the program were to understand the environmental forcing that impacts northern Bering and Chukchi sea ecosystems and to predict the future effects of reduced sea ice and ocean warming on these ecosystems (Mueter et al., 2017). The goal of the work presented here was to study Arctic fish larval distributions and oceanographic habitat associations. The northern Bering and Chukchi seas are mostly shallow shelves (< 60 m depth) with currents typically flowing northward due to the difference in sea level between the Pacific and the Arctic (Aagaard et al., 2006). Local winds can slow the northward flow or even redirect the flow to the south or west, depending on the direction of the winds (Panteleev et al., 2010). Water masses in the northern Bering and Chukchi seas include warmer, fresher Alaska Coastal Water flowing along the eastern shore and Anadyr/Bering Summer Water flowing across the shelf with moderate temperatures and salinities (Fig. 1). The Anadyr/Bering Summer Water transforms to Chukchi Summer Water as it flows north over the Chukchi Sea shelf. Near-bottom cold and salty Bering and Chukchi Winter Waters are the result of previous winter cooling and are resident to each shelf area. Finally, Melt Water is colder, fresher water at the surface formed by melting of sea ice and in summer is only found in the northern Chukchi Sea (Danielson et al., 2017). These different water masses have different nutrient concentrations and productivity. The colder shelf and winter waters are typically nutrient-rich and productive whereas the Alaska Coastal Water is low in nutrients and productivity (Danielson et al., 2017; Springer and McRoy, 1993).

Atmospheric and oceanographic conditions observed during the Arctic EIS surveys were different between 2012 and 2013, leading to subsequent variations in water mass distribution (Danielson et al., 2017). Sea level pressure and the resulting wind fields strongly contrasted between years. In 2012, low pressure was centered over the northwestern Chukchi Sea resulting in the typical winds from the southwest. In 2013, zonally (longitudinally) elongated low pressure over the Bering Sea resulted in zonal winds from the east. Drifter and high-frequency radar data suggest that the result of these wind differences was that the freshwater core of the Alaska Coastal Current was mostly absent from the Northeast Chukchi Sea during 2013. These differences in winds and currents resulted in pronounced differences in the distribution of water masses. In 2012, Alaska Coastal Water was observed close to shore from the northern Bering Sea all the way to the Northeast Chukchi Sea (Point Barrow). In contrast, in 2013, Alaska Coastal Water was only observed as far north as Ledyard Bay in the Chukchi Sea; and it spread at least 100 km farther offshore in the Northern Bering Sea compared to 2012. Along with more extensive northerly distribution of Alaska Coastal Water in 2012 the Anadyr/Bering Summer Water/Chukchi Summer Water mix extended farther north in 2012 than in 2013. There were also interannual differences in temperature, salinity, nutrients and chlorophyll biomass (Danielson et al., 2017). Surface waters were warmer and near-bottom waters were less saline in 2013 than 2012. Macronutrients, particularly in surface waters, were also different between years: there was less surface nitrate, ammonium and phosphate in 2013 than in 2012, likely leading to nutrient limitation of phytoplankton growth in 2013. In fact, average integrated chlorophyll was lower in 2013 than in 2012

(Danielson et al. 2017). Sea-ice conditions in 2012 and 2013 were similar. Winter sea ice was relatively high but June sea-ice concentrations were below normal in both years.
To investigate the potential impact of interannual variability in water mass distribution, we compared the spatial distribution of fish larvae collected in the northern Bering and Chukchi seas in 2012 and 2013. Our expectation was that larvae would be distributed farther north in 2012, and farther offshore in 2013. We propose that this would be a result of spawning location and subsequent advection within the water masses. To understand larval fish habitat associations, we mapped the distribution of larvae relative to water mass and to explore the potential foraging value of water masses, we examined their biological characteristics in terms of chlorophyll and zooplankton biomass. We also mapped the distribution of eggs and compared larval length frequency distributions for clues about spawn timing and location. The overall goal of our research presented here is to define larval oceanographic habitat and to improve our understanding of the mechanisms and the magnitude of climate variability that impact Arctic fish early life history.

Methods

Ichthyoplankton and oceanographic data were collected at stations spaced 28 or 55 km apart, depending on location, over a survey grid that spanned the U.S. northeastern Bering Sea and Chukchi Sea shelves (157–170°W, 60–72°N, Fig. 2). Sampling occurred from 7 August – 24 September in both years, with a similar order of station occupations. Ichthyoplankton were collected at the primary stations (55-km spacing) and at the higher resolution stations (28-km) with a 60-cm bongo sampler fitted with two 0.505 mm mesh nets with detachable codends at 138 stations in 2012 and 143 stations in 2013. During all cruises, quantitative oblique tows were made to a maximum depth of 200 m (or to within 10 m of the substratum), resulting in vertically integrated estimates of larval fish abundance. The ship speed was monitored and adjusted (1.5 to 2.5 knots) throughout each tow to maintain a wire angle of 45° from the ship to the bongo net. The nets were equipped with a calibrated flow meter; therefore, catch rates were standardized to effort and converted to catch 10 m^{-2} of sea surface area (CPUE; number 10 m^{-2}). Sampling occurred during daylight hours as per ship protocol. Samples were preserved in 5% formaldehyde-sea water solution buffered with sodium borate.

Samples were sorted and fish eggs, larvae and juveniles identified to the lowest taxonomic level possible at the Plankton Sorting and Identification Center in Szczecin, Poland. Taxonomic identifications were verified at the Alaska Fisheries Science Center (AFSC) in Seattle, WA, following Matarese et al. (1989), Busby et al. (2017), and the Ichthyoplankton Information System (https://access.afsc.noaa.gov/ichthyo/). Some fish eggs and larvae were categorized as taxonomic groups (e.g. *Limanda* spp., *Liparis* spp.) due to limitations associated with identifying egg and larval stages to the species level. In the case of *Limanda* spp. eggs, *Limanda aspera* were by far the most common species of *Limanda* larvae, so we treated *Limanda* spp. eggs as *L. aspera* in the analyses. In some cases, identifications of damaged specimens were made at the family level. In these instances, the identifications were not included in counts of species richness or diversity because they were considered to be of taxa that could normally be successfully identified. Taxonomic nomenclature follows (Mecklenburg et al., 2018), except for Bering flounder (*Hippoglossoides robustus*) which, according to Mecklenburg et al. should now be classified as flathead sole (*Hippoglossoides elassadon*) in the Arctic. However, the American Fisheries Society (Page et al., 2013) still lists the occurrence of flathead sole as Pacific only, and Bering flounder as Pacific and Arctic. We defer to the latter source and use Bering flounder in this paper. We use Arctic cod for the common name of *Boreogadus saida* after Mecklenburg and Steinke (2015).

Fish were measured for standard length (SL) to the nearest 1.0 mm. The separation point between the larval and juvenile stages for *B. saida* is 25.0 mm standard length (SL) based on the size at transformation of *Gadus chalcogrammus* determined by Brown et al. (2001). For other taxa, definition

of the juvenile stage follows Kendall et al. (1984) as a fish having complete adult complements of fin elements, scales and "the appearance of a small adult". The only taxa for which we caught juveniles was *B. saida*. Macro- and mesozooplankton were also collected with the 60-cm bongo frame (505 um mesh). Meso- and microzooplankton were sampled with a 20-cm PairVet net with 150 µm mesh attached to the array with the 60-cm frame. PairVet samples were only analyzed for the 2012 cruise, due to loss of data sheets at sea during 2013. All samples were preserved in 5% formalin, buffered with seawater for later processing. In the laboratory, each net sample was subsampled and taxa were identified, staged, counted and weighed. All animals in the samples were identified to the lowest taxonomic category possible. Sibling species *Calanus marshallae* and *C. glacialis* co-occurring in the Bering and Chukchi seas (e.g. Nelson et al., 2009) were not discriminated and are named as *C. glacialis* hereafter. Recent studies confirm that the vast majority of *Calanus* spp. in the northern Bering Sea are *C. glacialis* (Campbell et al., 2014). Copepodites stages were identified and recorded. Biomass values by station were computed for each species in grams m^{-3}. See Pinchuk and Eisner (2016) for details of zooplankton sampling and laboratory analyses. At the primary stations (55-km spaced), ocean temperature and salinity were determined from conductivity-temperature-depth measurements collected with a Sea-Bird (SBE) 911 or SBE 25 CTD equipped with a Wetlabs Wet-Star fluorimeter to estimate in vivo Chl*a*. In addition, a SBE 49 or SBR19+ CTD was towed with the bongo net to obtain hydrographic data at higher spatial resolution (between primary stations). At the primary stations, water samples for total Chl*a* were collected at ~10 m depth intervals.

Danielson et al. (2017) identified four different bottom water masses-based on T/S diagrams derived from the survey oceanographic data: Alaska Coastal Water (ACW), Anadyr Water/Bering Shelf Water/Chukchi Shelf Water (AW Mix), Bering Winter Water (BWW) and Chukchi Winter Water (CWW). ACW was the warmest and freshest (7 – 12 °C; 20 – 32 salinity). CWW and BWW were the coldest and most saline (-2.0 to 0 °C; 30 – 33.5 salinity). The AW Mix was intermediate in temperature and high in salinity (0 – 7 °C; 30-33.5 salinity). Surface water masses were: Melt Water, which was relatively cool and fresh (-2 – 7 °C; 25 – 30 salinity); and AW Mix and ACW (as defined above). Ichthyoplankton distributions were overlaid on water mass distributions using ArcMap 10.5 (ver 10.5.0.6491).

A statistical test based on a generalized two-sample Cramér-von Mises test was employed to test for differences between the spatial distributions of ichthyoplankton between years (Syrjala, 1996). The null hypothesis for this specific test is that across the study area, the distributions of the populations are the same. The alternative hypothesis for this test is that there is some unspecified difference in the underlying distributions. The distributions are normalized so the test is sensitive to differences in the way populations are distributed across space, but insensitive to differences in abundance. The test is nonparametric, so no assumptions are required about the distributions of the populations. The test was implemented in R version 3.3.2 (R Core Team, 2016) using the "syrjala" function. The Kruskal-Wallis rank sum test was employed to test for differences in chlorophyll and zooplankton biomass density among water masses. A non-parametric test was used because the skewed distributions and heterogeneity of variances could not be remedied by data transformation. The test was implemented in R version 3.3.2 (R Core Team 2016).

Results

A total of 1057 individuals and 31 taxa of larvae and juveniles were sampled by the ichthyoplankton nets in 2012 and 2013 (Table 1). The four most abundant taxa collected were Pacific capelin (*Mallotus catervarius*), Arctic cod (*Boreogadus saida*), Bering flounder (*Hippoglossoides robustus*) and yellowfin sole (*Limanda aspera*). These four taxa were the focus of further analysis. Juvenile fish caught in the nets were all Arctic cod. Eggs of only 5 taxa were caught, mostly Bering flounder and yellowfin sole. Walleye pollock (*Gadus chalcogrammus*) eggs were only caught in the northern Bering Sea.

Bering flounder eggs were distributed in the north Chukchi Sea over the shelf during 2012 (Fig. 3 a). Very few eggs were caught in 2013, but they were found in a similar area as in 2012 (Fig. 3 b). In contrast, yellowfin sole eggs were found farther south, in the northern Bering Sea, and in the south/central Chukchi Sea, and relatively close to shore compared to Bering flounder (Fig. 4). No eggs of either Arctic cod or Pacific capelin were caught during the surveys.

Arctic cod larvae and juveniles were distributed in the north and northeast area of the survey in both years (Fig. 5a, b.). Arctic cod were the only taxa for which we caught juvenile fish. The distributions of the two life stages overlapped, such that for further analyses, we combined the data. The Cramer von-Mises test indicated that there was not enough evidence to support a statistically significant difference in the distribution of Arctic cod between years (ψ=3.233, P=0.165). Bering flounder larvae were distributed throughout the Chukchi Sea, and in the northern Bering Sea (Fig. 5b, c). The catch density of Bering flounder in 2013 was much less than 2012. Similar to Arctic cod, the Cramer von-Mises test indicated that there was not enough evidence to support a statistically significant difference in the distributions between 2012 and 2013 (ψ=1.498, P=0.767).

Yellowfin sole and capelin larvae had more southerly distributions than Arctic cod and Bering flounder (Fig. 6). Similar to the other two taxa, there was no statistically significant difference in the distributions between 2012 and 2013 (yellowfin sole: ψ=3.216, P=0.065; capelin: ψ=2.462, P=0.779).

Flatfish larval length-frequency distributions were examined along with their egg distributions (reported above) for information on spawning locations that could explain the distribution of larvae. No eggs of either Arctic cod or capelin were caught. Bering flounder larvae distribution was discontinuous around 70°N in 2012 (Fig. 5c). Very few larvae were caught in 2013. There was little overlap in the length-frequency distributions north and south of 70°N (Fig. 7) – larvae were smaller north of 70°N and larger south. Yellowfin sole larvae distribution was discontinuous at around 65.5°N (Fig. 6a, b). However, in contrast with Bering flounder, the length- frequency distributions of yellowfin sole larvae were similar north and south of 65.5°N in both years (Fig. 8).

Overlaying the distribution of ichthyoplankton on bottom water masses shows that Arctic cod were only present in the CWW and AW Mix in both years (Fig. 5a, b). Similarly, Bering flounder were most abundant in the CWW and AW Mix (Fig. 5c, d). The relatively northerly extension of the AW Mix and ACW in 2012, reported by Danielson et al. (2017), is also evident. The distributions of yellowfin sole and capelin (Fig. 6) are shown overlaid on surface water mass distributions because there was spatial coherence between larvae and both bottom and surface ACW and the oceanographic signal of ACW was more pronounced in surface waters. BWW and CWW were not evident in surface waters (Fig. 6), only in waters at depth (Fig. 5). The ichthyoplankton tows were not depth-discrete, so it is unknown at which depths the larvae occurred. Yellowfin sole and capelin were distributed in the southern two-thirds of the study area and were virtually restricted to ACW in both years (Fig. 6), in contrast to the more northerly Arctic cod and Bering flounder, which occurred in the cold, high salinity water masses as described above.

The difference in integrated chlorophyll biomass among water masses was statistically significant in 2012 (Kruskal-Wallis Chi-squared = 12.085, p-value = 0.002), but not in 2013 (Kruskal-Wallis Chi-squared = 3.4023, p-value = 0.182) (Fig. 9 a, b). Post-hoc tests showed that chlorophyll biomass was significantly greater in ACW compared to CWW and greater in AW Mix compared to CWW in 2012 (Fig 9 a). There was no significant difference in chlorophyll biomass between ACW and AWMix. Post-hoc tests comparing BWW with other water masses were not conducted, because BWW was only observed at one station (n=1).

The difference in *Calanus glacialis* biomass density among all water masses was significant in 2012 (Kruskal-Wallis Chi-squared = 25.724, p-value <0.001), and marginally significant in 2013 (Kruskal-Wallis Chi-squared = 4.5013, p-value = 0.10) (Fig. 9 c, d). Post-hoc tests showed that *Calanus glacialis* biomass density was significantly greater in AW Mix than ACW in both years; and significantly greater in CWW than ACW in 2012. The smaller-sized stages of *Calanus glacialis* copepodites (C2 and C3) were proportionally most abundant in CWW in 2012 (Fig. 10) and even more so in 2013 (Fig. 11). C2 stages were only found in CWW in both years.

In contrast to *Calanus glacialis,* the biomass density of nauplii and smaller taxa of copepods (sampled with the PairVet net) was similar or higher in ACW compared to the other water masses in 2012. The PairVet net samples collected in 2013 were not analyzed due to loss of data sheets at sea. Calanoida nauplii biomass density was significantly different among water masses (Fig. 12 a; Kruskal-Wallis Chi-squared = 8.1041, p- value < 0.05). Post-hoc tests showed that nauplii biomass density was significantly greater in ACW compared to AW Mix. *Pseudocalanus* spp. biomass density was not significantly different among water masses (Fig. 12 b; Kruskal- Wallis Chi-squared = 1.8085, p-value = 0.40). *Acartia* spp. and *Oithona* spp. biomass densities were significantly different among water masses (*Acartia*: Kruskal-Wallis Chi-squared = 34.34, p-value <0.001. *Oithona*: Kruskal-Wallis Chi-squared = 32.5, p-value < 0.001) (Fig 12 c, d). Post-hoc tests showed that *Acartia* and *Oithona* biomass densities were greater in ACW compared to AW Mix and compared to CWW. *Oithona* biomass density was also significantly greater in AW Mix compared to CWW.

In summary, Arctic cod and Bering flounder were most abundant in cold, high salinity water masses (AW Mix and CWW), which had elevated large copepod (*Calanus glacialis*) biomass density compared to Alaska Coastal Water. In contrast, yellowfin sole and capelin were only found in warm, low salinity Alaska Coastal Water that was high in Calanoida nauplii and small copepod biomass density (*Acartia* spp. and *Oithona* spp.) compared to the cold, high salinity water masses (AW Mix and CWW).

Discussion

Arctic cod, Bering flounder, yellowfin sole and capelin were the four most abundant species in the ichthyoplankton catch during the 2012 and 2013 Arctic EIS surveys. Previous ichthyoplankton surveys have caught a similar mix of species (Busby et al., in review; Norcross et al., 2010; Randall et al., 2019; Wyllie-Echeverria et al., 1997), although Randall et al. (2019) also caught relatively high numbers of Arctic sand lance (*Ammodytes hexapterus*) and Arctic shanny (*Stichaeus punctatus*); and Busby et al. (in review) caught relatively high numbers of snailfish (*Liparis gibbus*). Arctic cod and capelin are important energy-rich prey for upper trophic level predators (Hop and Gjøsæter, 2013). Arctic cod are consumed by beluga whales (*Delphinapterus leucas*), ringed seals (*Pusa hispida*), bearded seals (*Erignathus barbatus*), harp seals (*Pagophilus groenlandicus*), black guillemot (*Cepphus grylle*) and thick-billed murres (*Uria lomvia*) (Bradstreet, 1976; Bradstreet et al., 1986; Bradstreet and Cross, 1982; Huntington and The communities of Buckland, Elim, Koyuk, Point Lay, 1999).

Alaska Arctic communities on the Chukchi Sea coast rely on many of these marine mammal species for subsistence use (Hovelsrud et al., 2008; Huntington and The communities of Buckland, Elim, Koyuk, Point Lay, 1999). Capelin are preyed upon by mammal, bird and fish predators such as harp seals (Stenson et al., 1997), thick-billed murres (Provencher et al., 2012) and Atlantic cod (Mehl and Sunnana, 1991; Rose and O'Driscoll, 2002). Flatfishes are also important subsistence and ecological resources in the Arctic (Grebmeier et al., 2006a). Furthermore, yellowfin sole is one of the most abundant flatfish species in the eastern Bering Sea and currently is the target of the largest flatfish fishery in the world (Wilderbuer et al., 2017).

There were no statistically significant differences between 2012 and 2013 in the distributions of Arctic cod, Bering flounder, yellowfin sole and capelin larvae. This was observed despite wind-driven changes in water mass distribution between 2012 and 2013 (Danielson et al., 2017). We expected that larvae would be distributed less far north and further offshore in 2013 due to the reduced northerly extension of the Alaska Coastal Water and Anadyr Water Mix; and the offshore spread of Alaska Coastal Water. We did observe fewer Bering flounder larvae in 2013 compared to 2012. Perhaps the lower nutrient concentration and phytoplankton biomass observed in 2013 (Danielson et al., 2017) reduced the magnitude or delayed the timing of Bering flounder spawning and/or negatively impacted the survival of early larvae. The larval densities of the three other species were similar during the two years.
In both years, Arctic cod and Bering flounder larvae were found in cold water masses that we suggest provided good foraging opportunities. Arctic cod were only found in the northern third of the survey area in the Anadyr Water/Bering Shelf Water/Chukchi Shelf Water Mix (AW Mix) and Chukchi Winter Water (CWW). Bering flounder were similarly virtually restricted to these two cold and high salinity water masses. We suggest that the association of larval fish with particular water masses is the result of spawning location and subsequent entrainment of eggs and larvae in the currents that are associated with the water masses. Arctic cod spawn under the ice in late winter. Eggs are buoyant and develop near the surface, beginning under the ice cover and ending near the surface in ice-free areas after melting of the ice cover (Rass, 1968). Bering flounder spawn from April to June on the Bering and Chukchi sea shelves (Stark, 2004). It is not surprising that Arctic cod larvae are found in the north, given that they spawn under the ice in late winter. In addition, Arctic cod and Bering flounder were not found in Alaska Coastal Water which was expected given that they spawn in shelf waters.

AW Mix is formed from Bering Shelf Water, Chukchi Shelf Water and Anadyr Water. Anadyr Water is cold, saline and nutrient-rich that is delivered across the Gulf of Anadyr to the Bering Strait. This exogenous nutrient supply fuels much of the summer production on the Chukchi Sea shelf (Danielson et al., 2017). The two other components of the AW Mix, Bering Shelf Water and Chukchi Shelf Water, are cold and saline because of cycles of freezing, brine rejection and then summer warming (Danielson et al., 2017). Chukchi Winter Water (CWW) is the cold remnant of the previous winter's heat loss (Danielson et al., 2017). We found that these two cold water masses (AW Mix and CWW) had elevated large copepod (*Calanus glacialis*) biomass, compared to the warmer, fresher Alaska Coastal Water (ACW). The smallest stages of *Calanus* (C2) were proportionally most abundant in CWW.
Published information about the diets of larval Arctic cod supports the idea that the colder water masses were good foraging areas. We caught Arctic cod larvae from 10 mm to 55 mm SL, spanning flexion larvae to post-flexion larvae to juvenile stages (Ponomarenko, 2000). Arctic cod flexion larvae sampled from the Canadian Beaufort Sea consumed copepod nauplii and C1-C2 *Calanus glacialis* copepodites. Post-flexion larvae consumed copepod nauplii, *Pseudocalanus* spp. and C1-C2 *Calanus glacialis* copepodites. Arctic cod juveniles (26-55 mm length) consumed C2-C4 *Calanus glacialis* copepodites (Walkusz et al., 2011). No Arctic cod larval diet data are available for the Chukchi Sea, but if larval diets are comparable across adjacent seas, then the AW Mix and CWW could be hypothesized to be good foraging areas for Arctic cod larvae in the Chukchi Sea.

There is no published information on larval Bering flounder diets. In a review of latitudinal and taxonomic patterns in larval feeding ecology, Llopiz (2013) found that 85% of the diet of flatfish (Order: Pleuronectiformes) was comprised of appendicularians, nauplii, and calanoids. Other studies of specific flatfish taxa showed similar results. American plaice (*Hippoglossoides platessoides*) and Yellowtail flounder (*Limanda ferruginea*) relied on nauplii and copepodites of *Pseudocalanus*, *Oithona similis* and *Temora longicornis* (Pepin and Penney, 1997). Copepods (*Copepoda*) have been found to make up 88% to 99% of the total gut contents of Greenland halibut (*Rheinhardtius hippoglossoides*) (Simonsen et al., 2006). Bering flounder likely consume smaller prey than Arctic cod, however the colder water masses could provide sufficient biomass of some smaller prey taxa such as *Pseudocalanus* spp. and C2 stages of *Calanus glacialis*.

Advection and the timing of seasonal sea-ice retreat contribute to the formation and productivity of the cold, high salinity water masses (AW Mix and CWW), which we suggest are good foraging habitat for Arctic cod and Bering flounder. Advection through the Bering Strait brings nutrients and plankton-rich Pacific Ocean water into the Chukchi Sea, across the shelf and through Barrow Canyon (Pickart et al., 2005; Woodgate et al., 2015). The seasonal sea-ice zone provides ice algae and early stabilization of the water column by melting ice, which initiates a spring bloom of phytoplankton. Both of these features, advection and sea ice retreat, have been shown to be impacted by global climate change. Ocean warming has resulted in reduction in seasonal sea-ice extent and earlier sea-ice retreat (Frey et al., 2014; Grebmeier et al., 2006b). This change in timing of ice break up means that although ice melt still stabilizes the water column, sunlight is not sufficient to initiate an intense spring bloom (Clement, 2004), suggesting a lowering of overall primary production. Alternatively, earlier sea-ice breakup could result in increased primary production due to a longer growing season, as has been observed in the Arctic Ocean (Arrigo et al., 2008). The second process of interest here, advection through the Bering Strait, has increased by almost 50% from 2001 to the present (Woodgate et al., 2015). A larger-scale analysis of flow patterns from 1979 to 2014 shows, in contrast, that there was slightly less poleward advection across the Chukchi Sea shelf since the turn of the century (Bond et al., 2018). Although the present study from two years' surveys suggests some potential mechanisms, further research over multiple years and over a broader study area is needed to confirm how the dynamics of advection and sea-ice retreat impact the habitat of larval fishes.

In contrast to Arctic cod and Bering flounder, yellowfin sole and capelin larvae were found more towards the south and exclusively in nearshore Alaska Coastal Water (ACW) in both years. Yellowfin sole spawn in June and July in nearshore waters (Nichol and Acuna, 2001), and capelin spawn in summer on beaches (Frost and Lowry, 1987). So it is perhaps not surprising that the larvae of both species would be entrained in the ACW. Alaska Coastal Water was the warmest and freshest water observed in the survey, and it is typically low in nutrients, chlorophyll-*a* and phytoplankton productivity after the spring bloom of phytoplankton and associated nutrient depletion (Springer and McRoy, 1993). We observed reduced large copepod (*Calanus glacialis*) biomass in ACW during our surveys. However, copepod nauplii and small copepod biomass (*Acartia* spp. and *Oithona* spp.) were relatively high, compared to the other water masses.

Due to a paucity of relevant published diet information, it is difficult to assess whether ACW could be good foraging habitat for larval yellowfin sole and capelin. There are no published diet data for yellowfin sole larvae. The larval diets of a related species, common dab (*Limanda limanda*) collected in the southern North Sea, were comprised mainly of nauplii and copepodites of the copepod *Temora longicornis* (Last, 1978). Yellowtail flounder (*Limanda ferruginea*) caught off the coast of Newfoundland similarly relied on nauplii and copepodites of *Pseudocalanus*, *Oithona similis* and *Temora longicornis* (Pepin and Penney, 1997). There are no studies of capelin diets in the Pacific arctic or subarctic. Studies of capelin diets in the Barents and Norwegian seas showed that larvae were feeding on *Calanus* eggs and nauplii (Bjorke, 1976; Karamushko and Reshetnikov, 1994). Capelin diets off the coast of Newfoundland were comprised of nauplii and copepodites of *Pseudocalanus*, *Oithona similis* and *Temora longicornis* (Pepin and Penney, 1997). Other forage fish taxa, such as Pacific herring (*Clupea harengus*) and sandlance (*Ammodytes* spp.) similarly consume copepod nauplii and copepodites, including *Acartia* spp. (Fortier et al., 1995; Robert et al., 2013). If copepod nauplii and small copepods such as *Acartia* and *Oithona* are suitable prey for yellowfin sole and capelin larvae in the Chukchi Sea and Northern Bering Sea, then the ACW could provide good foraging habitat. Previous ichthyoplankton surveys of the Chukchi Sea have made similar conclusions about the distribution of Arctic fish larvae in relation to water masses. Surveys in 1990-1991 (Wyllie-Echeverria et al., 1997) and in 2004 (Norcross et al., 2010) found Arctic cod in cold offshore water and yellowfin sole in nearshore ACW. Wyllie-Echeverria et al. (1997) also found capelin in ACW; Norcross et al. (2010) did not catch any capelin in 2004. One conflict among these results is that Norcross et al. (2010)

found Bering flounder larvae in cold offshore waters, similar to what we observed, but Wyllie-Echeverria et al. (1997) showed Bering flounder associated with ACW. Randall et al. (2019) documented species assemblages of ichthyoplankton during marine mammal and plankton surveys in 2010-2015 and found interannual associations between communities and the dominant water masses similar to our results. For instance, in years where ACW occupied more of the study area, the ichthyofauna was characterized by a yellowfin sole-driven community. In years when there was more cold water on the shelf, a community typified by Arctic cod was present at most stations.
The distribution and large size of Arctic cod larvae was expected given what is known about the timing and location of Arctic cod spawning. The transport pathways between Arctic cod hatching locations and larval distributions have been investigated using a biophysical transport model that simulates larval growth and dispersal (Vestfals et al., in prep). The results of this modeling effort indicate that Arctic cod larvae caught during the Arctic EIS surveys were likely spawned in the northern Bering Sea or southern Chukchi Sea in winter and then transported to the north by late summer.

Flatfish larvae in the Chukchi Sea could have resulted from local (Chukchi Sea) or remote (Bering Sea) spawning. Our data on egg distributions and larval length-frequency patterns provided clues about flatfish spawning areas. Bering flounder eggs were caught in the northern Chukchi Sea and there was an aggregation of larvae in the same area. There were also Bering flounder larvae in the southern Chukchi Sea and northern Bering Sea, but no eggs were found in those areas. The length-frequency distributions of the northern versus the southern Bering flounder larvae were different. The larvae to the north were smaller, consistent with later spawning and/or slower larval growth rates. The larvae to the south were larger, consistent with earlier spawning and/or faster growth rates. These patterns in egg distribution and larval length-frequencies could indicate that Bering flounder larvae in the northern Chukchi Sea were spawned locally, in the northern Chukchi Sea, later than flounder to the south and in colder water resulting in slower growth and smaller size. In contrast, larvae in the southern Chukchi Sea could have been spawned to the south in the Bering Sea earlier and in warmer water resulting in faster growth rate, and were then transported north, in the Bering Shelf and/or Anadyr Current. It is unlikely that larvae in the south were advected from the north where we caught eggs because this is in the opposite direction of the prevailing currents. An alternative mechanism is that Bering flounder larvae in the southern Chukchi Sea were spawned locally, but sufficiently earlier that eggs were no longer present when that area was surveyed.

Yellowfin sole eggs were found throughout the survey area and larval length-frequency distributions were similar to the north and south. This is consistent with local spawning of yellowfin sole larvae in the southern Chukchi Sea and northern Bering Sea at the same time of year. An alternative mechanism is that yellowfin sole spawning only occurred in the southern Bering Sea and their eggs and larvae were transported to the northern Bering Sea and Chukchi Sea in the Alaska Coastal Current.
Currents across the Chukchi Sea shelf are slow, on average, around 5 cm s^{-1} (Stabeno et al., 2018; Weingartner et al., 2005; Woodgate et al., 2005), such that it is less likely that larval flatfish found in the Chukchi Sea were transported from the south. At 5 cm s^{-1} (4.32 km day^{-1}), it would take an egg or larvae 179 days to transit the 777 km from the Bering Strait to the northernmost station in the survey. Pelagic durations of flatfish larvae are less than that transit time, on the order of 30-60 days for yellowfin sole in the Gulf of Alaska, and 30-120 days for *Hippoglossoides platessoides* (American plaice) in the North Atlantic (Duffy-Anderson et al., 2015). Randall et al. (2019), analyzing data from a collection of other ichthyoplankton surveys conducted in 2010-2015 as part of marine mammal studies (CHAOZ and ArcWest), similarly concluded that Bering flounder in the Chukchi Sea were likely to have been spawned locally.

Conclusions

The distributions of Arctic fish larvae were not statistically different between 2012 and 2013 despite the differences in water mass distribution between the two years. Larvae of Arctic cod, Bering flounder, yellowfin sole and capelin were found in similar locations in both years and were associated with water masses that had elevated biomass of zooplankton taxa that could potentially have been prey. We suggest that the distribution of larvae is a product of spawning behavior that results in the larvae being located in habitat suitable for successful foraging even as oceanographic processes vary from year-to-year. In other words, Arctic fishes have evolved spawn timing and location such that larval distributions are resilient to the degree of interannual climate variability observed between 2012 and 2013. Biophysical transport models such as Vestfals, et al. (in prep) can demonstrate the advective connections between spawning location and larval distribution and can be used to explore this hypothesis. This study describes the habitat for larval Arctic cod, Bering flounder, capelin and yellowfin sole and provides baseline information on their early life history. Understanding the associations between larval oceanographic habitat and spawning-related resilience helps us to better understand the mechanisms and the degree of oceanographic change due to ocean warming and loss of sea ice which may have the potential to impact the early life histories of Arctic fishes.

Acknowledgments

We thank the captain and crew of the FV *Bristol Explorer*, and all of the Arctic EIS scientists who helped carry this program forward, particularly Franz Mueter and Jared Weems. Thanks also to the Bureau of Ocean and Energy Management program manager Catherine Coon. Thank you to C. Ladd and C. Vestfals for reviews of earlier drafts of this manuscript and to two anonymous reviewers and the editor for journal review. This is Eco-FOCI contribution #0920. CHAPTER 6 - Climate-driven shifts in pelagic fish distributions in a rapidly changing Pacific Arctic

Objective 2: Quantify the distribution, abundance, and condition of pelagic marine fishes, in particular young-of-the-year Arctic gadids and other forage fishes

Robert Levine, Alex De Robertis, Daniel Grunbaum, Sharon Wildes, Edward V. Farley, Phillis J. Stabeno, Christopher D. Wilson (in preparation)

Abstract

Age-0 Arctic cod (*Boreogadus saida*) have historically dominated the pelagic fish community in the Chukchi Sea in summer, with few adults present in the region. Recently, reductions in sea ice and increases in warming and transport have led to an increase in Pacific-origin waters on the Chukchi shelf in summer. To examine the potential effects of these environmental changes on the pelagic community in this rapidly changing environment, we extended a time series of acoustic-trawl surveys originally conducted in 2012 and 2013 with additional surveys in 2017 and 2019. Age-0 Arctic cod were the most abundant pelagic fish in all four survey years. However, age-0 walleye pollock (*Gadus chalcogrammus*), which were scarce and confined to the southern Chukchi in the 2012 and 2013, were present at high abundance throughout the Chukchi shelf in 2017 and 2019. Age-0 Arctic cod was substantially more abundant in 2017 than in any other year. This was possibly due to increased survivorship of larvae under warming conditions. Arctic cod and pollock were spatially separated in 2019, with Arctic cod primarily present in the northeastern portion of the survey area, which was characterized by cooler surface and bottom temperatures. The substantial increase in age-0 pollock in recent years suggests that environmental conditions now allow this species to extend its northern range into the central and southern Chukchi Sea, at least on a seasonal basis. We hypothesize that the changes in abundance and species composition based on our 2012-2019 time series are tightly coupled to recent changes in temperature and the transport of Bering Sea waters onto the Chukchi shelf.

Introduction

Arctic gadids, particularly Arctic cod (Boreogadus saida, also referred to as polar cod), have historically dominated the pelagic fish community in the Pacific Arctic ecosystem of the northern Bering, Chukchi, East Siberian, and Beaufort Seas (Quast, 1974; Logerwell et al., 2015; De Robertis et al., 2017). Arctic cod are a circumpolar-distributed species found throughout the Central Arctic Basin and surrounding marginal seas (Mecklenberg et al., 2018). The relatively abundant Arctic cod are lipid-rich (Copeman et al., 2017; Copeman et al., 2020), and serve as an energy-dense trophic link between lower trophic levels and piscivores such as seabirds and marine mammals (Bradstreet et al., 1986; Matley et al., 2012). Trophic mass balance models for the Chukchi Sea indicate that Arctic cod are central to the food web and represent a substantial portion of seabird (>20%) and piscivorous mammal (>40%) diets (Whitehouse et al., 2014). The Chukchi Sea and the entirety of the Pacific Arctic is experiencing substantial and rapid warming (Danielson et al., 2020), and the impacts of these environmental changes on pelagic fishes such as Arctic cod remains unclear.

The Chukchi Sea is warming rapidly: mean summer/fall water column temperatures in the Chukchi Sea have increased by 0.1 °C decade^{-1} over the past century (Danielson et al., 2020). This warming is likely to accelerate as air temperatures in the Arctic are anticipated to increase by >5 °C by 2100 (Overland et al., 2019). Climate predictions (Wang et al., 2018) suggest that the duration of seasonal ice cover will continue to decrease at a rate of -0.94 days year^{-1} as transport of water and heat into the region continue to increase.

Increased input of warm Pacific Water into the Chukchi Sea has created a feedback loop which further increases heating in the region (Danielson et al., 2020; Huntington et al., 2020). The Chukchi is highly advective, with substantial transport of warm water from the Pacific entering through the Bering Strait in spring and summer (Woodgate et al., 2005; Stabeno et al., 2018). This transport through the Bering Strait has been increasing from its previous climatology of ~0.8 Sv at a rate of ~0.01 Sv $year^{-1}$ in recent decades (Woodgate, 2018). The associated northward heat flux helps to initiate the retreat of the Chukchi shelf sea ice (Woodgate et al., 2010). Shorter periods of ice cover further reduce the albedo of the sea surface in spring and summer which increases solar warming, further accelerating ice melt in spring and delaying ice formation in fall (Danielson et al., 2020).

The physiology and recruitment success of Arctic gadids is highly temperature dependent and species specific (Mueter et al., 2011; Laurel et al., 2016; Koenker et al., 2018). Changes in habitat suitability that result from changes in Bering Strait transport are particularly important for early life stages when recruitment is largely dependent on the ability to maximize growth prior to winter (Bouchard et al., 2017). Thus, changes in transport and input of heat into the Chukchi are likely to affect the abundance and role of fishes in energy transfer within Arctic food webs. Increased warming may affect the relative abundance and distributions of different species (Laurel et al., 2016; Baker, 2021). For example, boreal (subarctic) species such as walleye pollock (Gadus chalcogrammus, hereafter pollock) and Pacific cod (Gadus macrocephalus) may benefit from warming (Marsh and Mueter, 2020), while Arctic species may be negatively impacted by reduced habitat (Baker, 2021) and increased competition (Bouchard et al., 2017).

Globally, boreal species have expanded their distributions northwards into the Arctic as high-latitude regions have warmed (Wassman et al., 2011). The Barents Sea, for example, is a shallow marginal sea of the Arctic Ocean which shares many commonalities with the Chukchi Sea (Hunt et al., 2013). Rapid warming in that region has changed the spatial distribution of fish communities as subarctic species expand northward (Fossheim et al., 2015). These spatial shifts in pelagic community structure can alter ecosystem function due to changes in food web structure (Kortsch et al., 2015). Evidence for this is seen in the distribution of adult fishes in the Bering Sea, where boreal species such as pollock and Pacific cod have expanded their range northwards (Stevenson and Lauth, 2019; Eisner et al., 2020; Spies et al., 2020). Similarly, the southern limits of Arctic species such as Arctic cod have shifted further north, with boreal species taking their place (Marsh and Mueter, 2020; Baker, 2021).

Northward advection from the Bering Sea contributes to the structure of the species composition of pelagic communities in the Chukchi Sea. This transport from the south brings planktonic organisms of Pacific-origin onto the Chukchi shelf (Eisner et al. 2013; Sigler et al., 2017). Northward advection across the Chukchi shelf is also hypothesized to structure the spatial distributions of age-0 fish, as the current speeds surpass their swimming abilities (Levine et al., 2020; Vestfals et al., 2021). Age 1+ gadids are scarce in the Chukchi Sea (De Robertis et al., 2017), likely because they are transported northward off the shelf as juveniles by the prevailing currents (Levine et al., 2020; Vestfals et al., 2021). Increased transport may further reduce the residence time for growth in regions of high productivity on the Chukchi shelf (Levine et al., 2020).

Acoustic-trawl (AT) surveys were conducted in 2012 and 2013 by De Robertis et al. (2017) to establish a baseline of the distribution of pelagic fishes in the northern Bering and Chukchi Seas. Similar to previous observations in the region (Norcross et al., 2013; Logerwell et al., 2015), large numbers of Arctic cod were observed, with the greatest abundances in the northern Chukchi Sea. However, these were primarily age-0 fish with an average length of 3.5 cm and <0.3% greater than 6.5 cm (De Robertis et al., 2017). Given the relatively high abundances of age-0 fish at a critical life stage, the Chukchi shelf may serve as an important nursery area (De Robertis et al., 2017; Levine et al., 2020). However, continued warming of the Chukchi has the potential to negatively impact the growth and survival of this population. Further investigations to address how environmental factors influence Arctic cod abundance and distribution are needed to better understand how changing climate will potentially alter this ecosystem.

To examine longer-term trends in pelagic fishes in this rapidly changing environment, we extended the time series of observations collected in 2012 and 2013 with additional AT surveys in 2017 and 2019. The AT methodology provided extensive spatial coverage and comparable measurements to previous surveys. This enabled us to address the impacts of temperature and transport on the distribution of the pelagic fish population in this highly dynamic region. The primary objectives of this study were 1) to characterize the abundance and distribution of the major pelagic fishes in the Chukchi Sea and 2) identify environmental drivers that influence the Chukchi Sea pelagic fish community. Future changes in sea ice, temperature, and transport that result from a changing climate on the Chukchi shelf are likely to be dramatic and the consequences for the age-0 Arctic cod population are unclear. Our goal is to better understand the mechanisms structuring the pelagic fish community in the Chukchi Sea, as this can improve predictions of how future environmental changes will affect these populations.

Methods

Acoustic-trawl surveys were conducted in the U.S. continental shelf region of the Chukchi Sea and coastal regions of the western Beaufort Sea (Fig. 1). The surveys occurred from 1 August to 27 September 2017 and 27 August to 26 September 2019 on the R/V Ocean Starr. Bottom depths were <60 m in 93% of the survey area in 2017 and 91% of the survey area in 2019. Stations were arranged on a 1° longitude and 0.5° latitude grid in 2017. Transect spacing was increased to a 0.75° latitude grid in 2019. Sampling stations were occupied as the vessel reached these locations along the transects. The survey began in the northern Chukchi Sea and progressed south. Acoustic data were collected as the ship transited at ~3.3 m s^{-1} along survey transects oriented in an east/west direction during daylight. Observations collected during daylight while transiting between transects were included in the analysis.

Survey methods were consistent with previous work conducted in 2012 and 2013 (De Robertis et al., 2017). The 2012 and 2013 surveys of the Chukchi Sea both took place from 7 August to 8 September. This was approximately 3 weeks earlier than the surveys in 2017 and 2019. These earlier surveys transited from south to north along the same transects indicated in Figure 1a, with equal sampling station spacing as the 2017 survey.

Acoustic data collection

Acoustic backscatter at 38 and 120 kHz was measured using a split-beam Simrad EK60 echosounder operating ES38B and ES120-7C transducers mounted at 3.7 m depth on the vessel's hull. Data were collected using a pulse length of 0.5 ms at a ping rate of 2 Hz. In deep water (>250 m depth), longer pulse lengths (1 ms at 120 kHz, 4 ms at 38 kHz) were used to increase signal-to-noise ratios, and the ping rate was slowed to ~0.3-0.5 Hz. The echosounders were calibrated at the beginning and end of each survey using the standard sphere technique (Demer et al., 2015). Results from the two calibrations were averaged before being applied in post-processing. Calibration results were consistent among surveys. Gains from the averaged pre- and post-survey calibrations for the 0.5 ms pulse length differed by 0.09 dB (2.2%) at 38 kHz and 0.17 dB (4.0%) at 120 kHz. Gains at the longer pulse lengths used in deeper waters differed between years by 0.04 dB (0.2%) at 38 kHz and 0.4 dB (8.9%) at 120 kHz.

Midwater trawl sampling

The composition of pelagic acoustic scatterers was determined from targeted midwater trawls in areas of high backscatter. Backscatter was generally evenly distributed throughout the survey area. Many trawl hauls were conducted at the survey sampling stations for logistical convenience, but hauls were targeted to the depth of greatest backscatter. Acoustically observed fish aggregations were sampled using a modified Marinovich herring trawl equipped with a fine-mesh 2 by 3 mm codend liner used in previous surveys (De Robertis et al., 2017). Prior to the 2017 survey, this trawl was modified with a redesigned aft section which resulted in lower selectivity and better retention of small fishes (De Robertis et al. in prep). Midwater trawls were conducted at 33 sites in 2017 and 43 sites in 2019 (Fig. 1), with an average ship

speed of 1-1.5 m s^{-1} during trawling. Net openings and depths were monitored with either a Simrad FS70 or Marport Trawl Explorer net sounder attached to the headrope. The trawl opening was approximately 8 m horizontal by 7.5 m vertical, with a mean headrope depth of 27.1 m (range 11.4-46.7 m) in 2017 and 34.9 m (range 13.2-227.9 m) in 2019.

Trawl catches were weighed, sorted, and identified to species. Fish lengths (3392 in 2017, 9124 in 2019) and jellyfish bell diameters (1211 in 2017, 751 in 2019) were measured on a subsample of individuals (up to 60 gadids, 10 of all other species) to the nearest 1.0 mm using an electronic measuring board (Towler and Williams, 2010). Length measurement methodology varied among years for the key gadid species. Age-0 gadids length was measured as fork length in 2012 and 2013, total length in 2017, and standard length in 2019. To account for these differences, we conducted repeat measurements of fork, total and standard length on the same individuals and calculated linear models to convert among length types (Table S1). Tissue samples from a subsample of measured gadid fishes (894 in 2017, 3155 in 2019) were collected and used to confirm field identifications based on genetic markers. Genetic analyses indicated that field identifications of gadids were unreliable, particularly when distinguishing between age-0 Arctic cod and pollock (see Wildes et al., in prep for details). For gadids with a tissue sample (40% and 56% of gadids specimens in 2017 and 2019, respectively), the species identifications were updated based on the genetic identifications. For the remaining gadid specimens with no genetic sampling, species was assigned probabilistically based on the length-dependent species composition of the genetically identified individuals in that haul (see supplementary material S2).

A subsample of gadid specimens collected in 2012 and 2013 (De Robertis et al., 2017) were validated using the same genetic analyses. This indicated that few pollock were present in the survey region during this period (Wildes et al., in prep). This provided confidence for further comparison of the 2017/2019 surveys with the historical 2012/2013 data despite the lack of a genetic-based species assignment in the 2012/2013 surveys.

Data processing and abundance estimation

Fish abundances were estimated by combining backscatter measurements and size and species composition information from genetically corrected trawl samples following methods in De Robertis et al. (2017). 38 kHz acoustic backscatter was integrated in 0.5 nmi along-transect intervals with a minimum Sv threshold of -70 dB re 1 m^{-1}, excluding data shallower than 6.5 m and deeper than 0.5 m above the seafloor. Trawl catches were corrected for size- and species-dependent net selectivity based on fine-mesh recapture nets mounted to the trawl to account for the size and species-specific likelihood of capture (De Robertis et al., in prep). The corrected size and species composition estimates were combined with size- and species-specific scattering properties to allocate observed acoustic backscatter to each species in the catch. Target strength relationships from the literature were used to estimate acoustic scattering for each species in the trawl catch (Table 1 in De Robertis et al., 2017). The proportion of total areal backscatter attributable to each species was then calculated along acoustic transects using species and size compositions from the nearest trawl (De Robertis et al., their equations 1-7). The AT method is best-suited for abundant, strongly-scattering species (Simmonds and MacLennan, 2005). The analysis thus was limited to Arctic cod, pollock, Pacific cod, saffron cod (Eleginus gracilis), Pacific herring (Clupea pallasii), and capelin (Mallotus catervarius), which accounted for 96.2% and 67.7% of fish by number in the trawl catch in 2017 and 2019, respectively. The contribution of other less abundant or weakly scattering species to backscatter was estimated, but abundance estimates were not made. For example, as in previous surveys, we were unable to estimate Arctic sand lance (Ammodytes hexapterus) abundance using AT methods with confidence because they are weak acoustic scatterers due to their lack of a swimbladder, which results in high uncertainty if stronger scatters are misclassified as sand lance (Yasuma et al., 2009; De Robertis et al., 2017). Pelagic fish abundances from surveys conducted in 2012 and 2013 were used in our analyses (De Robertis, 2021).

Environmental data collection and processing

Water column properties were measured using a conductivity, temperature, and depth (CTD, Sea-Bird Electronics 911plus) sensor. At all stations a CTD sensor was deployed from surface to ~5 m above seafloor. Mean water column temperature and salinity in 2017 and 2019 were calculated at each station for the upper 10 m (hereafter referred to as surface temperature/salinity), and the deepest 5 m (hereafter referred to as bottom temperature/salinity) of each cast. Equivalent measures were available for the CTD casts from the 2012 and 2013 surveys (Danielson et al., 2017). Measurements were included from 68 stations in 2012, 55 stations in 2013, 39 stations in 2017, and 46 stations in 2019. To associate fish with environmental conditions, each 0.5 nmi interval of transect was assigned to the nearest CTD station, and the average fish abundances (fish m^{-2}) for each grouping of intervals were calculated. Water mass classifications from Danielson et al. (2017) were used to describe station conditions based on temperature; 2 °C and 7 °C were used to represent the boundaries between Alaskan Coastal Water (>7 °C), Bering/Chukchi Summer Water (2-7 °C), and Bering Chukchi Winter Water (<2 °C).

Results

Trawl catches

Catch rates were >6-fold higher in 2017 (mean catch per unit effort for all fishes of 0.247 fish m^{-3} in 2017 and 0.037 fish m^{-3} in 2019) primarily due to high abundances of Arctic cod (0.209 fish m^{-3} in 2017 and 0.017 fish m^{-3} in 2019). Trawl catches were dominated by small fishes (80% <7.3 cm in 2017 and <8.0 cm in 2019). Gadids (Arctic cod, pollock, saffron cod, Pacific cod), Arctic sand lance, pricklebacks (Stichaedae), Pacific herring, and capelin accounted for 98.6% of catch by number (16.0% by weight) in 2017, and 93.4% of catch by number (6.7% by weight) in 2019 (Fig. 2a, b). With the exception of pollock, the same species accounted for 95.2% and 87.3% of the catch by number in 2012 and 2013, respectively (De Robertis et al., 2017). Jellyfish composed a small portion of the catch by number (0.7% in 2017, 5.5% in 2019), but a large portion of the catch by weight (83.8% of the biomass in 2017, 93.1% in 2019). Chrysaora melanaster was prevalent throughout the survey area in both years and accounted for 60.8% of all jellyfish by weight in 2017 and 58.3% in 2019.

Age-0 Arctic cod dominated the catch throughout the survey region in 2017 except in the southern Chukchi (south of 68.5 °N) where the catch composition was highly variable (Fig. 2a). Age-0 pollock were widely distributed and captured at lower abundance throughout the survey area (Fig. 2a). The catch composition was much more spatially stratified in 2019, with Arctic cod primarily restricted to the northeastern part of the survey area (Fig. 2b). The northwestern portion of the survey area was dominated by pollock and Arctic sand lance. South of 71 °N, pollock were the most abundant fishes in the trawl catches, with capelin and Pacific herring occurring at some nearshore locations (Fig. 2b).

Acoustic backscatter

In the region north of Bering Strait (>66 °N), mean backscatter in 2017 was 3.1-fold higher than in 2019 (Table 1), 4.3-fold higher than 2013, and 15.5-fold higher than 2012. Acoustic backscatter in 2017 was high throughout the survey region north of 68 °N, which coincided with the areas where age-0 Arctic cod were numerically abundant in trawl catches (Fig. 2c). The greatest backscatter levels in 2019 were found between 70 and 72 °N, where both age-0 Arctic cod and pollock were the dominant species in the catch (Fig. 2b, d). Patchy high-backscatter schools in the southern Chukchi Sea in 2019 were attributed to Pacific herring (Figs. 2d, S2). Similar to the trawl catches, Arctic cod, pollock, saffron cod, and Pacific cod were the dominant acoustic scatterers. These species accounted for 93.6% of the backscatter in 2017 and 85.6% in 2019. Capelin and Pacific herring were the next most abundant sound scattering pelagic species in the catch. Together, they accounted for 2.3% of the backscatter in 2017 and 7.1% in 2019. Although jellyfish dominated the biomass, they have a much lower mass-specific target strength than fishes with swimbladdders (De Robertis and Taylor, 2014) and were not major contributors to the observed backscatter (<1.3% in both years). Thus, the primary contributors to 38 kHz backscatter were age-0 gadids.

Fish abundance and distribution

Gadids dominated the acoustic-trawl abundance estimates in 2017 and 2019. They composed 98% of fishes in 2017 and 96% in 2019. Arctic cod was particularly abundant and composed 89.5% of fish abundance in 2017 and 65.1% in 2019. Arctic cod also dominated AT abundance estimates for the 2012 and 2013 surveys. Relatively large pollock abundance estimates were also observed in 2017 and 2019. Pollock made up 7.4% of fishes in 2017 and 29.8% in 2019. This was not the case in earlier survey years; pollock only accounted for 0.1% of fishes in 2012 and <0.001% of fishes in 2013 in the catches north of 66 °N. Abundances of Arctic cod and pollock in 2017 were 7.3- and 1.3-fold greater than in 2019, respectively (Table 1). Arctic cod and pollock densities in 2017 were greater in the central and northern Chukchi compared to other survey years (Fig. 3). Furthermore, the relatively high densities of Arctic cod in 2017 were widespread and extended throughout much of the shelf. Pollock were also distributed throughout the survey region at much greater densities than previously observed (Fig. 3e, f).

The lengths of Arctic cod and pollock were consistent with age-0 fish for these species (Figure 4, Brodeur et al., 2002; Helser et al., 2017). The mean length of Arctic cod was 4.4 cm (±0.5 cm SD) in 2017, and 4.8 (±0.5 cm SD) cm in 2019 (Fig. 4a). The Arctic cod in 2017 and 2019 were on average ~1 cm larger than those observed north of the Bering Strait in 2012 and 2013 (3.5 cm in both years, Fig. 4a). Pollock mean length was 5.1 cm (±0.6 cm SD) in 2017 and 5.0 cm (±0.5 cm SD) in 2019 (Fig. 4b).

Environmental conditions and associations

Arctic cod and pollock densities were highest in regions of intermediate surface waters in all surveys (Fig. 5). Surface temperature and salinity at sampling stations ranged from 2.5 to 7.5 °C and 25.4 to 32.3 in 2017 (Fig. 5g), and 3.2 to 10.6 °C and 27.1 to 32.1 in 2019 (Fig. 5h). Relative to other years, surface temperatures in 2017 were within a relatively narrow band of intermediate temperatures. Bottom temperature and salinity ranged from -0.7 to 6.5 °C and 31.0 to 34.7 in 2017 (Fig. 5g), and -1.4 to 10.6 °C and 29.1 to 34.7 in 2019 (Fig. 5h). The coldest surface and bottom waters were encountered in the northeastern portion of the survey area in both years (Fig. S1).

Arctic cod and pollock distributions overlapped broadly and inhabited similar water masses in 2017 (Figs. 3d, g, 5e, f). In contrast, the two species were spatially separated and largely present in different thermal environments in 2019 (Figs. 3d, h, 5g, h). That is, pollock were the primary gadids in the southern and western portion of the survey area in 2019 (Fig. 3h), which exhibited warm (>7 °C) surface temperatures that typify the Alaskan Coastal Water and warm (>2 °C) bottom waters typical of Bering/Chukchi Summer Water (Figs. 5g, h, S1). Conversely, Arctic cod were largely restricted to the northeastern region of the survey area in 2019 (Fig. 3d), where surface temperatures were <7 °C (Figs. 5g, S1d) and bottom temperatures were <2 °C, typical of Bering/Chukchi Winter Water (Figs. 5h, S1h). Arctic cod were observed in 2012 and 2013 in similar surface water conditions but in the full range of bottom temperatures observed (Fig. 5).

Arctic cod and pollock were higher in the water column in regions with cold bottom water (Fig. 6). Fish were relatively evenly distributed throughout the water column in 2017 (Fig. 6a, b) when water across the shelf was well mixed (Figs. 5e, f, S1c, g), and >65% of the total survey abundance was in areas with bottom water >2 °C. Only 25% of abundance was in areas with bottom water >2 °C in 2019, and fish in these locations were more evenly distributed throughout the water column (Fig. 6c, d), with only 28% of the abundance shallower than 25 m. Arctic cod were largely restricted to areas with bottom waters <2 °C in 2019, which was not the case in previous years (Fig. 5h). In the colder regions of the survey area (bottom temperature <2 °C), >55% of the fish were shallower than 25 m in 2019, driven by the relatively large abundance of Arctic cod high in the water column (Fig. 6c).

Discussion

Abundance and distribution of fishes

Observations from four surveys spanning a seven-year period suggest that the pelagic fish community in the Chukchi Sea is changing. We observed that age-0 gadids continue to dominate the pelagic fishes on the Chukchi shelf (Quast 1974; Logerwell et al., 2015; De Robertis et al., 2017). However, their abundance and species composition was highly variable. Age-0 gadids were substantially more abundant in 2017 relative to the other years, which was apparent in both the AT abundance estimates and the trawl catch rates. This was due to both a large increase in Arctic cod and an influx of pollock which were sparse in previous years. While age-0 Arctic cod continue to be the dominant pelagic fish in much of the Chukchi Sea, age-0 pollock, which were previously near-absent in the region, were present in 2017 and 2019.

Arctic cod, pollock, saffron cod, Pacific cod, and capelin were the most abundant species in 2017 and 2019. Pacific herring were also present in the southern portion of the survey area within Kotzebue Sound in 2019 (Table 1, Fig. S2). With the exception of pollock, these same species groups were dominant in the 2012 and 2013 AT survey observations (De Robertis et al., 2017) and in previous surveys of the Pacific Arctic (Eisner et al., 2013; Goddard et al., 2014; Logerwell et al., 2015). Although we were unable to confidently estimate their abundance using acoustic-trawl methods due to their weak acoustic scattering, Arctic sand lance were abundant in trawl catches in the central and northwestern portion of the survey region in 2019 (Fig. 2b).

Few age-1+ gadids were present in the region, consistent with previous surveys of the eastern Chukchi Sea (Goddard et al., 2014; Logerwell et al., 2015; De Robertis et al., 2017). Gadid lengths from both surveys support the acoustic observations made with a USV in 2018 which concluded that pelagic fishes were primarily age-0 gadids based on the strength of echoes from individuals (target strength) and found little evidence of scattering from adults (Levine et al., 2020). In addition, no large gadids were caught in surface trawls conducted using a large Nordic rope trawl (184 m long, ~315 m^2 net opening) during the 2017 and 2019 surveys (Farley and Levine, 2021a; Farley and Levine, 2021b). The absence of large gadids in 2017 and 2019 is not likely due to gear selectivity, as the Marinovich herring trawl used in this study has retained larger individuals when used in other regions. For example, pollock up to 61 cm were caught in several Marinovich herring trawl hauls in the Bering Sea (Honkalehto and McCarthy, 2015). A bottom trawl (3 m vertical and 12 m horizontal trawl opening) similar in size to the Marinovich has also been effective at capturing adult pollock when fished in midwater (Kotwicki et al., 2017). Thus, we are confident that relatively few pelagic adult gadids were present within the survey area based on our trawl sampling.

Small pollock and Arctic cod are difficult to distinguish based solely on external morphological characteristics in field collections (Mecklenberg et al., 2018). Without genetic analyses, we would have failed to identify the unexpected presence of pollock within the survey area in 2017 due to the unavailability of suitable field identification characteristics to differentiate pollock from Arctic cod (Wildes et al., in prep). Post-survey genetic identification was necessary to accurately estimate abundances and distributions of each species (see supplementary material S2 for details). Although the spatial coverage of specimens from previous surveys is limited, the same genetic analyses conducted on specimens from 2012 and 2013 suggests that pollock were not abundant in the survey region (Wildes et al., in prep). This supports the hypothesis that the dramatic increase in age-0 pollock in the Chukchi Sea is a recent occurrence, rather than the result of historical errors in species identification.

Temperature impacts on Arctic cod populations

The spatial distribution of Arctic cod and pollock closely resembles the distribution of warm and cold waters across the Chukchi shelf. The distributions of Arctic cod and pollock overlapped broadly in 2017 (Fig. 3c, g), with both species co-occurring in the relatively narrow range of surface and bottom temperatures found in the survey area compared to other years (Fig. 5e, f). In contrast, in 2019, Arctic cod and pollock were spatially distinct (Fig. 3d, h) and were associated with different water masses (Fig. 5g, h). Minimum temperatures observed in 2019 were colder than in 2017, and cold water (<2 °C) was more

widespread (Figure S1). In 2019, Arctic cod were primarily found on the northeast Chukchi shelf where bottom temperatures were <2 °C, which is typical of the colder water that forms in winter on the Bering and Chukchi shelves (Coachman et al., 1975; Woodgate et al., 2005). These Arctic cod were shallow (Fig. 6b), likely remaining in the intermediate temperatures between >2 °C in the upper water column. It is unlikely that this shallow distribution is due to limited vertical migration resulting from reduced swimming ability as the size of Arctic cod in 2019 was similar to that in 2017 when fish were relatively evenly distributed throughout the water column (Fig. 6a). This change in vertical distribution is likely behavioral. That is, Arctic cod may be avoiding colder waters at depth or remaining at depths where food availability is high.

Arctic cod in 2017 and 2019 were on average ~1 cm larger than those observed north of the Bering Strait in 2012 and 2013. We attribute this increase in length to a combination of the differences in survey timing and temperatures in the region. The summer is a period of rapid growth for age-0 gadids on the Chukchi shelf (Levine et al., 2020), and the recent surveys in 2017 and 2019 occurred approximately 3 weeks later than those in 2012 and 2013. For a 3.5 cm Arctic cod at a temperature of 9 °C (temperature of maximum growth, Laurel et al., 2017) an additional 21 days to account for the later surveys in 2017 and 2019 could explain an approximate 0.5 cm increase in length (based on Laurel et al., 2017, their Table 2 model B_0). However, even at this maximum growth rate, this would only account for approximately half of the increased size observed in 2017 and 2019.

Warmer water temperatures are also likely to have contributed to recent increases in gadid body size and higher gadid abundance. Mean water temperatures at Bering Strait (A3 mooring site, 66.29 °N, 168.96 °W, Woodgate, 2018; Woodgate and Peralta-Ferriz, 2021) in 2017 and 2019 were 0.5-1.5 °C warmer than in 2012 and 2013 between the approximate timing of Arctic cod spawning and the survey dates (January to August, Fig. 7; Bouchard and Fortier 2011). This was principally driven by warmer conditions in spring and summer (Fig. S3). Exceptionally warm temperatures in spring 2017 were observed at the Bering Strait (Fig. S3a), which were 0.5 °C warmer than 2019 and >1 °C warmer than in 2012 and 2013 (Fig. 7). Increased growth rates resulting from warmer temperatures may have led to larger individuals in 2017 and 2019 due to increased growth rates (Laurel et al., 2017). Based on the growth rates of age-0 Arctic cod laboratory specimens reported in Laurel et al., (2017), the ~1 °C difference in temperature between the spawning period and survey (Fig. 7) could account for a ~0.5 cm increase in length by the time of the survey in September.

Increased survival of early-hatched Arctic cod larvae may have also contributed to increased mean size in 2017 and 2019. Observations of Arctic cod in the Canadian Arctic suggest that higher temperatures reduce time-to-hatch and improve the survival of early hatching larvae (Bouchard and Fortier 2011; Bouchard et al., 2017). Dupont et al. (2020) proposed that increased early-season survival rates would lead to an increase in mean age and length during surveys. As length is strongly associated with hatch date (Bouchard et al., 2017), a greater proportion of older individuals leads to an increase in the mean length in the population. Improved early larval survival may also lead to increased size and lower mortality of age-0 fishes (Dupont et al., 2020), which may have contributed to the high abundances of age-0 Arctic cod observed in 2017.

Drivers of age-0 pollock appearance in the Chukchi Sea

The high abundances of age-0 pollock in the Chukchi Sea in recent years may be indirectly driven by increased temperatures in the northern Bering Sea, which resulted from decreased ice extent. Few pollock of any age class have been observed north of the Bering Strait in previous surveys (Quast 1974; Norcross et al., 2013; Logerwell et al., 2015; De Robertis et al., 2017). Ice cover in the Bering Sea has historically supported the formation of an extensive "cold pool" on the eastern Bering Sea shelf, a region where cold bottom waters (<2 °C) persist through the ice-free period (Wyllie-Echeverria and Wooster, 1998; Stabeno and Bell, 2019). Adult pollock typically avoid the cold pool and reside on the outer shelf region of the Bering Sea when the cold pool is large (Kotwicki et al., 2005; Stevenson and Lauth, 2019). Reduced ice

formation in warm years results in a less extensive cold pool, which reduces the barrier for adult pollock to remain on the inner and northern shelf throughout the year.

The Bering Sea has experienced extreme warming in recent years, which reduced the size of the cold pool in both 2017 and 2019 (Stabeno and Bell, 2019). Pollock distributions shifted northward during this period, which resulted in high densities of adult pollock in the northern Bering Sea (Stevenson and Lauth, 2019; Eisner et al., 2020). High abundances of juvenile and adult pollock were also observed in the Russian sector of the southern Chukchi Sea in 2019 (Orlov et al., 2020). This northern pollock population was likely not present during the 2012 and 2013 surveys due to the presence of an extensive cold pool (O'Leary et al., 2020). Our interpretation is that the recent northward movement of pollock resulted in increased production of pollock larvae in the northern Bering Sea, which were then transported into the Chukchi Sea by the prevailing northward transport (Vestfals et al., 2021).

Cold (<2 °C) Winter Water which forms during ice formation is gradually displaced to the north after seasonal ice melt by water entering the shelf from the Bering Sea (Lowry et al., 2015; Woodgate, 2018; Danielson et al., 2020). The intermediate temperatures of 2 to 7 °C and relatively high salinities (>30.4) observed in surface waters are typical of Bering/Chukchi Summer Water. Bering/Chukchi Summer Water originates in the Chukchi and northern Bering Seas (Danielson et al., 2017) and replaces the Winter Water and meltwater on the Chukchi shelf in summer (Weingartner et al., 2013). The temperature range of the Bering/Chukchi Summer Water is favorable for growth of both Arctic cod and pollock (Laurel et al., 2016).

We hypothesize that the spatial separation between pollock and Arctic cod distributions in the Chukchi observed in 2019 was driven by the association of each species with distinct water masses, which remained separate while undergoing increased transport from the Bering Sea. Bering Strait transport during the period between the approximate time of first spawning of Arctic cod and the survey (January to August) was substantially higher in 2019 relative to previous years (Fig. 7). Surface temperatures at the time of the 2019 survey exceeded 8 °C in the central and southern half of the survey area where pollock were abundant (Figs. 3, 5). These temperatures closely resembled the composition of Alaskan Coastal Water, which primarily originates on the inner Bering Sea shelf, driven by river input in spring and summer (Coachman et al., 1975; Woodgate et al., 2005). In previous surveys, this water was found in the nearshore regions of the eastern Chukchi. However, the Alaskan Coastal Water was found as far north as 72 °N and extended well offshore in 2019 (Fig. S1), which was likely due to southward winds forcing the current away from the coast (Woodgate et al., 2015; Morris, 2019). Age-0 pollock were likely advected within this Bering-origin water mass and may explain their widespread distribution in the Chukchi Sea. Similarly, the increased transport likely displaced age-0 Arctic cod northwards. Arctic cod were largely present in areas where bottom waters still reflected the conditions of Winter Water (Fig. 5f), which was present over the shelf prior to the input of warm water in spring. While age-0 pollock were found in high abundance in summer, it is unclear if these fish are able to establish permanent populations given the near-freezing temperatures they would experience on the shelf in winter (Woodgate et al., 2005; Stabeno et al., 2018).

The future of the Chukchi shelf pelagic community

If lower energy content subarctic species such as pollock continue to displace age-0 Arctic cod, the transition in gadid community structure could reduce energy available to higher trophic levels in the Chukchi Sea (Copeman et al., 2017). Our analysis suggests that the anticipated continued warming of the Chukchi shelf (Danielson et al., 2020) will substantially alter ecosystem function. We propose that the observations of gadids across the years encompassed by our survey data can be described by a conceptual model encompassing three environmental regimes. Under "historical" conditions (Fig. 8a), ice in the northern Bering Sea retreats in May and June (Frey et al., 2015), the Chukchi Sea remains relatively cool and surface waters reflect a mix of melt water, Bering/Chukchi Summer Water, and Alaskan Coastal Water (Danielson et al., 2017). In this regime, age-0 Arctic cod that are likely spawned to the south

(Vestfals et al., 2021) are the dominant gadids on the Chukchi shelf. They are primarily present in the northeastern Chukchi Sea where they experience intermediate temperatures as Winter Water warms in summer. These fish are then advected northwards during the fall towards the Chukchi and Beaufort shelf breaks and the central basin (Levine et al., 2020).

Under warming ocean conditions (Fig. 8b), when ice retreats from the northern Bering Sea earlier in spring (Wang et al., 2018), we propose a "warming" regime where temperatures are warmer across the shelf as a result of decreased sea ice extent. With a reduced cold pool in the Bering Sea, the density of adult pollock near the Bering Strait increases and leads to an increased supply of age-0 pollock on the Chukchi shelf, advected from the northern Bering Sea (Eisner et al., 2020; Baker, 2021). Hatch success for all gadids also increases as a result of warmer conditions on the Chukchi shelf and results in larger age-0 individuals in fall (Bouchard et al., 2017), prior to being advected farther north.

Under a third, "warming and increased transport" regime, northward transport increases along with temperature (Fig. 8c; Woodgate, 2018). Pelagic age-0 pollock and Arctic cod continue to be present on the Chukchi shelf in summer. As a result of increased transport, the residence time of age-0 gadids on the Chukchi shelf decreases. Arctic cod, which are known to spawn under sea ice (Ponomorenko, 2000), originate under this regime further north than pollock. Adult pollock increasingly overwinter and spawn in the ice-free central and northern Bering Sea. The population of age-0 Arctic cod is displaced to the Chukchi shelf break and Beaufort Sea earlier in the summer season, as the water present on the Chukchi shelf is transported north more rapidly. The consequences of this displacement are unknown for Arctic cod. For example, the displacement may result in a potential timing mismatch of their ontogenetic migration to take advantage of warmer Atlantic water along the Chukchi and Beaufort shelf breaks during transport off the Chukchi shelf in fall (Geoffroy et al., 2016). Age-0 pollock that may originate further south in the northern Bering Sea would be transported into the Chukchi along with the warmer water masses to subsequently dominate the gadid distribution on the central and southern shelf in late summer. Although adult pollock do not appear to be present in appreciable densities, under continued warming they may eventually colonize the Chukchi as they have the northern Bering (Eisner et al., 2020). While our time series of survey observations is limited, the 2012 and 2013 surveys are representative of the cooler historical regime (Fig. 8a), 2017 represents the warming regime (Fig. 8b), and 2019 represents the warming and increased transport regime (Figs. 7, 8c).

The spawning population that produces the age-0 Arctic cod observed in the northern Chukchi remains unknown. A migration path between spawning and feeding grounds for Arctic cod has been proposed (Forster et al., 2020) where fish spawn under sea ice in the northern Bering Sea, follow the ice retreat north to seasonal feeding areas, and return to the spawning grounds in late fall. This proposed migration may be altered by continued warming, as the reduction in suitable habitat (bottom temperatures <2 °C) for Arctic cod in the northern Bering Sea has led to decreases in summer populations (Baker, 2021). Modelling efforts based on regional advection have identified likely spawning grounds (Vestfals et al., 2021). However, spawning Arctic cod are difficult to sample due to seasonal ice cover. Without direct observations and tracking of spawning populations, our understanding of the spatio-temporal distributional patterns exhibited by age-0 gadids as they develop and return as adults, and the key environmental drivers that determine juvenile and adult survival and reproductive success is limited. Year-round in situ observations of Arctic cod migration and transport, for example through moorings or autonomous vehicles, are needed to further confirm and quantify the roles of transport in the distribution and movement of these fish (Levine et al., 2020).

If the ongoing changes observed in the physical oceanography of the Chukchi Sea influence growth and transport of age-0 gadids as we hypothesize, indirect environmental measurements could provide a basis for predicting future summer-time distributions of pelagic fishes in this region. Mooring-, satellite-, and shore-based observations as well as model-based predictions of ice, temperature, and transport are well established in the region (Frey et al., 2015; Woodgate, 2018; Janzen et al., 2019; Wang et al., 2018).

These data sources are the basis for the predictions of continued warming and higher transport into the Chukchi Sea. Northward shifts in the distribution of other marine animals have been associated with these changes in the physical environment. For example, changes in water mass transport have strongly influenced shifts in zooplankton distributions (Spear et al., 2020), which in turn, have influenced distribution shifts of their mobile predators (e.g., seabirds, Kuletz et al., 2020). These shifts in populations, which are now also documented in the pelagic fish community, provide insight into potential future states of the Chukchi ecosystem. Developing a mechanistic understanding of how the anticipated rapid increases in warming and transport in the Pacific Arctic will affect fishes is key to understanding future impacts on pelagic fish communities, their role in the ecosystem, and effective management of these species.

Table 1: Mean fish backscatter and total number of fish for each key pelagic sound scattering species estimated with acoustic-trawl methods in 2017 and 2019. The total area of the survey region was 1.48 x 10^5 km^2 in 2017 and 1.53 x 10^5 km^2 in 2019, with >92% of the survey area overlapping between both years.

	2017	2019
Mean fish backscatter (s_A, m^2 nmi^{-2})	1118.5	354.8
Arctic cod	8.7×10^{11}	1.2×10^{11}
Walleye pollock	7.2×10^{10}	5.7×10^{10}
Capelin	1.5×10^{10}	3.7×10^{9}
Saffron cod	4.6×10^{9}	1.8×10^{9}
Pacific cod	9.4×10^{9}	8.9×10^{8}
Pacific herring	Not present	3.1×10^{9}

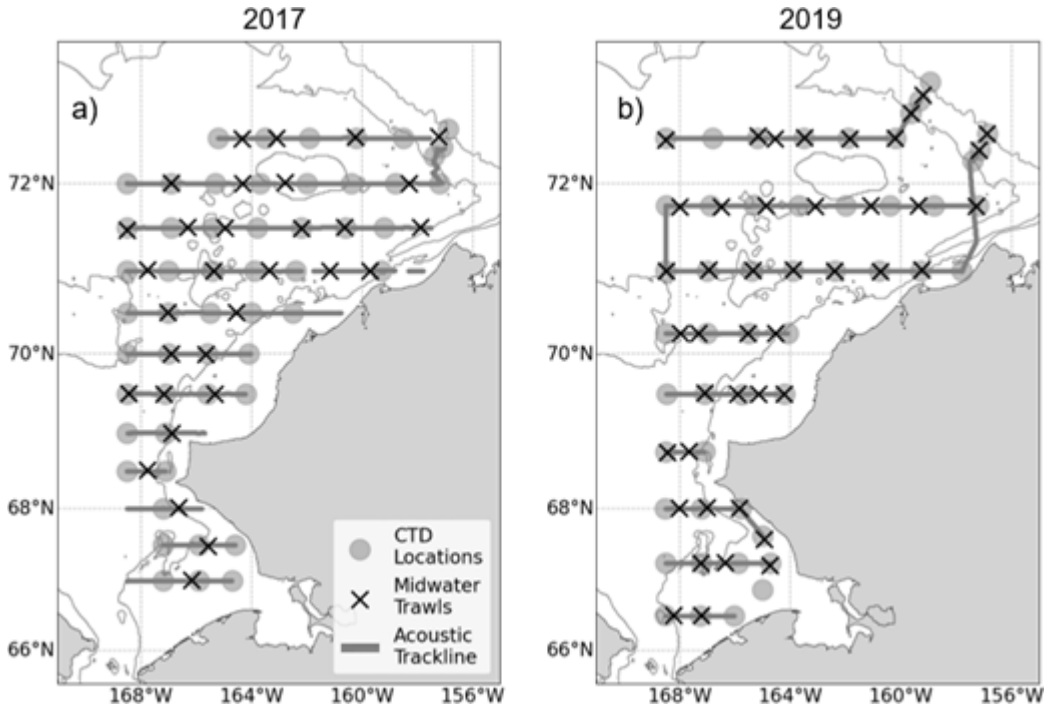

Fig. 1: Study area in (a) 2017 and (b) 2019. The 40-, 100-, and 1000-m depth contours are shown.

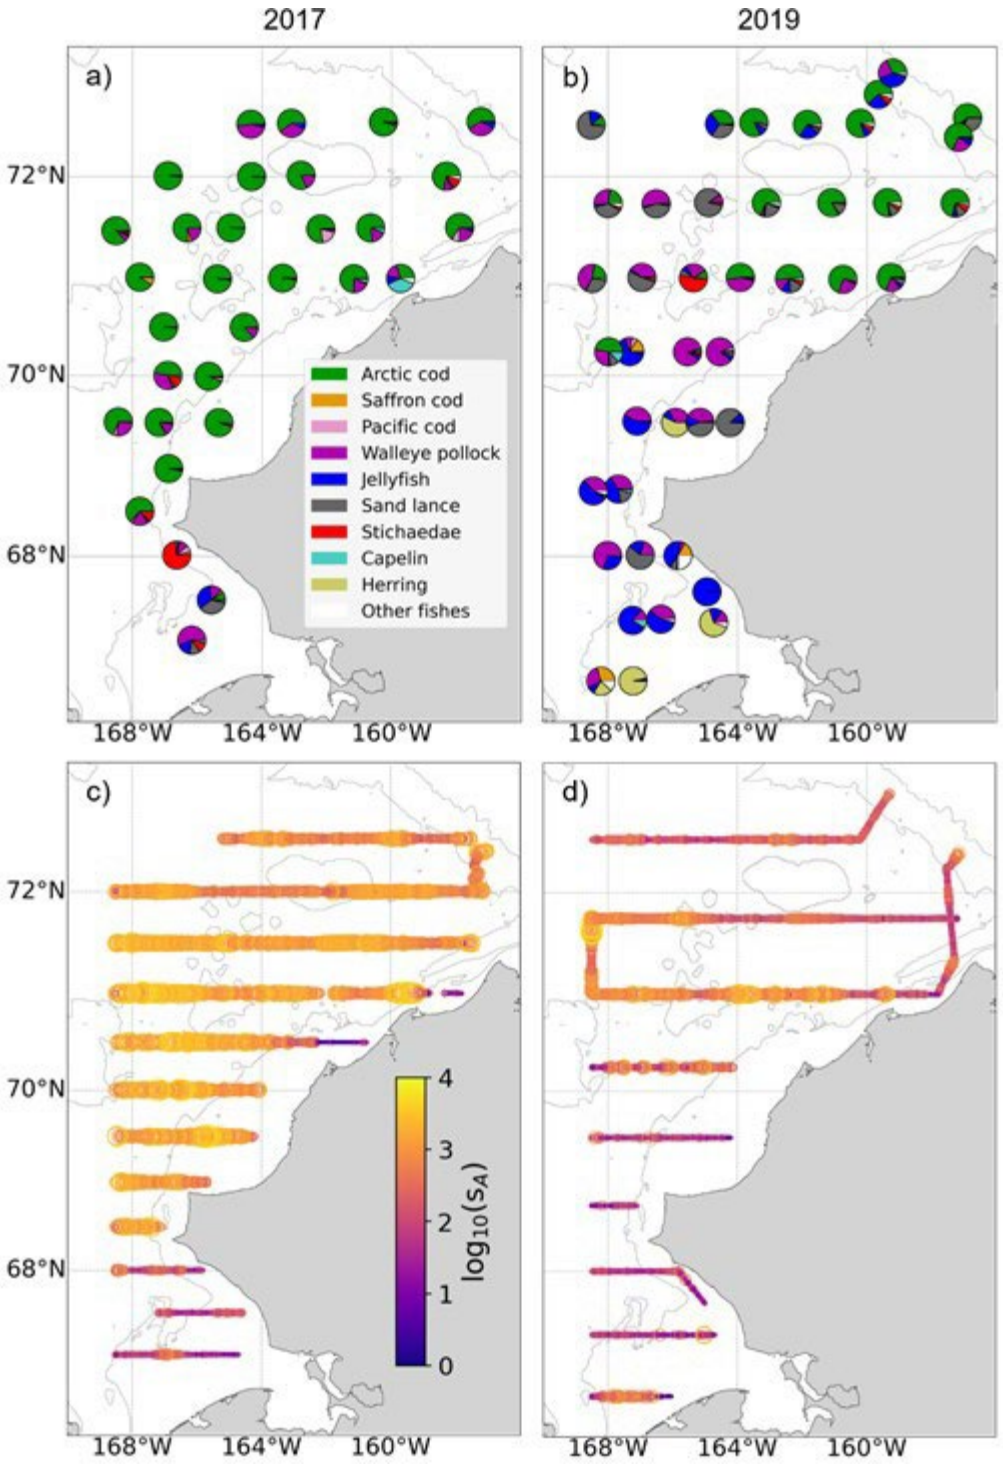

Fig. 2: Catch composition as proportion of individuals captured in each midwater trawl in (a) 2017 and (b) 2019. 38 kHz backscatter from fishes (s_A, m^2 nmi^{-2}) along the survey transects during the c) 2017 and d) 2019 surveys. The 40-, 100-, and 1000-m depth contours are shown.

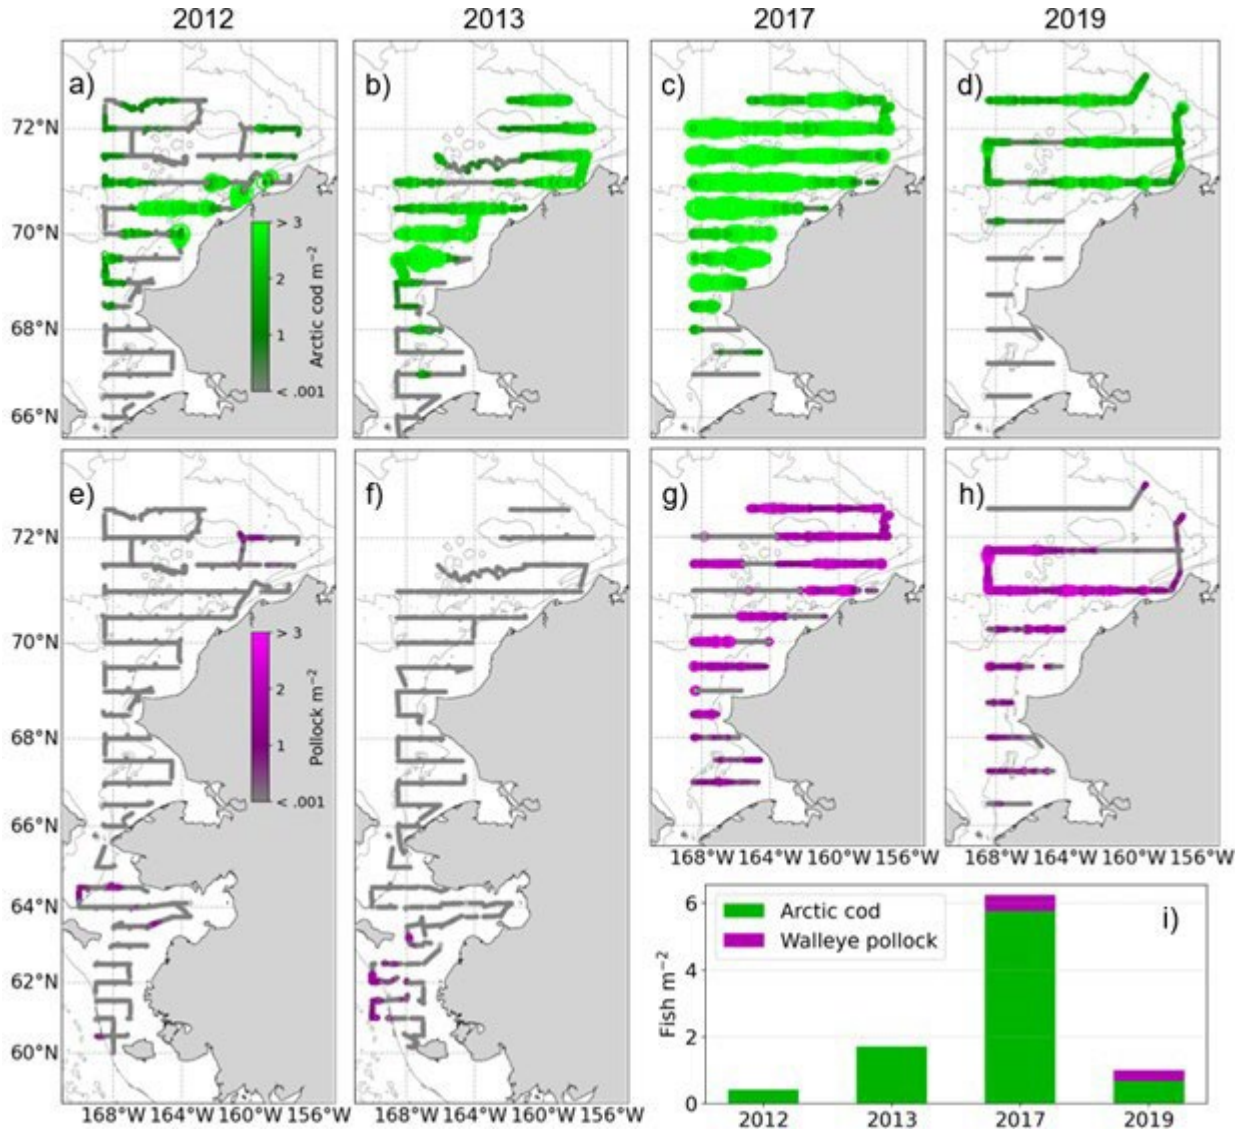

Fig. 3: Density of Arctic cod as estimated by acoustic-trawl methods in 0.5 nmi along-transect intervals in (a) 2012, (b) 2013, (c) 2017, and (d) 2019. Density of walleye pollock in (e) 2012, (f) 2013, (g) 2017, and (h) 2019. The 40-, 100-, and 1000-m depth contours are shown. In 2017 and 2019, the entire survey extent is shown. In 2012 and 2013, plots for Arctic cod (a, b) show only the region north of the Bering Strait (66 °N). This encompasses all Arctic cod except for an aggregation of large (age 1+) individuals captured in one trawl in 2012 at 65 N (not shown; see De Robertis et al., 2017, their Figure 2). (i) Mean areal density (fish m^{-2}) of Arctic cod and pollock north of 66 °N. Pollock were present in 2012 but their density was too low to be visible in the chart.

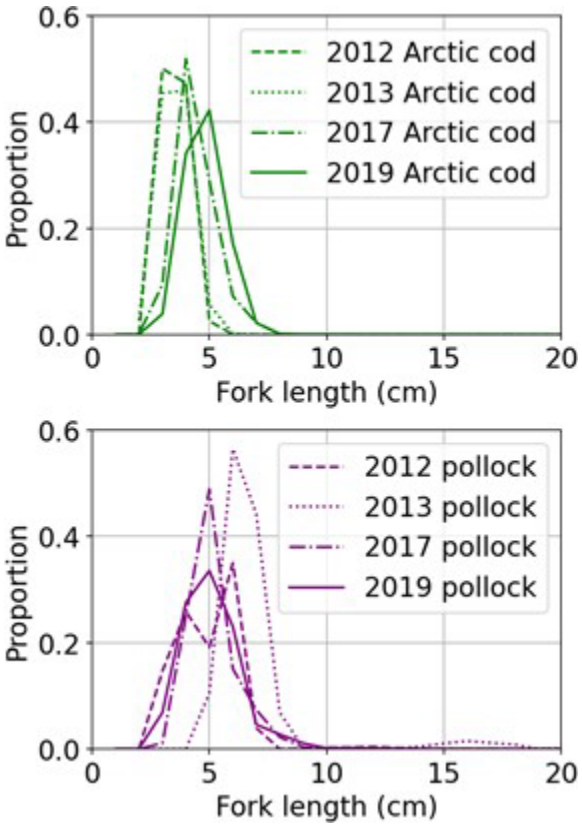

Fig. 4: Size distributions estimated by acoustic-trawl methods of (a) Arctic cod and (b) pollock in each survey year.

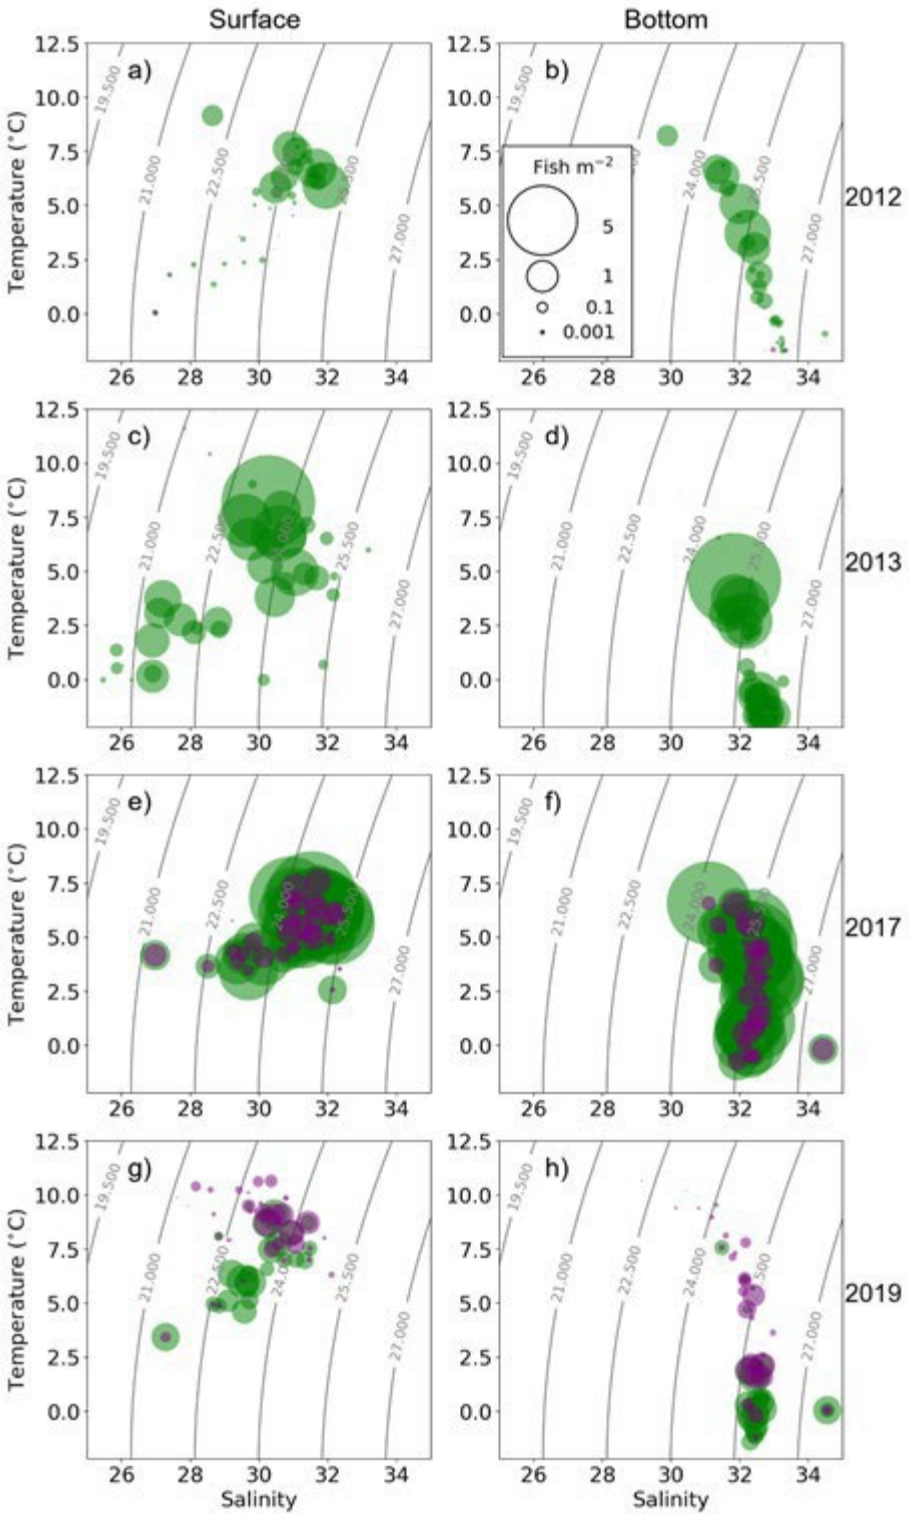

Fig. 5: Surface and bottom temperature and salinity at CTD stations in (a, b) 2012, (c, d) 2013, (e, f) 2017, and (g, h) 2019, where the size of each point indicates the abundance of Arctic cod (green) and walleye pollock (purple) in the transect intervals associated with the station (see methods for details).

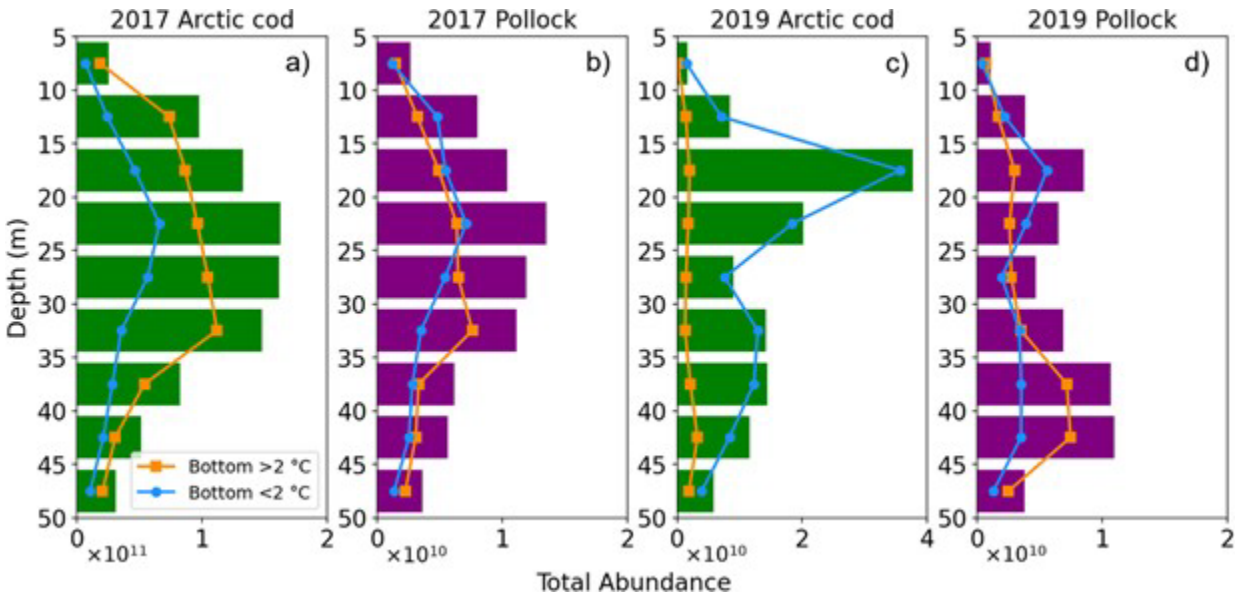

Fig. 6: Total abundance of Arctic cod (green) and pollock (purple) by depth in the water column in (a, b) 2017 and (c, d) 2019. The lines in each panel break down the total abundance into regions where bottom temperatures were >2 °C (orange) <2 °C (blue).

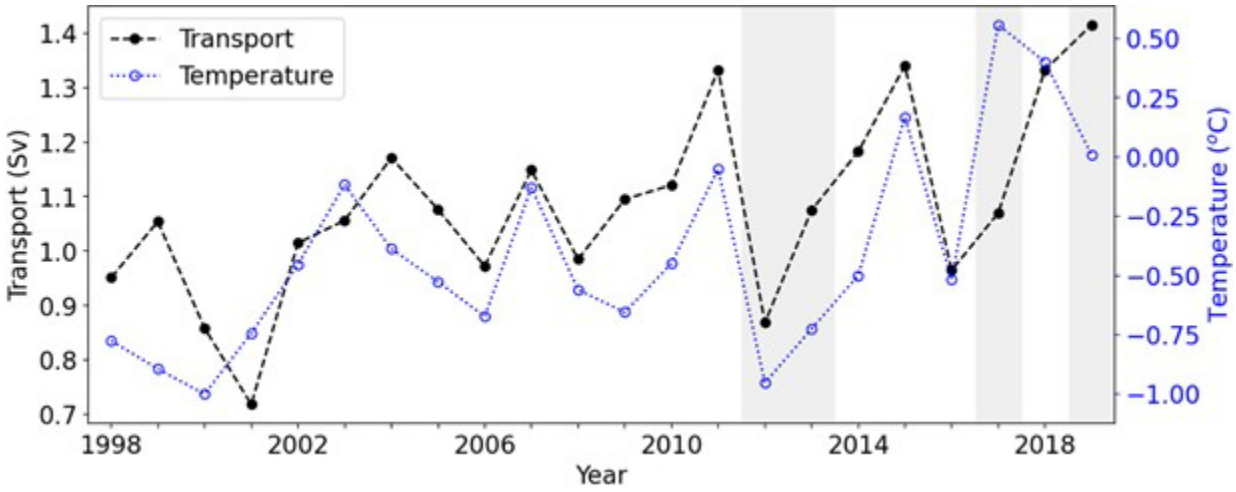

Fig. 7: Mean transport (black dashed line) and bottom temperatures (blue dotted line) measured at Bering Strait (A3 mooring, Woodgate, 2018; Woodgate and Peralta-Ferriz, 2021) from January to August of each year (1998 - 2019). Years of acoustic-trawl surveys (2012, 2013, 2017, 2019) are indicated by the grey-shaded regions.

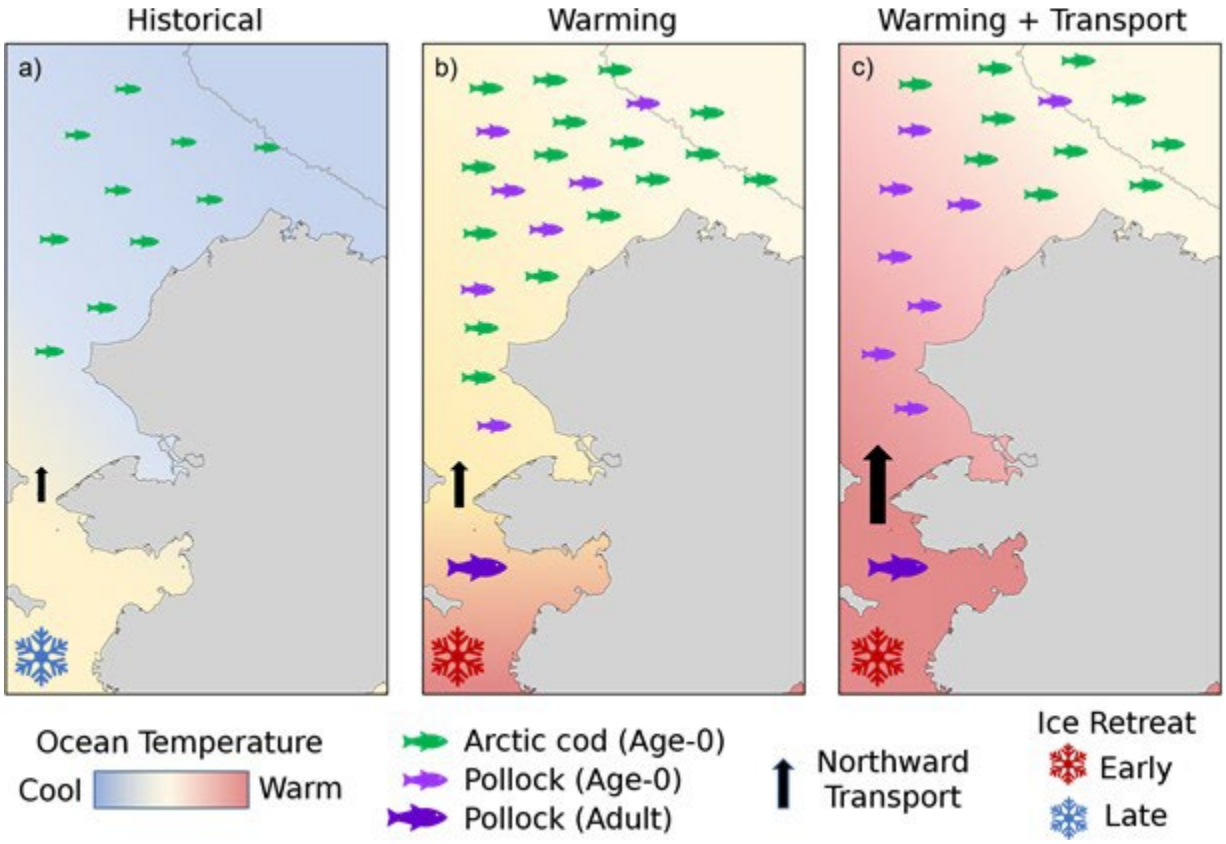

Fig. 8: Hypothesized scenarios based on observations of the Chukchi Sea gadid community. (a) Under historical conditions of later ice retreat, Arctic cod are observed in intermediate and cool waters across the Chukchi Shelf. (b) With increased warming and early ice retreat, age-0 Arctic cod increase in abundance and size across as a result of increasing temperatures. Increased presence of adult walleye pollock in the northern Bering Sea results in the transport of age-0 pollock into the Chukchi, where conditions are favorable for both gadid species. (c) With increased transport of warmer waters from the Bering Sea, Arctic cod are displaced further north along with the intermediate temperature waters. Age-0 pollock from the northern Bering Sea are transported with the warmer waters and become the dominant gadid in the southern portion of the shelf. The 1000-m depth contour is shown to indicate the Chukchi shelf break.

S1 Supplementary Figures and Tables

Table S1: Linear models used to convert TL to SL, TL to FL, and SL to FL based on the different length measurements taken on the same fish specimen. Number of observations (n) and the range of lengths used to fit each model are included. All models were significant ($p<0.001$).

Species	X	Y	n	Length range in model (mm)	Intercept	Slope	R^2
Arctic cod	TL	SL	1,055	18-189	0.364	0.909	0.999

S2 Genetic correction of gadid species assignment

Species identifications made during field sampling were modified based on the genetic verification of species identity described in Wildes et al. (in prep). In the midwater trawls, 40% of all (n = 2244) gadid specimens in 2017 and 56% of all (n = 5676) fish specimens in 2019 were genetically confirmed. Unverified specimens <24 cm in length were assigned to a species as a function of the gadid species proportion-at-length in each trawl as described below. In practice, only 59 specimens >10 cm in length were modified as a result of the model reassignment, which constitutes 0.3 % of all measured specimens. All fish >= 24 cm retained their species identification as determined in the field.

For a given trawl, the proportions of each of the five gadid species (B. saida, G. chalcogrammus, E. gracilis, G. macrocephalus, and A. glacialis) were determined from the genetically confirmed specimen. Proportions were calculated for specimen grouped into the following length classes: 2 cm <= standard length (SL) < 4 cm, 4 <= SL < 6 cm, and 6 cm <= SL < 30 cm. The proportion (P) of a species s of length class l in trawl t was calculated from the number of genetically confirmed individuals (N) of species s of length class l from trawl t,

$$P_{s,t,l} = \frac{N_{s,t,l}}{\sum_s N_{s,t,l}}$$

For each specimen that was not genetically analyzed, a species was assigned based on the determined genetically identified proportions. For example, trawl t contains the following probabilities P for length class l: P_(s_1,t,l)=0.55, P_(s_2,t,l)=0.25, P_(s_3,t,l)=0.2, P_(s_4,t,l)=0, and P_(s_5,t,l)=0. A value x is randomly generated where 0 <x≤1. The specimen is assigned to species s based on the following conditions:

$$s = \begin{cases} s_1, & x \leq P_{s_1,t,l} \\ s_2, & P_{s_1,t,l} < x \leq P_{s_1,t,l} + P_{s_2,t,l} \\ & \dots \\ s_n, & P_{s_1,t,l} + P_{s_2,t,l} \dots P_{s_{n-1},t,l} < x \leq P_{s_1,t,l} + P_{2,t,l} \dots P_{s_n,t,l} \end{cases}$$

To evaluate the performance of the genetic reassignment model, the identity of all genetically identified specimens were predicted using a leave-one-out method. The identity of each individual was predicted based on the other genetically identified gadid specimens from the same trawl haul. The model-predicted species matched the genetic identification for >80% for individuals in both years. The allocation of acoustic backscatter from trawl data is based on the length distribution and the proportion of each species in the catch, thus the model was also evaluated based on the ability to predict the proportions of each gadid species in each trawl and the impact of reassignment on the length distributions of each species.

The model reassignment introduces a random element due to the probabilistic species assignment of the specimens which were not genetically identified. However, the species compositions of gadids in a given haul after reassignment exhibited very little difference to those derived from the genetically identified specimens (Fig. S4). The mean of the absolute difference between the proportions of Arctic cod and pollock from only genetic specimens and all specimens for each haul was <5% in 2017 and <3% in 2019. The higher variability in 2017 is likely due to both a greater spatial overlap between species, and greater overlap in their size composition (Figure S5) and a higher proportion of unconfirmed identifications than in 2019.

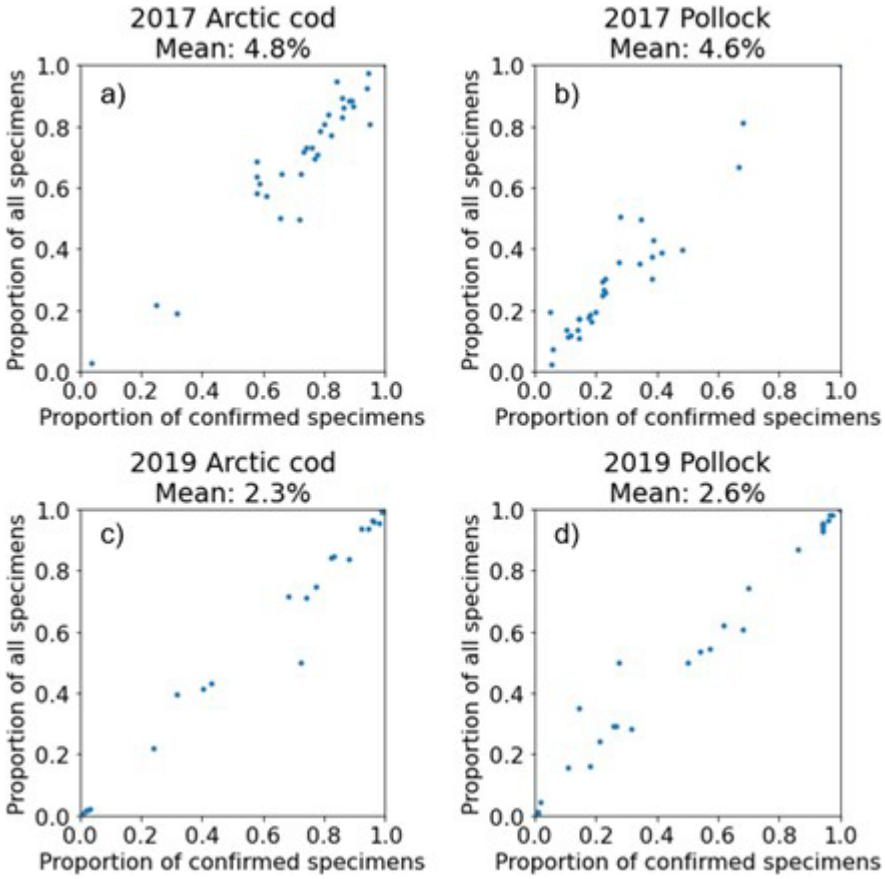

Fig. S4: Comparison of the proportion of (a, c) Arctic cod and (b, d) walleye pollock in each trawl determined from only the genetically confirmed specimens, and from all specimens after model reassignment. Mean absolute difference between the proportions from only genetic specimens and all specimens for each haul is indicated for each set of measurements.

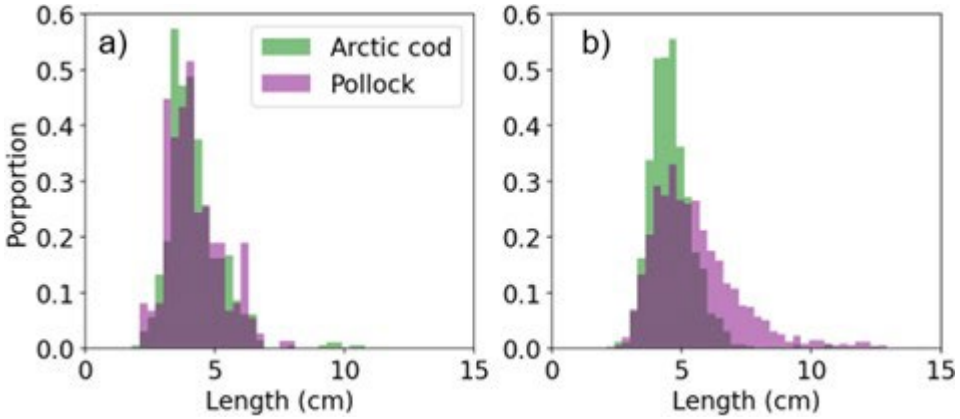

Fig. S5: Proportion at length of genetically identified Arctic cod and pollock in (a) 2017 and (b) 2019.

To quantify agreements in length between genetically identified versus all specimens, we calculated the two-sample Kolmogorov-Smirnov (KS) test between the known and model-assigned lengths for each gadid species in each trawl. The KS statistic was not significant in any trawls, indicating no significant differences between the length-frequency distributions between the genetically confirmed specimens and all specimens after model reassignment. Mean absolute differences between known and reassigned mean species length in each trawl haul was < 0.5 cm for both Arctic cod and pollock in both years (pollock: 0.43 in 2017 and 0.23 in 2019, Arctic cod: 0.07 in 2017 and 0.09 in 2019).

When catches were subsampled, total catch weights and abundances were modified based on the updated identifications of specimens to accurately reflect the final species composition in each trawl catch. This can introduce changes in the weight and number of individuals of a given species in a trawl haul due to the extrapolation from the measured subsamples to the total catch (Figs. S6, S7). To evaluate the potential changes to the total catch resulting from species reassignments, total weight, total number, sampled weight, and sampled number of each gadid species in each trawl in both years were calculated from the original field assignments and the genetically reassigned data. Changes to these measures as a result of reassignment were typically <0.5% (total samples of each gadid species in all trawls = 106 in 2017, and 92 in 2019), with only 5 samples across both years showing changes in any of the metrics by >1% (Figs. S6 and S7). These errors were identified as a result of rounding errors for the mean weight of individuals (i.e., mean individual weights were assigned as .002 kg rather than .001) introduced by the 0.001 kg precision used in the field collection database.

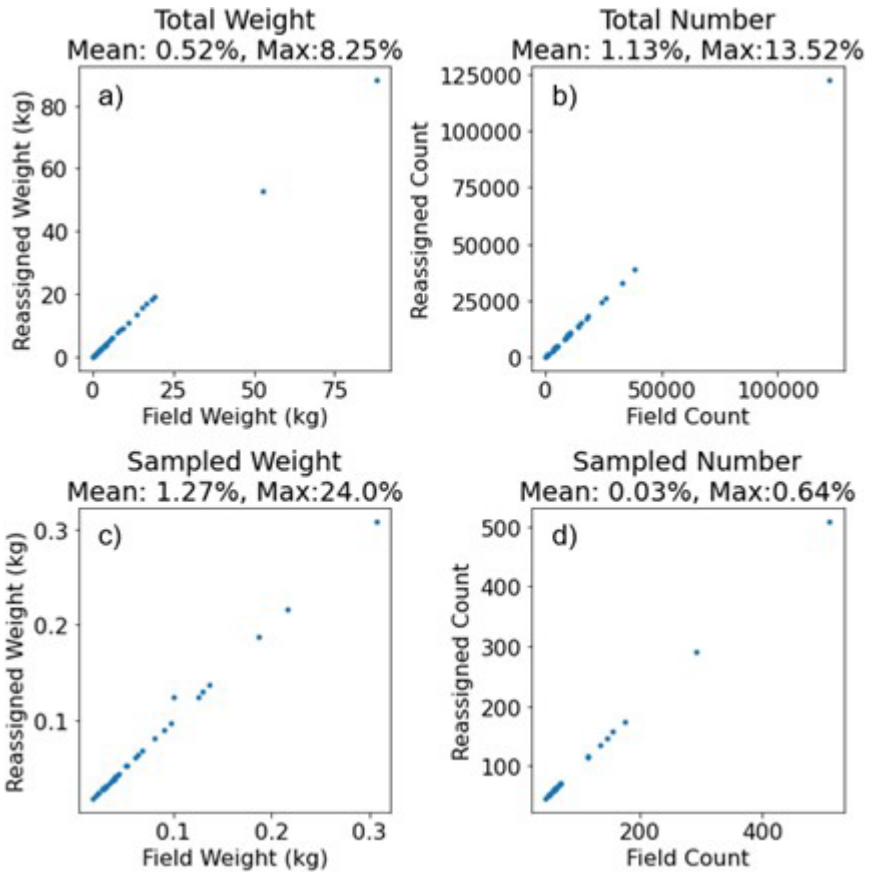

Fig. S6: Comparison of field and reassigned (a) total weight, (b) total number, (c) sampled weight, and (c) sampled number of gadids for all 2017 trawls. Each point represents the total for a single gadid species in a trawl. Mean and maximum values of the absolute difference between the field and reassigned values for each haul are indicated for each set of measurements.

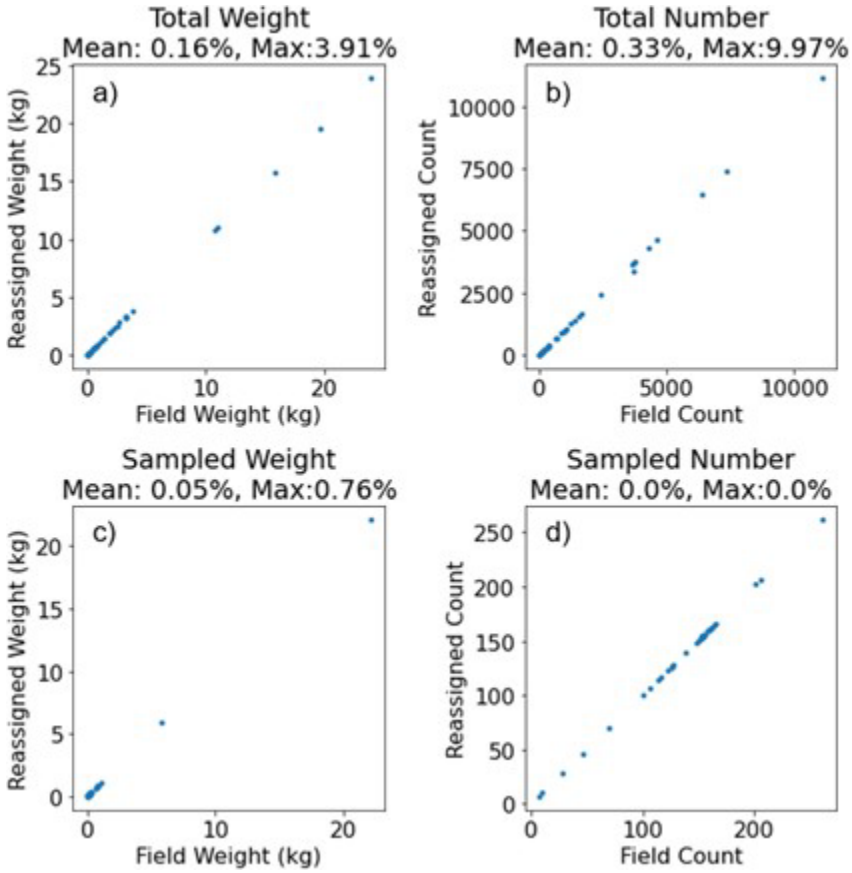

Fig. S7: Comparison of field and reassigned (a) total weight, (b) total number, (c) sampled weight, and (c) sampled number of gadids 2019 for all trawls. Each point represents the total for a single gadid species in a trawl. Mean and maximum values of the absolute difference between the field and reassigned values for each haul are indicated for each set of measurements.

CHAPTER 7 - Modifying a pelagic trawl to better retain small Arctic fishes

Objective 2: Quantify the distribution, abundance, and condition of pelagic marine fishes, in particular young-of-the-year Arctic gadids and other forage fishes

Alex De Robertis, Robert Levine, Kresimir Williams, and Chris Wilson

Abstract

The small, abundant pelagic fishes of the Alaska Arctic are challenging to sample with trawls. They are sufficiently motile to avoid small fine-mesh trawls, but small enough to escape through the meshes of pelagic trawls designed to capture larger fishes. A pelagic herring trawl equipped with a fine-mesh codend liner was used to quantify the size and species composition of pelagic fishes during a baseline acoustic-trawl survey of the Chukchi shelf. Subsequent experiments with recapture nets attached to the outside of the trawl web suggested that escapement of small fishes was substantial, particularly in the aft net section. Thus, the trawl was further modified by reducing the taper in the aft net section, and adding a small-mesh section in front of the codend to potentially reduce escapement. Further use of recapture nets during two subsequent acoustic-trawl surveys confirmed that this trawl modification substantially increased retention of small fishes, and resulted in less size selectivity. These improvements will reduce biases in estimates of abundance, size and species composition of pelagic Arctic fishes. This work highlights the importance of quantifying escapement from survey trawls, and demonstrates that escapement estimates can guide successful trawl modifications.

Introduction

Pelagic trawls are one of the primary methods of sampling midwater fishes, and are widely used in pelagic and acoustic-trawl surveys. These trawls rely on behavior to capture fishes, as the majority of meshes are much larger than the fish being targeted. Pelagic trawls typically gradually decrease in diameter and mesh size from the trawl mouth, leading to a long intermediate section followed by a small-mesh codend. Most meshes in the trawl forward and intermediate sections are large enough to allow fish to escape. However, fish are reluctant to pass through these larger meshes, and instead orient themselves parallel to the netting (Glass et al., 1993). The fish tire, becoming increasingly concentrated as they fall back towards the smaller diameter codend where they are retained in smaller meshes (Kennelly and Broadhurst, 2021). This graduated mesh and gradual narrowing (low taper) of this trawl design reduces drag so larger nets can be deployed to improve catch rates. However, if herding behaviors are species and size-specific (He, 1993), the catch composition will not be representative of the fish the trawl mouth opening. These fish herding behaviors have been extensively exploited to reduce commercial catches of unwanted species and/or size classes (Kennelly and Broadhurst, 2002). Thus, the primary goal of trawl gear designed for commercial fishing is to increase size and species selectivity to maximize the catch rates of target species while reducing the proportion of unwanted species and size classes in the catch.

The requirements for research survey trawls differ from those of commercial fish trawls. Ideally, a survey trawl should be unselective, and capturing all species and size classes with equal efficiency. This is rarely, if ever possible in practice, so a more attainable goal should be to design trawls that capture all species and sizes of interest at high and constant efficiencies. Trawl catches can then be corrected for species/size selectivity if these average size- and species-dependent probabilities of capture (i.e. selectivity) are known (Bethke et al., 1999; Kotwicki et al., 2017). If species and size selectivity were known without error, the corrections would fully account for trawl selectivity. In practice, corrections are imprecise (Williams et al., 2011; De Robertis et al., 2017a). Thus, designing survey trawl gear with high catch rates important, as when the probability of retention is high, the absolute corrections for selectivity will be smaller, and uncertainties in the correction result in smaller impacts abundance estimates.

Selectivity corrections are particularly desirable in the context of acoustic-trawl surveys, as species and size compositions derived from trawl sampling are used in combination with scattering models to convert acoustic backscatter into animal densities (Simmonds and MacLennan, 2005). If the proportion of one species or size class is under-estimated relative to others, its abundance will not only be under-estimated, but the abundance of other species and sizes will also be over-estimated (McClatchie and Coombs, 2005; De Robertis et al., 2017b). Therefore, selectivity corrections are desirable for acoustic-trawl surveys, as errors in species or size composition introduced by trawl selectivity affect the abundance estimates of all the other organisms present.

While substantial effort has gone into making trawls more selective to reduce unwanted bycatch (Kennelly and Broadhurst, 2021), comparatively little work has been conducted to design less selective pelagic trawls for research surveys, or to quantify the selectivity of these survey trawls. Pelagic trawls designed for commercial fishing are regularly used as survey trawls (Bethke et al., 1999; Williams et al., 2011). Fishes that escape from pelagic trawls are generally smaller than those that are retained (Matsushita et al., 1993; Suuronen et al., 1997) and a small-mesh liner is often added to the codend to improve retention of smaller fishes (Simmonds et al., 1992). This is a pragmatic and simple first step as selection in the codend is often high (Matsushita et al., 1993; Wileman et al., 1996; Kennelly and Broadhurst, 2021). However, this does not address escapement from the meshes forward of the codend, which can be substantial, particularly for smaller organisms large enough to be retained in the codend but not the rest of the trawl (Williams et al., 2011; Herrmann et al., 2018).

Although trawl selectivity can be investigated via gear comparisons (Kotwicki et al., 2017), acoustic and optical imaging (Williams et al., 2013, Underwood et al., 2020), or small-mesh recapture nets to capture fishes escaping through the trawl meshes (Matsushita et al., 1993; Skúvadal et al., 2011), the selectivity of most survey trawls is unknown. In many applications, it is implicitly assumed that all species and size classes are equally likely to be retained by the survey trawl (Simmonds et al., 1992). While this assumption is sometimes acceptable, it is tenuous in other situations such as in areas of mixed species and size aggregations. Quantifying trawl selectivity allows selectivity corrections to be implemented, thus reducing a major source of uncertainty in acoustic-trawl abundance (Williams et al., 2013).

The Pacific Arctic, which was sampled as part of the Arctic Integrated Ecosystem Research Program (AIERP), presents a challenging case in terms of the potential for biases to be introduced by trawl selectivity. The dominant pelagic fishes are small (~5 cm), and it is highly probable that they will be poorly retained in large-mesh trawls. However, they are also sufficiently mobile to avoid smaller fine-mesh nets designed for larval fishes and invertebrates (Kwong et al., 2018). Acoustic-trawl surveys of the Chukchi Sea required the ability to sample both large and small fishes, and a large Cantrawl pelagic trawl was used in an initial baseline survey (De Robertis et al., 2017b). A smaller Marinovich herring trawl was introduced in a subsequent survey after it became clear that small fishes likely to escape from the Cantrawl dominated this Arctic pelagic fish community. The Marinovich trawl was equipped with a small mesh codend liner in an effort to better retain small fishes (De Robertis et al., 2017a; De Robertis et al., in press). Although the Marinovich captured pelagic fishes in the Chukchi Sea more efficiently than the larger Cantrawl, experiments with a recapture nets indicated that escapement and size-selectivity remained high, particularly in the aft area of the Marinovich trawl (De Robertis et al., 2017a; see De Robertis et al., in press for a corrigendum). Specifically, the Marinovich trawl was selective in the size range of most pelagic fishes in this Arctic region. For example, only ~23% of 4 cm Arctic cod, the most common species and size class in this environment were retained. Retention of Arctic cod was highly size dependent: ~10% at 3 cm and ~45% at 5 cm. Given the relatively low catch efficiency and substantial size selectivity of the trawl, the aft section of the Marinovich trawl was further modified for continued use during the AIERP program in an effort to improve retention of all small fish species and to reduce the trawl size-selectivity. This study thus has two aims: 1) establish size-dependent selectivity curves for abundant fish species to correct the retained catch for escapement for use in acoustic-trawl abundance estimates of fish abundance (Levine et al., in review), and 2) evaluate whether the Marinovich trawl modifications increased the catch rates of small fishes present in this Arctic region.

Materials and Methods

Trawl modification

The mod-1 Marinovich herring trawl used in previous surveys of the Chukchi shelf in 2013 (De Robertis et al., 2017b) is a symmetrical 4-seam box trawl constructed of diamond (T0) meshes (Fig. 1a). It was modified from the original design by fitting the codend with a 2 by 3 mm oval mesh liner to improve retention of small organisms and enlarging the wings to allow it to be fished with oversized doors as the logistics of this project required fishing both the Marinovich and a larger pelagic trawl without swapping trawl doors (De Robertis et al., 2017b).

The trawl was further modified (Fig. 1b) in an effort to better retain the small fishes observed in the study area (this trawl is hereafter referred to as mod-2 Marinovich). The aim was to increase capture rates of the small fishes to reduce the uncertainties in estimates of animal size and species composition used to convert measurements of acoustic backscatter to estimates of abundance by species and size (De Robertis et al., 2017b). Given that escapement was substantially higher in the aft area of the net, we focused on this part of the trawl.

The mod-1 trawl was modified by replacing the 3.8 cm mesh panel immediately forward of the codend with two new panels after reviewing the recapture net results and consulting with trawl manufacturers and commercial fishers. One panel was redesigned with the same mesh (3.8 cm T0 meshes) but with a lower taper (Fig. 1b). A second panel of 1.9 cm T0 meshes was added immediately aft of the first new section, increasing the overall length of the mod-2 trawl by 249x1.9 cm meshes (Fig. 1b). The codend liner covered the codend and 26.5 of the 1.9 cm meshes of the second new panel (Fig. 1b). These modifications increased the overall length of the net, reduced the taper towards the rear of the net and reduced the mesh size in the area immediately forward of the lined codend where escapement was greatest (De Robertis et al., in press). Hereafter, the two forward panels of the mod-2 Marinovich are referred to jointly as the forward section, the two middle panels are referred to as the middle section, and the new small-mesh panel as the aft section (Fig. 1b).

Recapture nets

The Marinovich trawls were fitted with small-mesh recapture nets designed to quantify the degree to which fish escape through the mesh panels of the trawl (Nakashima, 1990; Williams et al., 2011). The recapture nets were constructed with the same 2 by 3 mm oval mesh material as the codend liner. They were designed with a diamond-shaped mouth equivalent to a 2.4 m stretched diamond mesh, a 2.6 m long tapered body, and codend (see De Robertis et al., in press, their Fig. S1.2 for details). The recapture nets were dyed black to reduce visibility and permanently attached to the trawl netting on the outside of the trawl.

The mod-1 trawl was fitted with 8 recapture nets, one in the forward section and one in the aft section on each of the four sides of the trawl (i.e., top, bottom, port and starboard). The recapture nets were placed at the center of each section (i.e. same number of meshes in front of and behind the recapture net, Fig. 1a). The number of meshes covered by the recapture nets were counted, and the proportion of the area covered by the recapture net was computed (see De Robertis et al., in press, their section S2). The recapture nets covered 6.5% of the area in the front section and 13.2% of the area in the aft section.

The Mod-2 trawl was fitted with 9 recapture nets in the center of the forward, middle, and aft sections of the net (Fig. 1). Recapture nets were mounted on the top, bottom and starboard sides. To reduce the effort required to process the catch, we did not mount nets on the port side and assumed equal escapement from the port and starboard sides of the net. The recapture nets covered 6.5% of mesh area in the front section, 12.7% of mesh area in the middle section, and 30.5% of the unlined mesh area in the aft section.

Field Sampling

The mod-1 Marinovich equipped with recapture nets was used in 30 hauls as part of an acoustic-trawl survey of the continental shelf of the US Chukchi Sea in 2013. These deployments are described

elsewhere (De Robertis et al., 2017a), but results are included here as a reference to judge the effectiveness of the subsequent modifications made to the mod-2 Marinovich.

The mod-2 Marinovich equipped with recapture nets was used in acoustic-trawl surveys in 2017 and 2019, which sampled the same area as the previous survey with the mod-1 trawl (Fig. 2). The mod-2 Marinovich was fished with Nor'Eastern Trawl Systems 3 m^2 Series 2000 doors, synthetic rigging with 55 m long bridles, and 170 kg weights on each wingtip. A Simrad FS70 3rd wire trawl sonar was mounted on the headrope to monitor trawl geometry and fish entering the net. A total of 75 hauls with the Mod-2 trawl (Fig. 2, n=32 in 2017, n=43 in 2019) were conducted during daytime as part of an acoustic-trawl survey (Levine et al., this issue). Most trawls were shallow (average depth of 31.7 ± 32.3 m (mean ± SD), range 11.6 - 228.8 m), with 95% of trawls < 40.2 m. The trawl was fished at 1.2 ± 0.2 m s^{-1}, and exhibited a vertical mouth opening of 7.8 ± 0.9 m and a horizontal opening of 7.5 ± 0.6 m while fishing.

Biological sampling

Catches in the codend and the recapture nets were weighed, subsampled if large, sorted to species and enumerated. The lengths of individuals in the codend (up to 60 for gadids and 20 for other species) and in each recapture net (up to 20) were measured to the nearest mm using an electronic measuring board (Towler and Williams, 2010). For species other than gadids and Arctic sand lance (*Ammodytes hexapterus*), fork length was measured. Gadid lengths were not measured consistently across years: in 2013, fork length was measured, in 2017, total length was measured, and in 2019, standard length was measured. These measurements were converted to standard length using species-specific linear regressions (see Levine et al., in review, their appendix A) for further analysis.

Small gadids (particularly age-0 Arctic cod (*Boreogadus saida*), and pollock (*Gadus chalcogrammus*) could not be reliably identified at sea based on external morphology (Wildes et al, this issue). Thus, species for juvenile gadids in 2017/2019 were assigned probabilistically based on size-dependent genetic sampling of the catch (see Levine et al., in review, their appendix B). Pollock were almost absent in 2013, and saffron cod (*Eleginus gracilis*) which easier to distinguish at this size were spatially distinct from that of Arcitc cod (De Robertis et al., 2017b). The identifications of juvenile gadids in the 2013 survey are thus believed to be generally reliable (Levine et al., in review; Wildes et al., in review).

Estimation of trawl selectivity

The most abundant fishes in the catch (Arctic cod, saffron cod, walleye pollock, capelin (*Mallotus catervarius*), Arctic sand lance) were aggregated by species for analysis. In addition, a grouping for 'other fishes' (i.e. all other fishes pooled) was defined. In the mod-1 deployments, catches of 'other fishes' were dominated by pricklebacks (*Stichaeidae*, 40%), sculpins (*Cottidae*, 33.3%), and snailfishes (*Liparidae*, 13.5%). In the mod-2 deployments, catches of other fishes were dominated by pricklebacks (41.9%), sculpins (16.3%), and Pacific herring (16.2%). A selectivity relationship was fitted to the 'other fishes' complex as an approximate selectivity relationship is required to correct the size and species composition of low-abundance species encountered in the acoustic-trawl survey (Levine et al., this issue). However, given the differences in species and size composition, the selectivity of the 'other fishes' group should not be compared directly between the mod-1 and mod-2 Marinovich trawl designs. For each species grouping listed above, hauls in which >10 individuals were measured were used for further analyses.

Each specimen (i.e. a measured fish) was associated with a scaling factor indicating the total number of individuals that fish represents in the total catch if in the codend, or the total number of fish escaping from the trawl meshes if in the recapture nets. The scaling factor W for each measured individual i in the catch is defined as

$$W_{i,s,j} = \frac{1}{p_{i,j,s}} \cdot \frac{1}{c_j} \quad (1)$$

where $p_{i,j,s}$ is the proportion of individuals of species s in captured in trawl location j (referring to the codend or recapture net location) that were measured , and c_j is the proportion of the area in location j covered by the recapture nets or codend liner. In the case of the mod-1 Marinovich, c_j = 0.065 for the front recapture nets and 0.132 for the aft recapture nets. In the case of the mod-2 Marinovich, in the top and bottom sides of the trawl, c_j was 0.065 for the front recapture nets, 0.127 for the middle recapture nets, and 0.305 for the aft recapture nets. Given that only the starboard side of the net was fitted with recapture nets, escapement was assumed to be the equivalent from both sides. Escapement from both the port and starboard sides was approximated from the catch on the starboard side by fixing c_j to account for the fraction of meshes on both sides of the trawl covered by the starboard recapture nets (front = 0.033, middle= 0.064, aft =0.152). The codend was fully covered by the 2 by 3 mm oval mesh, thus c_j = 1 for both trawls.

Thus, the total number of fish of species s escaping from the trawl (E_s) can be determined by summing the scaling factors for all fish measured from the recapture nets

$$E_s = \sum_i (W_{i,s,j=recapture\ net}). \quad (2)$$

Likewise, the total number of fish retained in the codend (R_s) is estimated as

$$R_s = \sum_i (W_{i,s,j=codend}). \quad (3)$$

Selectivity estimates

Selectivity was treated as a binomial process, where a fish entering the net is either retained in the codend or escapes through the meshes. To model this as a length-dependent process, a logistic curve was used. To estimate the parameters of the logistic curve, a generalized linear model was fitted (Millar and Fryer, 1999) where the dependent binomial data are logit transformed into a linear variable and two linear coefficients are estimated (i.e. the slope a and intercept b).

The selectivity, as a function of length, l, is described as

$$S(l) = \frac{\exp(a+bl)}{1+\exp(a+bl)}, \quad (4)$$

where $S(l)$ represents the length-dependent probability of being caught in the codend.

These coefficients can be re-defined (Williams et al., 2011) in terms of the length at which 50% of the fish are retained (L_{50}= -(a/b)), and the selection range (SR = (2 $\log_e(3)$)/b which represents the length range between 25% and 75% retention). A length-dependent logistic function was parametrized from L_{50} and SR as

$$S(l) = (1 + \exp^{\left(\frac{k(L_{50}-l)}{SR}\right)})^{-1}, \quad (5)$$

where l is length in cm and k = 2 $\log_e(3)$ (Millar, 1993).

Bootstrap estimates of confidence intervals

Uncertainty in the fitted selectivity relationships was estimated using a 2-stage bootstrap approach (Millar, 1993; Kotwicki et al., 2017). In the first stage, between-haul variation was simulated by selecting n hauls with replacement from the n hauls used to fit equation 4 for each species. In the second stage, within-haul variation was simulated by separately resampling the same number of fish measured in the codend and the recapture nets as in the original haul. The approach mimics the sampling of individual fishes in the catch by separately sampling the escapees captured in the resample nets and the retained fish in the codend. The probability of selecting a given measured specimen, i was equivalent to its contribution to the proportion of the fish retained in or escaping from the net (i.e. W_i). Given that the total

number of escaped fish depends on the expansion factors of randomly drawn fish, which differ among the recapture nets, the total number of escapees varies between bootstrap replicates in a given haul.

Selectivity curves for each of 5000 bootstrap replicates was computed following equations 1-4. The approximate 95% confidence intervals were computed for each size class by computing the 2.5% and 97.5% percentiles of the selectivity curves at that length. Confidence intervals for other descriptive parameters of interest (e.g. the proportion of fish or sizes of fish escaping from a given area of the net) were computed in an analogous fashion from the bootstrapped data sets.

Results

Similar species were captured in the mod-1 and mod-2 deployments. However, pollock were much more abundant in the mod-2 catches, and Arctic sand lance and saffron cod represented a larger proportion of the catch in the mod-1 trawl hauls (Fig. 3). Given the time differences (≥ 4 years) between sampling the differences in species composition between trawls primarily reflect temporal changes in species composition in the study area (Levine et al., in review). Small fishes continued to be abundant in the study area, and large numbers were captured in the codend and recapture nets during the mod-2 deployments (Table 1). For example, 355,390 Arctic cod were captured in the codend, 7596 in the recapture nets, and 6386 Arctic cod were measured.

The recapture net catches indicated that that a consistently higher proportion of fishes entering the trawl mouth were retained in the codend of the mod-2 Marinovich than previously observed with the mod-1 trawl (Fig. 4a). Escapees tended to be smaller than retained fish for both trawls (Table1, Fig. 4b), and the ratios of mean size for retained and escaped fish were similar for the mod-1 and mod-2 trawls (Fig. 4b). The mod-2 Marinovich trawl exhibited lower and more uniform escapement from the top, side, and bottom of the trawl, and forward, middle and aft sections of the trawl than the mod-1 trawl (Fig. 5). The mod-2 Marinovich trawl exhibited less escapement from the aft section of the trawl than the mod-1 trawl, (Fig. 5). As the aft section of the mod-1 trawl was converted into the middle and aft sections of the mod-2 trawl (Fig.1) it is informative to note that the combined escapement in the mod-2 middle and aft sections was less than the escapement in the equivalent aft section of the mod-1 trawl (Fig. 5, panels on right side). Escapement was highest in the middle section of the mod-2 trawl, and escapement was low in the new aft section of the mod-2 trawl (Fig. 5), likely due to the low taper and small meshes (Fig. 1). Although the retained fish tended to be larger than the escapees, escapees in the top/side/bottom and the forward/middle/aft areas of the trawl were, in general, of consistent size (Fig. 6). Taken together, this indicates that the modification to the aft section of the mod-2 Marinovich trawl reduced escapement, and that escapement no longer disproportionately occurred in a particular area of the mod-2 trawl.

For all species and length classes, a higher proportion of fish were retained in the mod-2 Marinovich trawl compared to the mod-1 trawl (Fig. 7, compare the histograms). The fitted selectivity curves demonstrate that the estimated probability of retention increased with length for all species, particularly for the smallest size classes (Fig. 7). Retention of Arctic cod, capelin and Arctic sand lance was substantially higher for mod-2 than mod-1 for all size classes (Fig. 7, Table 2). The modifications also reduced size selectivity: this is evidenced when comparing the probability of capturing a large and small individual of each species. For example, the fitted selectivity curves in Fig. 7a indicate that a 5 cm Arctic cod was 5.2 times more likely to be retained in the mod-1 trawl (i.e. a mod-2/mod-1 selectivity ratio of 0.47/0.09), but only 1.3 times more likely to be retained (0.91/0.71) in the mod-2 trawl. This indicates that the mod-2 Marinovich exhibited both higher capture rates and lower size selectivity. Uncertainty in the fitted selectivity relationships was lowest for more abundant species and size classes (Fig 7). For example, the bootstrapped 95% confidence estimates of the selectivity curve for saffron cod for the mod-2 were very wide (Fig. 7b) as only 6 hauls with sufficient catch were available (Table 2). Similarly, few capelin were captured in the mod-2 recapture nets, and some bootstrap realizations led to predictions that larger fish were less likely to be retained than smaller ones (Fig. 7d). Overall, the differences in selectivity across species for mod-2 were similar to those for the mod-1. Arctic sand lance were less likely to be retained

than other species at a given size (likely due to their elongated morphology), as were saffron cod (which may have more developed escape responses).

Discussion

The reduced catches in the recapture nets of the mod-2 Marinovich compared to previous sampling with the mod-1 Marinovich indicate that the modifications to the aft section of the Marinovich trawl substantially decreased escapement of small Arctic fishes. Escapement was lower and no longer occurred disproportionately in a single area of the mod-2 trawl, indicating that further alteration of a limited area of the mod-2 trawl is unlikely to produce a substantial benefit. The mod-2 Marinovich also exhibited less size selectivity over the size range of fishes encountered. The increased capture rates and lower size selectivity of the mod-2 Marinovich trawl will reduce biases in estimates of abundance, size and species composition (Williams et al., 2011). The selectivity relationships derived from these data were applied in an acoustic-trawl survey to correct survey trawl catches for the size- and species-specific probability of escapement from the trawl (Levine et al., in review). Applying these selectivity relationships, avoids the need to assume that all organisms are captured with equal efficiency, which reduces biases in the abundance estimates (Williams et al., 2011; De Robertis et al., 2017b).

The mod-2 Marinovich was modified to decrease the rate of taper in the aft areas of the net and a small-mesh panel was added in front of the codend (Fig. 1). The changes were motivated by previous work with recapture nets which indicated that escapement in the aft part of the mod-1 trawl was high (De Robertis et al., 2017a; De Robertis et al., in press). As we had hoped, the additional modifications successfully decreased escapement in the aft area of the net compared to the mod-1 Marinovich trawl (Fig. 5). Escapement of small fishes often increases in the aft trawl sections (Matsushita et al., 1993; Williams et al., 2011; Kennelly and Broadhurst, 2021), likely due to increased interaction with the netting due to increased concentration of organisms as the net reduces in diameter, and decreased flow rates near the codend.

Pelagic trawls are designed to exploit the herding responses of large fish, and are unlikely to be optimized to capture smaller indivisuals. Small fishes have limited swimming abilities, and are likely to exhibit different behavioral responses during the capture process (He, 1993; Kwong et al., 2018). For example, a 5 cm fish would have to swim at 24 body lengths s^{-1} to keep pace with the forward progress of trawl, which is above their burst swimming capability (He, 1993). In this context, one should recognize that the modifications to the Marinovich trawl share common elements with commercial krill trawls, which are designed to capture small animals with relatively limited swimming capabilities. Krill trawls are long, comprised of small meshes, and have small mouth openings compared to pelagic trawls designed to capture large fishes (Herrmann et al., 2018). The gradual reduction in diameter (i.e. low taper) results in animals encountering meshes with a relatively low angle of attack, reducing escapement (Krag et al., 2014). Although we did not directly observe the interaction of fish with the Marinovich trawl during the hauls, we surmise that the behavioral interactions of the small Arctic fishes with our trawl gear during the capture process may be more similar to those of krill (Herrmann et al., 2018) rather than those of large fishes due to lower swimming speeds and endurance (He, 1993). That is, the combined effects of encountering trawl meshes at lower angles due to the reduced taper, the presence of smaller meshes in the aft portion of the net where fish are more likely to encounter the netting likely contributed to the higher catch rates of the mod-2 Marinovich.

The selectivity of the pelagic trawls used in many survey applications is unknown. One reason for this is that field experiments to estimate selectivity are time consuming and expensive (Kotwicki et al., 2017). A practical advantage of the recapture net approach (Matsushita et al., 1993; Williams et al., 2011) employed here is that the trawling was conducted as part of a survey (De Robertis et al., 2017b; Levine et al., in review) and did not require dedicated vessel time. This approach allowed a relatively large sample size (number of hauls and individuals captured) to be collected at minimal cost. Another benefit of conducting the recapture net study during a survey is that the trawls were conducted under the size and species compositions relevant to that survey. Furthermore, environmental conditions potentially

influencing the capture process (e.g. temperature and light level, He, 1993; Ryer and Olla, 2000) will also be representative of those encountered during a survey.

It is also important to recognize the limitations of the recapture net method. The recapture net method allows one to quantify the probability that a fish entering the trawl will be retained in the codend (i.e. mesh selection). Although selection within the body of the trawl is an important source of trawl selectivity (Nakashima, 1990; Williams et al., 2011), recapture nets do not address the probability that a fish within the trawl path will actually enter the trawl opening. In other words, the approach does not account for reactions to the vessel or the trawl gear affecting the probability that the fish will enter the trawl (Handegard and Tjøstheim, 2005; Kaartvedt et al., 2012). The magnitude of these reactions can be established by comparing trawl catches to other measurements of abundance such as acoustic observations (Handegard and Tjøstheim, 2005; Somerton et al., 2011; Underwood et al., 2020). While these factors are currently not characterized for Arctic fishes, small fishes may be less likely to avoid the net or to be herded into the net due to their limited swimming ability (He, 1993).

When selectivity is quantified using modified gear such as the recapture nets, the resulting selectivity may not be representative of the unmodified gear (Kotwicki et al., 2017). This was less of an issue in our case with the Marinovich modifications as the recapture nets are permanently mounted for the duration of the survey, and are considered integral to the trawl (i.e. the recapture nets will be used on future surveys). However, the recapture nets were mounted in the center of trawl sections, and the observed escapement was assumed to be representative of escapement in the other uncovered meshes. Although we did not evaluate how the recapture nets affected the trawl, previous observations with cameras have indicated that recapture nets of similar design do not appreciably distort the shape of pelagic trawls or alter fish behavior compared to uncovered meshes (Matsushita et al., 1993; Williams et al., 2011). While escape reactions prior to entering the trawl mouth and biases related to sampling with recapture nets remain important areas for further study, our view is that these limitations should not deter future uses of recapture nets until better or more comprehensive methods to characterize trawl selectivity become available as they provide a practical method to quantify mesh selection during the trawl capture process.

One advantage of a using a sizeable pelagic trawl to sample small fishes rather than using a smaller trawl is that the gear is also able to capture large fishes if they are present. For example, during initial testing of the mod-2 Marinovich in the Bering Sea, adult pollock up to 61 cm in length were captured (Honkalehto and McCarthy, 2015). The ability to identify the presence of large fishes, is important in rapidly changing environments such as the Alaska Arctic. For example, there is potential for adult gadids to colonize the Chukchi Sea from the south as the environment warms as has happened in the Northern Bering Sea to the south (Stevenson and Lauth, 2019). The lack of adult gadids in the mod-2 Marinovich catches described here provides evidence that pelagic adult gadids are not abundant during the 2017 and 2019 AIERP program surveys (Levine et al., in review).

Trawls with both known and high capture probabilities are advantageous as these characteristics lead to more accurate estimates of species composition, organism abundance, and size distribution. In the application of Arctic acoustic-trawl surveys examined here, the size and species selectivity has been reduced relative to the mod-1 Marinovich, and the probability of capture as a function of species and size has been established. This reduces uncertainty (because selectivity has been quantified), and biases (because small fishes are more likely to be retained) in future uses of the catch data, including acoustic-trawl surveys (Levine et al., in review). Although the probability of retaining small fishes has been improved, as with all trawls, the trawl remains species and size selective. It is thus best practice to correct the observed trawl catch ($catch_{obs}$) of a given species with the fitted selectivity relationships (i.e. $Catch_{corr,l} = \frac{\mathrm{Catch}_{obs,l}}{S_l}$, where S is the probability of retention in the trawl codend, and l is length) rather than assuming that the trawl catch is unbiased.

The use of trawls with characterized selectivity allows for the requirement for methodological consistency in order to maintain a consistent sampling bias to be relaxed in a survey time series. If selectivity has been

quantified, corrections for selectivity can be implemented and catches from different sampling gears can be combined. This is advantageous as it allows for improved trawl gear to be introduced as surveys are developed. This was the case for development of our acoustic-trawl surveys of the Chukchi sea. That is, a large pelagic trawl was replaced with the mod-1 Marinovich after it became clear that fishes were small (De Robertis et al., 2017b). Then, the mod-2 Marinovich was developed after it became clear that there was substantial escapement in the aft area of the mod-1 net (Levine et al., this issue). Gear with known selectivity would also improve confidence in conclusions drawn from the comparison of sampling with different gears (e.g., Logerwell et al., 2015; Deary et al., 2021). This is particularly relevant to environments such as the Alaska Arctic which lack well-established monitoring programs and data are scarce and sampling methods are not standardized.

Although this study focused on a particular application and ocean region, the principles are transferable to a broad range of applications with pelagic trawls. The primary situations where understanding trawl selectivity are most important are those where estimates of absolute abundance are desired (as escapees will not be enumerated), or cases where size and species composition are required, but there are large differences in the probability of capture. For example, in the case of acoustic-trawl surveys, situations characterized by mixed aggregations of fish species spanning a large size range will be most impacted by trawl selectivity (Williams et al., 2011; Davison et al., 2015). Likewise, acoustic trawl-surveys with mixed species aggregations of strong and weak acoustic scatters (e.g. fishes with and without gas-filled swimbladders) are highly sensitive to selectivity-induced biases in trawl species composition (McClatchie and Coombs, 2005; Davison et al., 2015). For instance, work with recapture nets may prove useful in constraining uncertainties in global abundance estimates of mesopelagic fishes, which remain poorly quantified. Both trawl and acoustic-trawl abundance estimates of mesopelagic fishes are highly dependent on trawl selectivity (Koslow et al., 1997; Davison et al., 2015; Kwong et al., 2018), and characterizing trawl selectivity will reduce the uncertainty in these estimates.

This work highlights the utility of quantifying the size and species selectivity of pelagic survey trawls. The use of recapture nets allowed the primary area of escapement from within a survey trawl to be identified, corrected by modification of the trawl, and finally the improved performance could be quantified. Estimates of trawl selectivity were used to reduce biases in both the abundance and size composition of acoustic-trawl abundance estimates of small Arctic fishes (De Robertis et al., 2017b; Levine et al., in review). The trawl gear was improved to reduce selectivity during these surveys, and catches from the three different trawls used in this survey could be integrated into a consistent abundance survey time series by estimating and then accounting for the impact of selectivity on abundance estimates. The work demonstrates that recapture nets can improve abundance estimates derived from sampling with midwater trawls, and that survey trawls can, and should, be modified to improve performance for specific applications.

Acknowledgements

Poul Pedersen of Dantrawl Inc. proposed the modifications to the Marinovich trawl and the staff at the Alaska Fisheries Science Center's (AFSC) net shed modified the trawl. We thank the cruise participants who processed many recapture net catches. This work was funded by the Arctic Integrated Ecosystem Research Program (IERP; http://www.nprb.org/arctic-program/), and is NPRB Publication ArcticIERP-XX. This paper is dedicated to the memory of the AFSC net shed's leader David King who was a fine co-worker and friend and a patient and encouraging teacher.

Table 1. Summary of the most abundant fishes captured in mod-2 Marinovich hauls equipped with recapture nets. The number of hauls in which >10 fish were measured is given, and the total numbers of individuals captured in the codend and all recapture nets combined are listed. The mean and standard error of the standard length of the specimens and the number of specimens measured also given. See De Robertis et al., 2017, their Table 1 for an equivalent summary of catches for the mod-1 Marinovich hauls.

Species	# hauls	Total # captured	# in codend	# in recapture nets	Length (cm) in codend $\bar{x}$ ± SE, (n)	Length (cm) in recapture nets $\bar{x}$ ± SE, (n)
Arctic cod	51	362986	355390	7596	4.5 ± 0.0 (4094)	4.0 ± 0.0 (2292)
Saffron cod	6	1206	1137	68	7.9 ± 0.2 (291)	4.9 ± 0.3 (38)
Pollock	57	116885	114501	2384	5.7 ± 0.1 (3197)	3.9 ± 0.0 (997)
Capelin	19	6967	6944	23	9.5 ± 0.1 (495)	8.7 ± 0.3 (23)
Arctic sand lance	34	27442	26125	1317	7.8 ± 0.1 (1899)	6.3 ± 0.1 (618)
Other fishes	57	29914	28456	1458	7.1 ± 0.1 (1823)	4.9 ± 0.0 (1047)

Table 2. Parameters of logistic selectivity curves fitted to for catch data from the mod-1 and mod-2 Marinovich pelagic trawl. *L50* represents the length in cm at which 50% of individuals are retained, the selection range (*SR*) is the length in cm between 25 and 75% retention. Bootstrap estimates of the 95% confidence intervals of *L50* and *SR* are given in parentheses. A negative *SR* indicates a prediction that small fish are more likely to be retained than larger fish. Insufficient pollock were captured during mod-1 deployments to compute a selectivity curve. Other fishes refers to the grouping of all fishes other than those specifically listed below.

Species	**Marinovich mod-1**		**Marinovich mod-2**	
	L50	*SR*	*L50*	*SR*
Arctic cod	5.1 (4.6, 5.9)	2.0 (1.3, 3.0)	1.8 (-0.3, 2.6)	3.1 (2.1, 6.2)
Saffron cod	8.8 (6.6, 30.7)	4.6 (2.5, 23.6)	3.5 (-6.1, 45.1)	5.0 (-30.7, 24.9)
Pollock	n/a	n/a	2.1 (-0.2, 2.9)	2.7 (1.7, 5.4)
Capelin	10.2 (-14.5, 34.2)	6.0 (-40.4, 49.4)	-19.0 (-156.7, 125.6)	17.4 (-72.0, 95.4)
Arctic sand lance	11.3 (6.9, 25.5)	6.1 (2.4, 24.2)	5.2 (3.3, 5.8)	3.6 (2.5, 6.5)
Other fishes	3.8 (3.6, 5.2)	0.7 (0.5, 2.0)	5.0 (4.0, 6.0)	2.9 (1.7, 4.3)

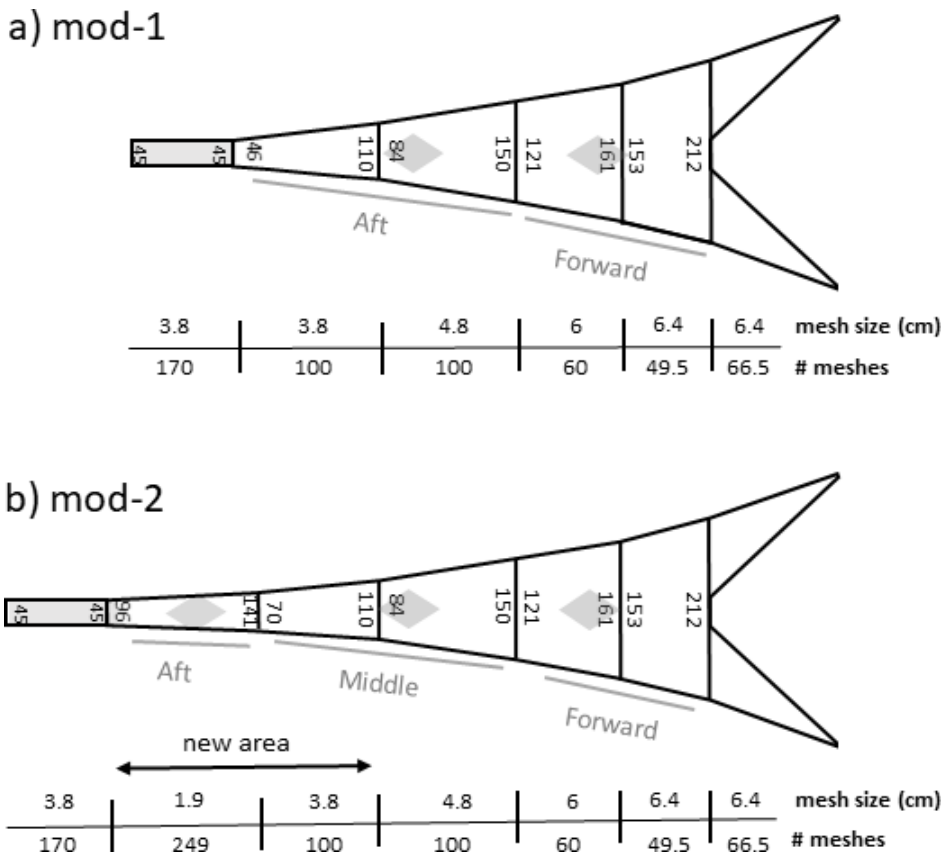

Fig. 1. Schematic of the a) mod-1 and b) mod-2 Marinovich trawls. The Mod-2 trawl was modified from the by replacing the aft-most 3.8 cm mesh panel of the mod-1 trawl forward of the codend with a new 3.8 cm mesh panel with reduced taper, and adding a smaller mesh section forward of the codend (the modified sections are annotated as "new area"). The size and number of meshes of each panel is annotated. This "box" trawl is symmetrical with an equivalent top, side and bottom. Only one view is depicted. For the purposes of analysis, the trawl body was divided into forward, middle and aft sections of similar mesh size. The approximate location of the recapture nets in the center of each section is given by the gray diamonds, and the 2 by 3 mm liner is indicated by gray shading.

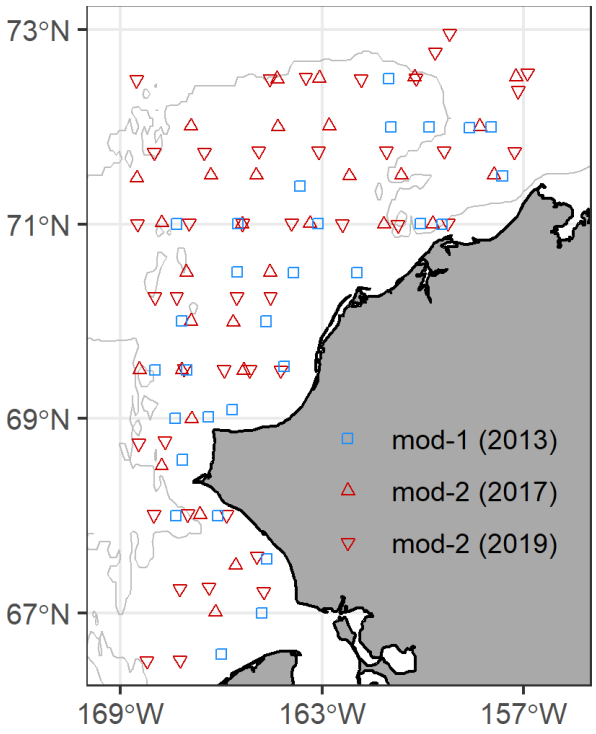

Fig. 2. Map of the study area indicating where locations where the mod-1 and mod-2 Marinovich trawls were fished during acoustic-trawl surveys. The 50 m depth contour is shown as a grey line.

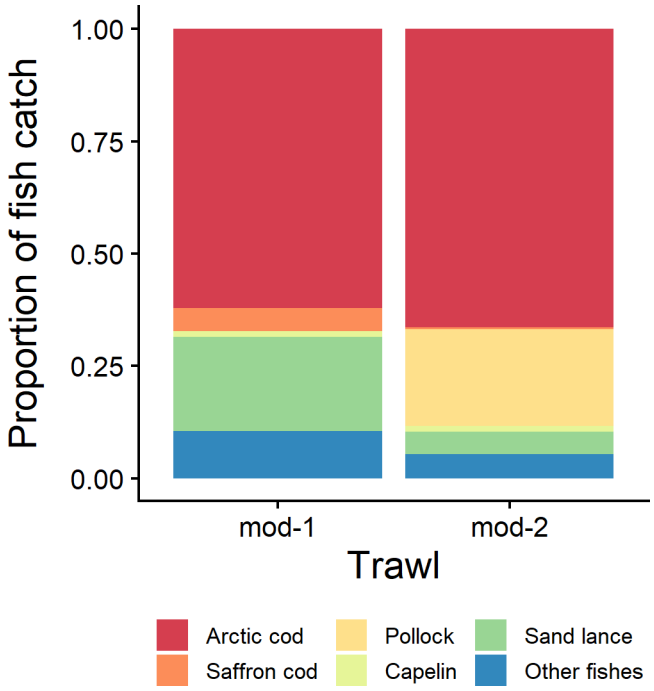

Fig. 3 Fish species composition based on codend catches of trawl hauls conducted with the Marinovich mod-1 and mod-2 trawls.

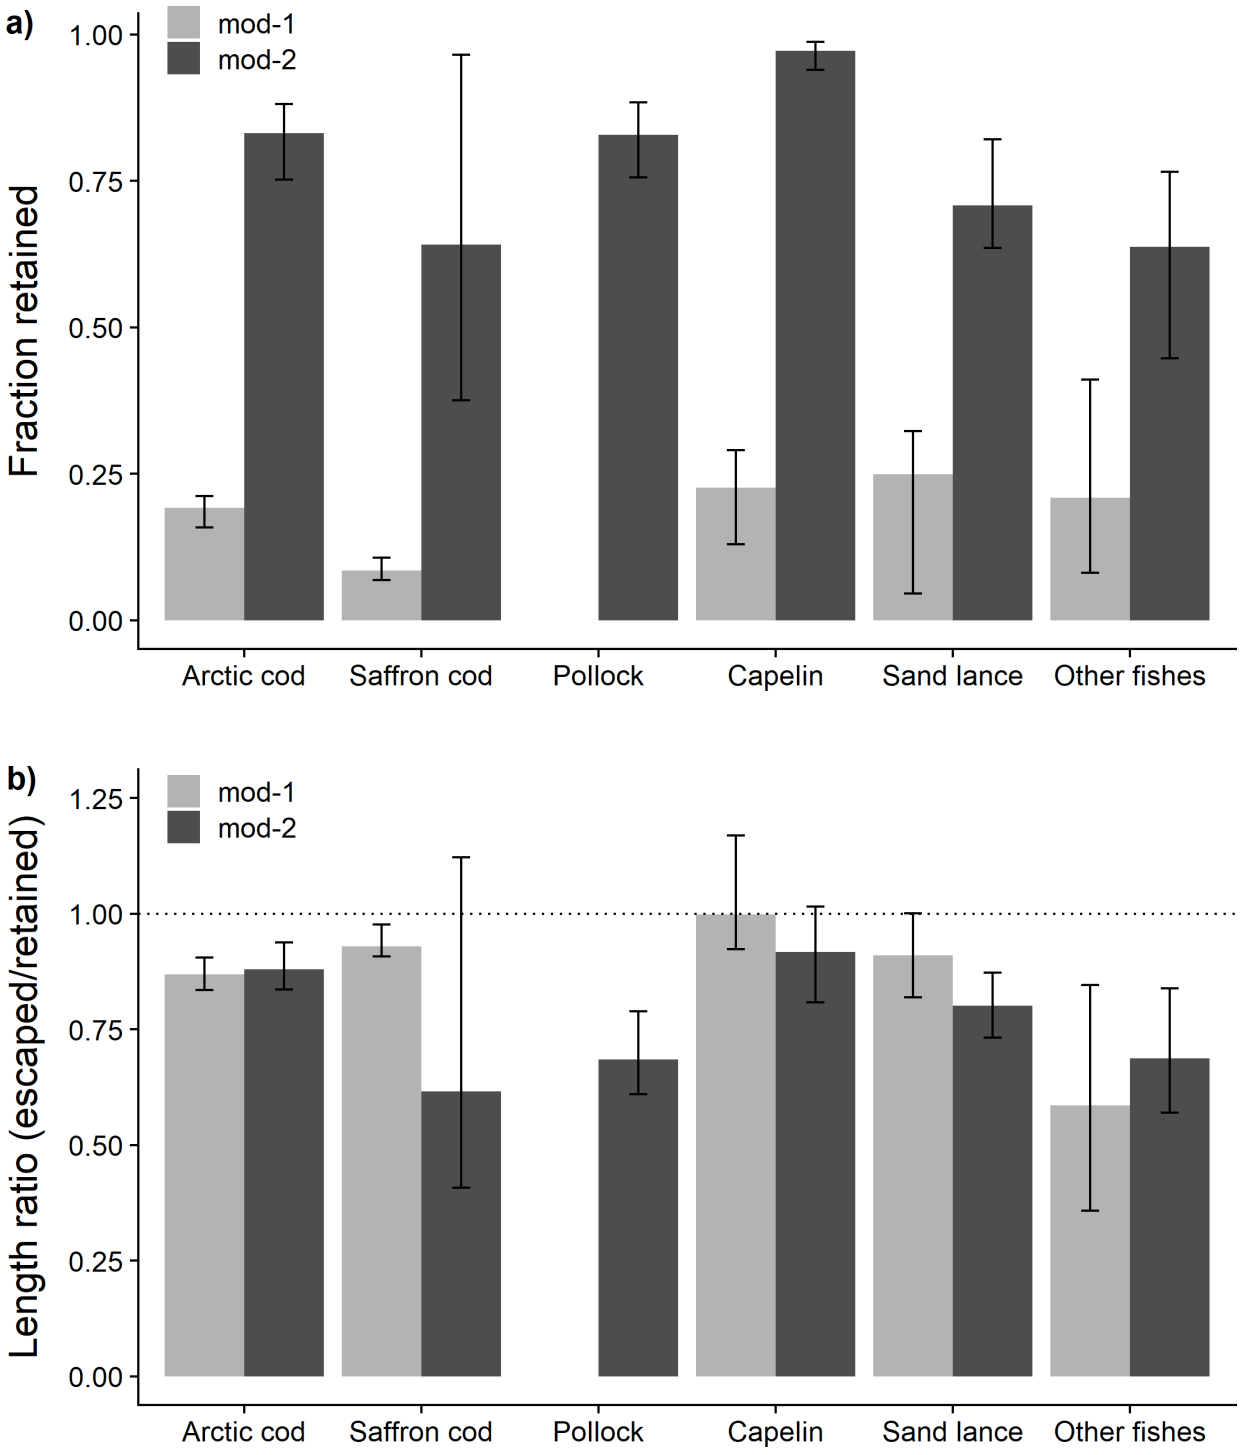

Fig. 4 Summary of a) proportion of fish entering the trawl that were retained in the codend and b) ratio in the mean standard length of the escaped/retained fish for the mod-1 and mod-2 Marinovich trawls. The error bars show the observed values (all hauls pooled) and the error bars are 95% confidence intervals computed via bootstrapping of the hauls catches and measured fish specimen lengths.

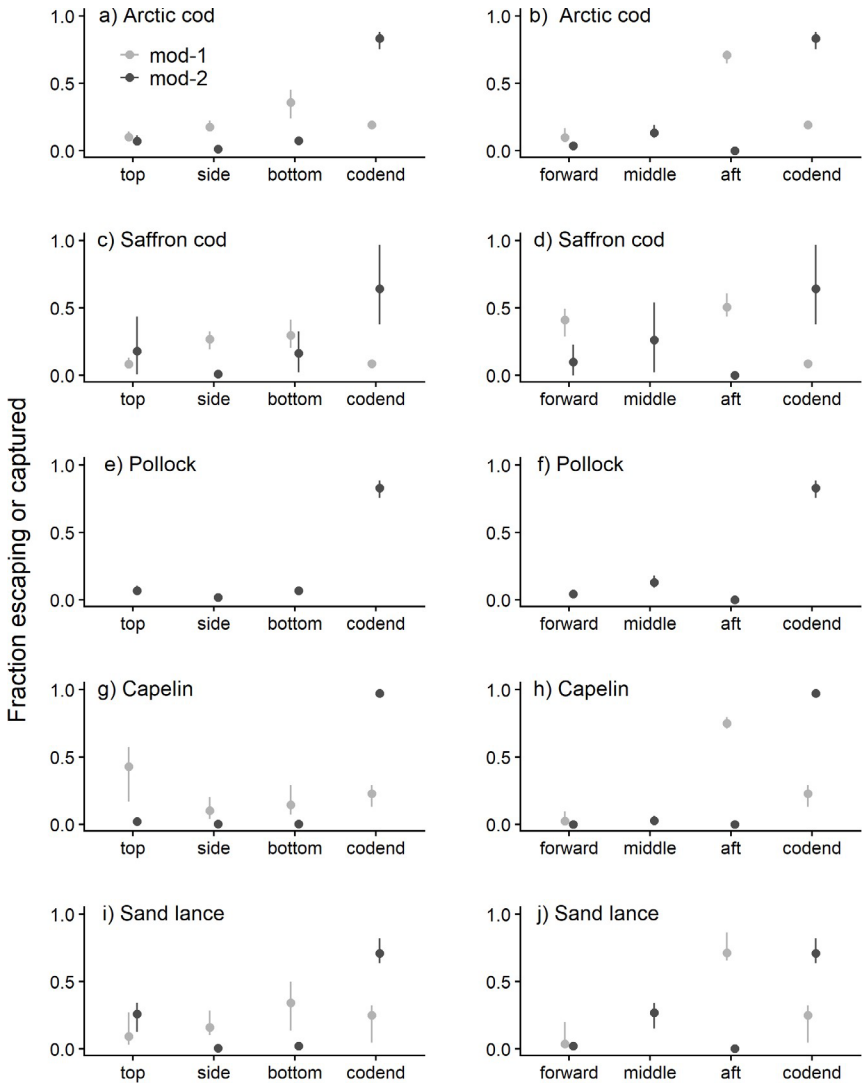

Fig. 5. Escapement pattern in mod-1 and mod-2 Marinovich trawl derived from recapture net and codend catches. a,b) Arctic cod, c,d) saffron cod, e,f) pollock, g,h) capelin, and i,j) Arctic sand lance. Panels to the left depict the estimated proportion of individuals escaping through the meshes in the top, each side, or bottom of the trawl, or retained in the codend. The mod-1 Marinovich lacks a middle section (see Fig. 1). Panels to the right indicate the estimated proportion of fish entering the trawl mouth escaping through the forward middle, or aft net sections or retained in the codend. The points represent the observed means, and error bars represent 95% bootstrap confidence intervals. In some cases, error bars are small and obscured by the symbols.

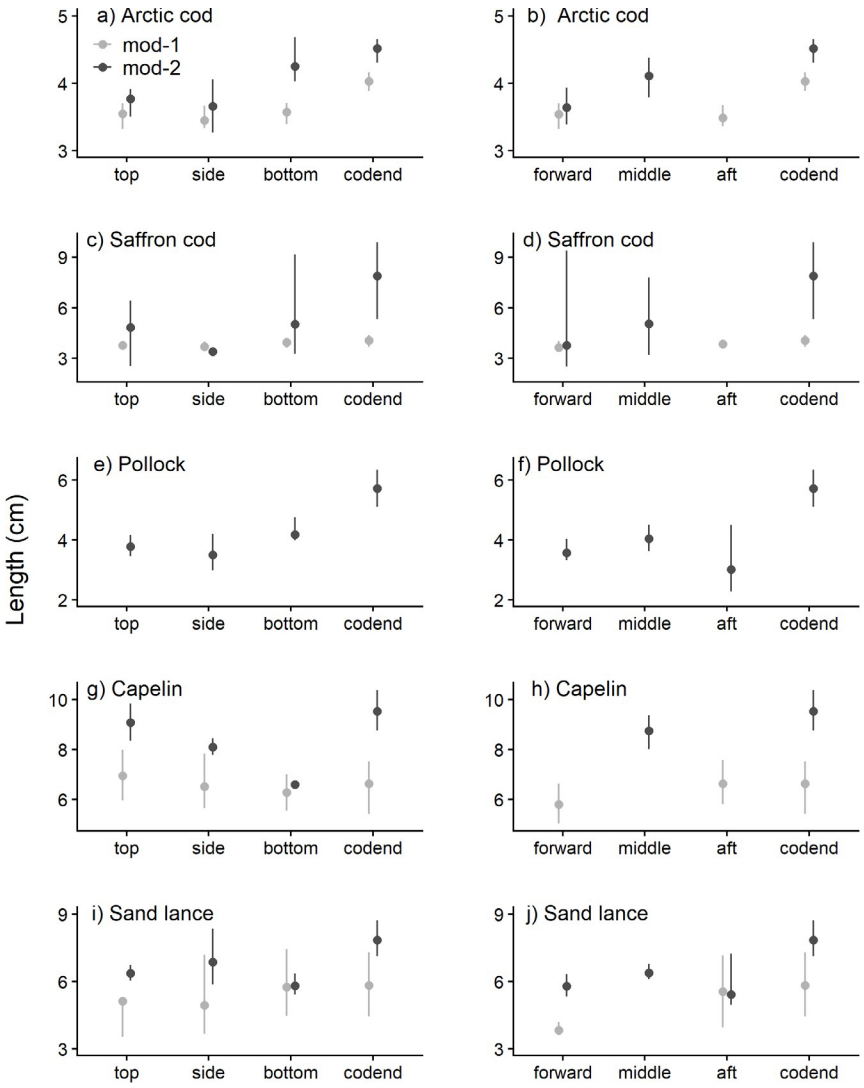

Fig. 6. Standard length of fishes caught in recapture nets and codend of mod-1 and mod-2 Marinovich trawl. a,b) Arctic cod, c,d) saffron cod, e,f) pollock, g,h) capelin, and i,j) Arctic sand lance. Panels to the left depict the lengths of fish caught in recapture nets on the top, side, bottom, or codend of the trawls. Panels to the right indicate the size of fish caught in the forward middle, or aft net sections or the codend. The mod-1 Marinovich lacked a middle section (see Fig. 1). The points represent the observed means, and error bars represent 95% bootstrap confidence intervals. Note that no capelin were captured in the forward and aft recapture nets of the mod-2 Marinovich, and that few were captured in the side (n=3) and bottom (n=2).

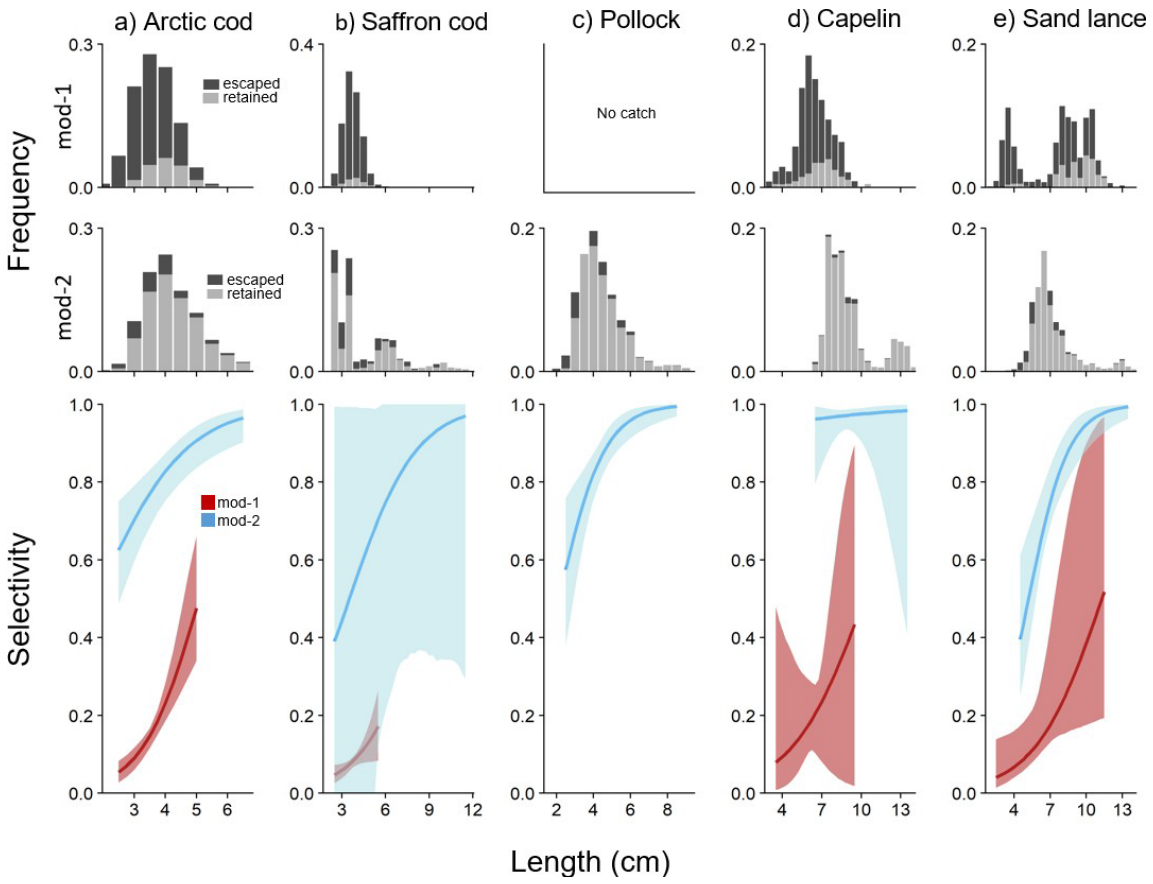

Fig. 7. Summary of escapement and fitted selectivity curves for a) Arctic cod, b) saffron cod c) walleye pollock, d) capelin, and e) Arctic sand lance. The top panel shows a size histogram with color shading representing the proportion of fish escaping through the meshes (dark gray) or captured in the codend (light grey) of the mod-1 Marinovich trawl. The middle panel shows an equivalent histogram for the mod-2 Marinovich trawl. The bottom panels compare the fitted selectivity curve and bootstrapped 95% confidence intervals for the mod-1 and mod-2 Marinovich. Pollock were effectively absent in the mod-1 data set.

CHAPTER 8 - The role of temperature on overwinter survival, condition and lipid storage in juvenile polar cod (*Boreogadus saida*): a laboratory experiment.

Objective 2: Quantify the distribution, abundance, and condition of pelagic marine fishes, in particular young-of-the-year Arctic gadids and other forage fishes

Copeman L, Salant C, Stowell M, Ottmar M, Spencer M, Iseri P, Laurel B

Abstract

In the Arctic, winter warming and loss of sea ice pose largely unknown risks to keystone species and the marine ecosystem they support. Young of the year juvenile polar cod, *Boreogadus saida*, are energy-rich forage fish that accumulate high levels of lipid in the summer but retain a relatively small body size during the winter. To address winter bioenergetics and survival, we held age-0 juveniles under simulated winter conditions (food deprived, 24-hr darkness) throughout a range of four constant temperatures (-1, 1, 3, 5 ℃). Our goals were to: 1) determine how small fish utilize lipid energy in muscle and liver across varying temperatures and durations of food deprivation, and 2) develop temperature-dependent survival trajectories based on energy loss (lipid, condition metrics, body weight) that would be useful for projecting winter outcomes of polar cod sampled pre-winter i.e, when fish are more easily sampled in the field. As expected, juvenile cod were able to better conserve lipids and survive longer at colder temperature in the absence of food. Further, there was no negative impact of freezing temperatures on this trend e.g. 50% mortality at ~170 days at -1℃ versus 94 days at 5℃. During the first 28 days of winter, polar cod preferential catabolized triacylglycerols (TAG) from muscle tissue and then shifted to storage lipids in the liver and muscle until starvation. Mortality occurred when whole body lipid concentrations fell below 12 mg. g^{-1} WWT within each temperature treatment. The temperature-dependent decline in morphometric condition (Hepatosomatic index (HSI) and Fulton's K) and lipid content were parameterized and a series of winter survival trajectory models are presented based on varying condition metrics. Using the lipid model on field collected fish, we demonstrate that winter survival is highly sensitive to small changes in temperature between -1 and 1 °C when fish are in good summer condition (e.g. 2013), alternatively polar cod will be required to continue foraging throughout the winter when in poor late summer condition (e.g. 2017). Collectively, these results suggest lipid-based indices (not size) offer a sensitive means of predicting overwintering success for polar cod experiencing climate-driven changes in summer and winter habitats in the Arctic.

Introduction

Overwintering ecology is a logistically challenging process to examine in cold and ice-covered marine systems (Berge et al. 2020b), but may be the most significant in terms of regulating species distribution and population dynamics in the era of climate change (Hurst 2007, Heintz et al. 2013, Siddon et al. 2013a). In the Arctic, winter conditions are particularly severe (long, cold, dark, and ice-extensive) and likely require specific physiological adaptations for survival e.g., cold-tolerance, energy allocation. Therefore, climate change impacts on species distributions within and adjacent to the Arctic may be limited by their ability to capitalize on warmer summer growth conditions (e.g., grow fast while storing fat) while also having the physiology to survive persistently harsh dark overwintering environments (Copeman et al. 2017, Copeman et al. 2020, Geoffroy & Priou 2020, Geissinger et al. 2021). The vulnerability of Polar cod (*Boreogadus saida*) to seasonal climate forcing are particularly concerning, given their tremendous ecological importance as a mid-trophic forage fish and role in channeling energy from plankton to upper trophic levels such as marine mammals, birds, and other fish (Hop & Gjosaeter 2013, Whitehouse et al. 2014). Estimates from the Canadian Arctic indicate that polar cod can funnel up to 75% of the carbon between zooplankton and top predators, such as seabirds and whales (Welch et al. 1992). Changes in the distribution and abundance of polar cod will therefore likely lead to broad trophic, subsistence hunting and economic impacts (Huserbråten et al. 2019, Huntington et al. 2020, Marsh & Mueter 2020), but studying these and other Arctic fish species is logistically challenging outside the summer, open-ice period (Geoffroy & Priou 2020).

Laboratory studies provide a tractable way of examining overwintering processes in high-latitude marine fish that are otherwise difficult to sample under the ice (Flores et al. 2015, David et al. 2016). Juvenile gadids have been focal species in recent laboratory experiments with results being used to validate several field observations of size-dependent overwintering mortality (Sogard 1997, McCollum et al. 2003, Shoup & Wahl 2011). Experimental studies also provide a means of tracking rates of energetic loss in juveniles during the overwintering period (Gotceitas 1999; Sogard and Olla 2000). Finally, overwintering environments (e.g., food, temperature) can be manipulated in the laboratory to examine impacts on survival and condition which in the future will allow annual forecasting of fish recruitment under different oceanographic conditions (Gotceitas et al. 1999, Sogard & Olla 2000, Kooka 2012, Geissinger et al. 2021).

The physiological response of polar cod to environmental variability provides an indication whether and how these species will persist with continuing climate change. Juvenile gadids must develop, grow and store lipid reserves rapidly during their 1st year to minimize predation and maximize overwintering survival (Copeman et al. 2008, Geissinger et al. 2021). This is especially important in the Arctic where the summers are short and prolonged winter-spring temperatures are <0°C (Bouchard & Fortier 2008). Food availability is highly seasonal in Arctic systems (Wassmann 2006) with consumers utilizing elevated summer lipid storage as a strategy to survive extended winter conditions characterized by lower food availability (Kattner et al. 2007, Falk-Petersen et al. 2009, Leu et al. 2011, Copeman et al. 2016). In general, high latitude fish are presumed to have physiology adapted to grow faster at colder summer temperatures than fish from lower latitudes, but within a narrower range of temperature preference and tolerance (stenothermic, Farrell and Steffensen (2005), (Pörtner & Farrell 2008)). Recent experimental studies have supported these assumptions (Laurel et al. 2016), but it is also clear that the thermal response of polar cod, shifts across ontogenetic stages (Laurel et al. 2017, Koenker et al. 2018b, Laurel et al. 2018). These results strongly emphasize the need to gather species-specific thermal response information spanning development across multiple critical time periods.

There are currently no studies on the overwintering processes of Arctic gadids, and how these and more well-studied boreal species may respond to new winter growth environments resulting from climate change. It is possible that juvenile polar cod utilize alternative developmental and energy storage

strategies to maximize overwintering survival compared to boreal congeners (Copeman et al. 2020). Field studies indicate that saffron cod (*Eleginus gracilis*) overwinter at a smaller size in more northern extremes of their range (Chukchi and Beaufort Seas) than in more southern areas (Gulf of Alaska and South East Bering Sea) (Helser et al. 2017). Further, Copeman et al. (2016) found that age-0 saffron cod from the Chukchi Sea were smaller (<55 mm) and had a much higher lipid concentrations (19 $mg.g^{-1}$ WWT) at the end of their 1st summer than larger (>75 mm) age-0 saffron cod from the Bering sea (12 $mg.g^{-1}$). These findings suggest that gadids living at high latitudes are under selection to store seasonal pulses of food as lipid energy rather than prioritizing accelerated growth. Comparative studies of gadids also indicate that age-0 polar cod store higher concentrations of lipid in their tissues (31 $mg.g^{-1}$, $mg.g^{-1}$ WWT) compared to other gadid species (i.e. saffron cod, ~16 $mg.g^{-1}$, Copeman et al. (2020), Copeman et al. (2017)). High levels of lipid storage in polar cod muscle tissue may offset limited capacity to store energy reserves in the liver at a small size; proportionally large lipid-rich livers are not found in gadids until > 60 mm in standard length which represents the 2nd year of growth for Arctic gadids compared to the 1st in Boreal gadids (Laurel et al. 2007, Helser et al. 2017)).

The goal of this study is to determine the size-, energy- and temperature-dependence of overwintering survival in juvenile polar cod held under simulated winter conditions in the laboratory. Our specific objectives were to parameterize the rates of juvenile mortality and energy loss (growth, condition, lipid) as well as determine the minimum energetic state for survival. We hypothesize that high energy density (pre-winter) and cold thermal conditions (winter) are necessary for elevated overwintering survival in juvenile polar cod.

Methods

Culture of juvenile polar cod

Juveniles used in these experiments were reared from incubated eggs of captive broodstock. Cod adults were originally collected as juveniles (age-0) in the Beaufort Sea (Prudhoe Bay, AK, 70.383°N - 148.552°W) and were held at the Alaska Fisheries Science Center (NOAA) laboratory in Newport, Oregon. Broodstock (age 3+) were maintained in a 6-m tank under seasonally adjusted temperatures ranging from 5 °C in the summer to 0.5 °C in the winter. In 2016, fish showed signs of maturity in early March and were checked daily by gently squeezing the abdomen to determine if eggs were freely flowing, clear and hydrated. Egg batches were made by combining the free-flowing eggs of a single female with the milt of three males in a dry, stainless steel bowl nested in crushed ice (following protocols described by Laurel et al. (2018)). A total of four egg batches were constructed in this manner and then transferred to corresponding meshed 4 L baskets floating in 2 °C water baths for incubation.

After 4 weeks, eggs were then transferred to a series of larger 400 L upwelling tanks to hatch and be cultured on live food. Larvae were reared at 2 to 3 °C on a 12:12 dark-light cycle and fed enriched rotifers at a density of 5 prey mL^{-1} 2x daily for a 4 wk period. After 4 wks, enriched *Artemia* were provided at a density of 1.5 prey mL^{-1} in addition to rotifers. After 10 wks, live prey consisted entirely of *Artemia* supplemented with dry food (Otohime A) 2x daily (Koenker et al. 2018a, Koenker et al. 2018b). At 20 wks, juvenile fish were transferred to 3-m diameter round tanks with flow-through seawater maintained at 5 °C and gradually weaned onto a gel food (diet details as in Copeman et al. (2017) and Copeman et al. (2013)). Juvenile fish (40 to 65 mm SL) were available for the experiment at ~7 months after initial egg fertilization in the laboratory. Juvenile fish were of similar size and lipid density (~55 mm; 30 mg lipids/g WWT) to those measured in late summer/fall collections in the Chukchi Sea during 2013 (Copeman et al. (2020), 2017 and 2019 (Copeman et al. in prep this report).

Temperature-dependent overwintering experiment

On October 13, 2016, age-0 juvenile polar cod were transferred from their large holding tank and separated into a series of smaller experimental tanks (n=12; dimensions 66L × 46H × 38W cm) held in an adjacent laboratory. Following transfer, fish were gradually acclimated (<0.5 ℃ in any day) to their respective overwintering temperatures (-1, 1, 3 or 5 ℃) and held with flow-through, temperature-controlled seawater over the course of the experiment. Three replicate tanks were used per temperature with each tank containing 50 fish. Fish were fed during the 12-day acclimation period but were not fed during the simulated overwintering experimental period. All tanks were covered in black tarp to keep fish in dark conditions throughout the entire experiment. Tanks were checked daily for mortalities using a red-lense flashlight. Daily fish mortalities were retained frozen (-80 ℃) for subsequent condition and lipid analysis (see below).

On October 25, 2016, the experiment was initiated by lethally subsampling 10 fish per tank for length (SL, mm, 0.01mm) and wet weight (WWT, 0.01 g). Variation in fish size (42 - 64 mm SL; 0.55 to 2.34 g) was equal across all temperature treatments (i.e. length, ANOVA $F_{3,8}$=1.31, p=0.34). All sub-sampled fish were frozen (-80 ℃) for later condition analyses based on both WWT (n=10), DWT (n=7) and tissue-specific lipid content (n=3, sampling numbers as in Table 1). After an additional 28 days of winter, 6 fish per replicate tank were measured and frozen for later condition analyses based on WWT (n=6), DWT (n=3) and lipid content (n=3). The final sampling period occurred when a temperature treatment approached 50% survival of the population, after adjusting for fish removals due to sampling events. At this time, all surviving fish in the tank were euthanized and processed for length and weight (n = 9 to 24 per tank) and frozen for later condition analyses based on WWT (n=7 to 20), DWT (7-10) and lipids (n=3, Table 1).

Condition metrics and weight loss

During morphometric and lipid processing, fish were removed from the -80 ℃ freezer in small batches (n<10) and were kept on ice during sampling to prevent lipid break-down. Fish were rinsed with water, patted dry and immediately measured for standard length (tip of the snout to end of the notochord, SL, mm) and wet weight (WWT, g, ± 0.001). Fish intestinal tracts were removed and livers were dissected and weighed on a microbalance (0.001 mg). A subset of eviscerated bodies and livers were dried separately at 65 ℃ to a constant weight (~1 week) and reweighed to calculate Fulton's K and hepatosomatic index (HSI) based on DWT (equations below). Conversion factors between tissue-specific WWT and DWT were also calculated and used to express lipids per DWT of tissue. Liver and body weights were used to calculate the following condition factors on both sampled fish and mortalities:

- Fulton's K_{wet} = (Whole body WWT(g)/(SL(cm)^3) * 100
- Fulton's K_{dry} = (Whole body DWT(g)/(SL(cm)^3) * 100
- HSI_{WET} = (Liver WWT(mg)/Whole Body WWT(mg)) * 100
- HSI_{DRY}= (Liver DWT(mg)/Whole Body DWT(mg)) * 100
- Concentration of total lipids per WWT = (Iatroscan summed lipid classes (µg))/ (weight of tissue (mg))
- Concentration of total lipids per DWT = (Iatroscan summed lipid classes (µg))/(WWT of tissue, (mg) * temperature and time-specific conversion factor (DWT:WWT))

Relative body weight loss (BW_l) was determined by subtracting the measured fish WWT from the WWT estimated from the length-weight relationship at the beginning of the experiment (see Fig.3) assuming negligible change in SL (mm).

BW_l was determined using the following equations:

$$BW_l=100-(e^{g}-1)$$

where g is the instantaneous growth coefficient obtained by the equation:

$$g=(\ln 〚WWT〛_2-\ln 〚WWT〛_1)/(t_2-t_1)$$

where WWi is the measured or estimated wet weight of an individual fish at time ti. Temperature-dependent BW_l was described using a 3-parameter polynomial function (SigmaPlot 14). Tank replicates (mean BW_l) was used as the level of observation for the temperature-dependent weight loss model.

Tissue-specific lipid analyses

Tissue-specific lipid analyses of muscle and liver were conducted for total lipids and lipid classes. Lipid analyses were based on whole livers and ~300 mg samples of dorsal muscle that excluded the skin. All samples for lipid analyses were stored in chloroform under nitrogen in a -20 °C freezer and were extracted and analyzed within 6 months of sampling. Total lipids were determined using thin layer chromatography with flame ionization detection (TLC/FID) with a MARK V Iatroscan (Iatron Laboratories, Tokyo, Japan) as described by Lu et al. (2008) and Copeman et al. (2017). Extracts were spotted on duplicate silica-gel-coated Chromarods, and a three-stage development system was used to separate wax esters, triacylglycerols, free fatty acids, sterols and polar lipids. Polar lipids are mostly phospholipids, with minor amounts of other acetone mobile polar lipids. The first rod development was in a chloroform: methanol: water solution (5:4:1 by volume) until the leading edge of the solvent phase reached 1 cm above the spotting origin. The rods were then developed in hexane: diethyl ether: formic acid solution (99:1:0.05) for 48 min, and finally rods were developed in a hexane: diethyl ether: formic acid solution (80:20:0.1) for 38 min. After each solvent development, rods were dried (5 min) and conditioned (5 min) in a constant humidity chamber (~32%) that was saturated with aqueous $CaCl_2$. Following the last development, rods were scanned using Peak Simple software (ver. 3.67, SRI Inc.) and the signal detected in millivolts was quantified with calibration curves using the following commercial standards from Sigma (St Louis, MO, USA): cholesteryl stearate (wax ester), glyceryl tripalmitate (triacylglycerols), palmitic acid (free fatty acids), cholesterol (sterols), L-alpha-phosphatidylcholine (polar lipids). Calibrated relationships between lipid class areas and standard lipid amounts (µg) had correlations with an r^2 >0.98 for all classes.

Temperature and size effects on survival

The effect of temperature on days to 80% and 50% population mortality for age-0 polar cod was investigated using a one-way ANOVA with Tukey's multiple comparison test on tank values (n=3 per temperature). The effect of size and temperature on days to mortality was investigated using a one-way ANCOVA but inequality of error variance required that we describe the effect of size using separate temperature-dependent linear regression models. Residuals from the regression of length and days to mortality were tested for temperature effects using a one-way ANOVA. A two-way ANOVA was used to investigate the effect of temperature and survival status on the mean SL (mm) of age-0 polar cod when the population reached 50% survival.

Effects of temperature on condition loss

Temperature-specific effects of starvation duration on condition metrics were analyzed by fitting linear and exponential decay functions (SigmaPlot 14). To describe the continuous temperature effect on rate-loss functions, we fit linear regressions between temperature and the slopes of the temperature-specific (-1, 0, 3 and 5 °C) relationships between condition and days of starvation. Hepatosomatic indices were nature log transformed to improve the fit of the models. Condition factors are expressed per WWT and per DWT. All analyses are run on tank means (n=3) with individuals sampled by tank as in Table 1.

The days to starvation over a wide range of winter temperatures were visualized for age-0 polar cod from both this experiment along-side field-collected fish with mean end of summer lipid levels from a divergent cold (2013) and a warm (2017) years (Central Chukchi Sea, see Table 5). Starvation levels (12.5 mg.g-1 WWT, Fig. 7d) as well as a lipid loss model ((mg.g^{-1} WWT).day^{-1} = -0.1879 -0.02122 (T), r^2=0.77 (Fig. 7d)) were determined from experimental treatments. Days to starvation were calculated as the days required to decrease in lipid concentration from end of summer levels (2013, 34.7 mg.g^{-1} and 2017, 16.0 mg.g^{-1}) to starvation status, 12.5 mg.g^{-1}.

Results

Survival

Temperature significantly affected starvation resistance of polar cod, with fish at colder temperatures surviving long than fish at warmer temperatures (Fig. 1). The duration to 80% and 50% population mortality were significantly different across temperature treatments (ANOVA 80%: $F_{3,8}$=22.12, p<0.001, ANOVA 50%: $F_{3,8}$=92.93, p<0.001). Polar cod had a mean survival time to 50% population mortality of 170 ± 11 days at -1°C compared to only 94 ± 1 days at 5 °C (Fig. 1).

Within fish that died, size only weakly explained survival time. The temperature-dependent slopes of this relationship were only significant at 1 and 3 °C (p<0.05) with the strongest correlation between size and survival time noted at 1°C (r^2 = 0.26, Fig. 2a). Size de-trended residuals for the relationship between size and time to mortality showed a significant effect of temperature treatment (ANOVA, $F_{3,190}$=136.37, p<0.001, Fig. 2b.), with fish at 5 °C having the lowest size de-trended survival duration.

At 50% mortality, we compared the effect of temperature and mortality status on the size (SL, mm) of polar cod (Fig. 2c). There was no interaction between temperature and mortality status and no significant difference in size due to temperature (ANOVA, $F_{3,18}$=2.66, p=0.08). However, fish that died were significantly smaller (mean SL of 53.5 ± 0.8) than fish that survived (mean SL of 61.1 ± 0.7 mm, ANOVA, $F_{1,18}$=51.44, p<0.001, Fig 2c), indicating that larger size provided some overwinter survival advantage.

Weight and morphometric condition loss

Length-weight relationships for age-0 polar cod at the beginning of the experiment ('pre-winter') were compared to this relationship at the time of mortality ('winter mortality', Fig 3). The winter mortality length-weight model is the theoretical lower weight threshold juvenile fish must maintain for winter survival. Temperature-dependent weight loss (Fig. 4) was determined using the difference in weight at the time of dead to length-based relationships of the pre-winter model. The rate of temperature-dependent weight loss for age-0 juvenile polar cod was well explained by the following 3 parameter polynomial function:

Growth loss (% WWT (g) day^{-1}) = -0.59 - 0.051(T) - 0.0015(T^2), r^2=0.93.

Temperature-specific Fulton's K based on both WWT (Fig. 5a) and DWT (Fig. 5c) were explained by the duration of winter conditions (r^2 ranged from 0.83 to 0.98). The relationship between the rate of change in Fulton's K_{dry} and K_{wet} and overwintering temperature were defined using the following linear regressions:

$K_{wet}.day^{-1} = -2.130e^{-3} - 1.721e^{-4}$ (T), r^2=0.90 (Fig. 5b)

$K_{dry}.day^{-1} = -2.922e^{-4} - 3.37e^{-5}$ (T), r^2=0.97 (Fig. 5d)

Condition measurements taken on mortalities allowed us to define the mean ± SD starvation condition for K_{wet} and K_{dry} as 0.44 ± 0.063 and 0.066 ± 0.0058, respectively.

Temperature-specific HSI based on both WWT (Fig. 6a) and DWT (Fig. 6c) were explained by an exponential decay in condition over the duration of the winter exposure (r^2 ranged from 0.83 to 0.98). The relationship between the rate of change in natural log transformed HSI_{dry} and HSI_{wet} and overwintering temperature were defined using the following linear regressions:

Ln $(HSI_{wet+1}).day^{-1} = -6.280e^{-3} - 6.96e^{-4}$ (T), r^2=0.87 (Fig. 6b)

Ln $(HSI_{dry}).day^{-1} = -0.0174 - 1.536e^{-3}$ (T), r^2=0.89 (Fig. 6d)

HSI metrics taken on fish that died allowed us to define the mean mortality stage for HSI_{wet} and HSI_{dry} as 0.65 ± 0.35 and 0.87± 0.5, respectively.

Lipid loss models

At time-0, fish ranged in SL from 42 to 66 mm and showed no significant relationship between length and whole body lipid storage per WWT (r^2=0.002, slope p>0.05). Temperature-specific lipid composition was calculated for whole fish over the duration of the experiment (Table 2) from measurements of tissue-specific levels in liver (Table 3) and muscle (Table 4). At time-0, fish had an average of 46.1 ± 15.4 mg of lipid per individual which dropped to 9.1 ± 4.0 mg at the time of 50% population mortality. Most of the lipid loss was due to decreased neutral storage lipids, triacylglycerols (TAG), which decreased from 86% in the liver and 56% of the lipids in the muscle to 8% and 2%, respectively (Tables 3 & 4). Fish that died were characterized by low total lipid concentrations (12 mg. g^{-1} WWT) and high relative proportions of polar lipid (PL, ~70%) and sterols (ST, ~20%), a state indicative of only membrane structures remaining with little lipid-based energy storage.

Across all temperatures, we measured a rapid decline in muscle tissue lipids from 29.1 ± 5.5 mg. g^{-1} WWT at time-0 to 20.8 ± 3.8 after day-28 of simulated winter (Fig. 7b). The opposite trend was measured in liver tissue, that increased in lipid density from 290.3 ± 56.7 at time-0 to 334.9 ± 62.3 mg. g^{-1} at day-28 (Fig 7a). Polar cod have small amounts of liver tissue relative to muscle mass and they store high proportions of lipid (TAG) in their muscle, which explains the general decrease in whole body lipid concentrations from day-0 (41.4 ± 5.3 mg. g^{-1} WWT) until day-28 (33.1 ± 6.0 mg. g^{-1}, Fig. 7c). The same trends were measured for total tissue-specific lipids based on DWT (Fig. 8a & 8b). Both muscle and liver tissue decreased rapidly in lipids from day-28 until 50% population mortality (Fig 7 & 8, Tables 3 & 4).

Temperature-specific lipid concentrations for whole fish based on both WWT (Fig. 7c) and DWT (Fig. 8c) were explained by the duration of winter exposure (r^2 ranged from 0.86 to 0.99). The temperature-dependent rate of whole body lipid loss based on WWT and DWT were explained using the following linear regressions:

Lipid loss (mg. g^{-1} WWT). day^{-1} = -0.1879 -0.02122 (T), r^2=0.77 (Fig. 7d)

Lipid loss (mg. g^{-1} DWT). day^{-1} = -0.9018 -0.08749 (T), r^2=0.64 (Fig. 8d)

Lipid measurements on fish that died allowed us to define the mean lipid composition at death based WWT and DWT as 12.1 ± 2.0 mg. g^{-1} and 65.3 ± 10.9 mg. g^{-1}, respectively.

The importance late summer lipid storage and winter temperatures on survival for age-0 polar cod is shown in Table 5 and Fig. 9. Tissue concentrations of lipids in polar cod from the Central Chukchi Sea in 2013 (from Copeman et al. 2020) and 2017 (Copeman et al. this report) were used with the equation for lipid loss (mg. g^{-1} WWT). day^{-1} = -0.1879 -0.02122 (T), r^2=0.77 (Fig. 7d) to calculate survival times. Specifically, we calculated the time need to achieve a change in lipid concentration equaled the difference between end of summer levels and starvation concentrations (12.5 mg. g^{-1}) (Table5) across a wide range of continuous simulated winter temperatures from -2 to 10 °C (Fig. 9). Starvation resistance at -1 °C was projected to be over 4.5 months compared to less than 1 month in fish from 2013 (cold) versus 2017 (warm), respectively. Further, small changes in temperature at the cold end of the overwintering range made a large difference in survival to high lipid fish (i.e. 1-month difference from -1 to 1 °C in 2013) but little difference to low lipid fish (i.e. 6 days difference from -1 to 1 °C for 2017 fish, Table 5, Fig. 9). Survival of high condition fish is dependent on winter temperatures while poor condition fish had low survival times across a full range of temperatures (24 to 13 days starvation resistance between -1 to 5 °C) (Fig. 9, Table 5).

Discussion

The importance of pre-winter lipid condition and winter temperature were highly apparent in our study. Age-0 polar cod conserved lipids and survived longest in our coldest temperature treatments (-1°C). Although fish that survived to 50% of population levels were categorically larger than those that died, juvenile body size only weakly explained survival times of fish that died (between 42-64 mm SL). In the field, we contend that polar cod overwintering success will be highly dependent on summer lipid storage as well as the availability of cold winter habitats that can minimize energy loss in the Arctic.

Small body size and energy allocation

As predicted, high mortality occurred when energy reserves (e.g., lipids) were exhausted during winter starvation (e.g., Thompson et al. 1991; Ludsin and DeVries 1997). Here, this level was found to be 12.5 mg. g^{-1} lipid per WWT of whole body tissues across all thermal conditions. However, counter to our expectations, there was no overall relationship between fish size and lipid storage at the beginning of the experiments (mg. g^{-1}). Although there was a modest size-effect on survival (~1mm = +1 day of survival), the size covariate in the survival model explained very little variation within any given temperature treatment (r^2 ranged 10 to 26%). We suspect small fish either have slightly higher metabolic requirements or behavioral activity (Kerr 1971), but size by itself appears to be a poor indicator of overwintering success for juvenile polar cod within the size range tested.

In contrast to size, application of laboratory rates to realized variability in the lipid storage of field-collected polar cod (Copeman et al. 2020) indicate that lipid content has an important bearing on winter survival potential. The annual differences in lipid density of field collected fish from the Central Chukchi Sea (2013: 34.7 ± 18.7 versus 2017: 16.0 ± 6.4) were particularly striking despite being similar in size (2013: 43.4 ± 3.9 versus 2017: 47.2 ± 10.3). The starvation models illustrate how winter thermal conditions are either highly important following summers that support fish in good conditions (e.g., 2013) or potentially irrelevant when the preceding summer conditions result in a poor energetic state for age-0 juveniles e.g., 2017, ‘dead fish swimming’. It also appears that small changes in temperature between -1

and 2°C have a dramatic effect on survival of fish entering winter in a high energetic state (Fig. 9). The importance of summer-fall prey availability and pre-winter condition are important processes regulating winter survival and thus recruitment of walleye Pollock (*Gadus chalcogramma*) in the Eastern Bering Sea (Hunt Jr et al. 2011, Mueter et al. 2011, Heintz et al. 2013). Regardless, the high prioritization for energy storage observed in small-bodied juvenile polar cod suggest there is a high winter mortality risk in the Arctic and that this risk is more likely due to starvation than predation (Ivan et al. 2015).

Size-dependent overwintering success may be more important in lower latitude regions where late fall/winter density-dependent predation rates are high (Laurel et al. 2003, Lough & O'Brien 2012) and size demographics are more variable in the summer and fall period (Geissinger et al in review). Overwintering survival has been shown to increase through size-advantages due to earlier spawning (Henderson et al. 1988, Morley et al. 2013) or growth (Mogensen & Post 2012) in more temperate systems. In the Eastern Bering Sea, young-of-the-year Pollock rarely survive their first winter following poor fall growth and lipid storage conditions (Heintz & Vollenweider 2010). Such size advantages are often attributed to reduced winter predations risk (Post & Evans 1989, Pangle et al. 2004, Morley et al. 2013), although size-dependent predation preceding winter may actually be more important (Jonsson et al. 2010). In such instances, it is generally assumed that size-dependent winter survival is linked to higher energy storage in larger fish (e.g., Heermann et al. (2009)) or lower metabolic rates (Werner & Gilliam 1984, Byström et al. 2006).

Condition loss models

We present three types of condition metrics: Fulton's K, a morphometric condition index that indicates the relationship between weight and length (Froese 2006, Nash et al. 2006), 2); HSI, a morphometric index that expresses liver weight relative to body weight and is often referred to as a metric of lipid storage due to high proportions of lipid in the liver ((Guy & Brown 2007, Aune et al. 2021)) and lastly, tissue-specific and whole body explicit measurements of lipid. The use of multiple different condition metrics allows our data to be broadly interpreted in relation to other field collections or laboratory experiments that may have only one metric, such as length-weight. The easy of performing morphometric condition measures can allow for the processing of larger numbers of individuals. However, morphometric condition in larval and juvenile marine organisms has shown a general lack of sensitivity (Suthers 1998, Copeman et al. 2008, Copeman et al. 2018), likely because they are insensitive to changes in high energy lipid storage. Polar cod store high concentrations of lipid in their muscle tissues relative to other boreal congeners (Copeman et al. 2017) making HSI potentially insensitive to changes in the lipid dynamics of polar cod. At time-0 polar cod had 29.9 ± 1.5 mg of lipid in their muscle tissues compared to 16.2 ± 1.6 mg in their liver but by the time of 50% population mortality almost all the remaining lipid was found in muscle storage (8.9 ± 3.9 per fish). The importance of muscle tissue was also demonstrated during the first month of our study when fish preferentially utilized muscle lipid over liver lipid. For future analyses of large field campaigns, age-0 polar cod whole body homogenates should be saved for lipid analyses. Dissections of livers from age-0 polar cod are incredibly time consuming and difficult due to both the small size and delicate nature of the liver tissue.

Future research

Understanding the impact of winter feeding scenarios will be an important component of future laboratory and field research. Small amounts of food during winter can dramatically improve survival of age-0 Atlantic cod with the addition of minimum rations to winter experiments resulting in prolonged survival and growth at low temperatures (-0.8 to 2.7 °C) (Geissinger et al. 2021). Field studies indicate active under-ice zooplankton production in the Arctic winter (Berge et al. 2020a, Geoffroy & Priou 2020), but we know of no such field studies in the Chukchi Sea region. Polar cod have specialized large eyes that enable more successful feeding at lower light intensities than boreal gadids (Wagner et al. 1998) and this

has been proposed as an additional barrier to the establishment of boreal gadid populations in Arctic regions (Kaartvedt 2008). In the waters surrounding Svalbard, Norway, adult polar cod and invading boreal gadids have been shown to forage during the polar night, although at a lower stomach fullness than in summer (Geoffroy & Priou 2020). However, adults were found to switch from zooplankton to larger prey such as fish (Cusa et al. 2019) during the winter. Prey switching was proposed as a solution to reduced light and a polar cod's limited ability to visually capture small zooplankton. Due to gape limitation, it is uncertain if small age-0 polar cod (30-60 mm) can also successfully switch to larger prey items during the winter. Although Polar Regions are becoming 'brighter' with climate change (Kristiansen et al. in review), the projected foraging gains to visual feeders will be mostly limited to the summer months as the polar night will continue to be dark regardless of sea-ice loss (Langbehn & Varpe 2017).

Overwintering processes may become logistically less challenging in the future as the Arctic will have increase periods of open-water and better technology for sampling polar cod and their prey under thin ice (David et al. 2015, Kohlbach et al. 2017). As polar cod tissue samples become available from these efforts, fall/winter lipid storage and trophic dynamics can be used to ground truth some of the survival trajectories from this study, all of which have implications for recruitment dynamics in Alaskan waters (Hurst 2007a, Farley et al. 2011, Heintz et al. 2013, Siddon et al. 2013). Currently, efforts to understand the bioenergetics of polar cod rely on models with many assumptions about physiological rates, consumption rates and trophic relationships (Hansen et al. 1993). The simple models we report do not account for trophic dynamics, however, they are stage-specific and provide an understanding of tissue lipid compartmentalization that are not typically captured in Wisconsin bioenergetics (Munch & Conover 2002).

Conclusions

Age-0 polar cod were able to minimize energy loss at temperatures <0°C with no apparent impact on survival before they reached the point of energetic starvation (Lipids per WWT = 12.5 mg. g-1, HSI_{wet} = 0.67, K_{wet} = 0.62). It is likely that they utilize antifreeze proteins in the liver and/or gills as a metabolically cost-effective way to utilize these extremely cold habitats (Chen et al. 1997, Fletcher et al. 2001). Energy density increases with body size for most fish species during the juvenile phase (pre-reproductive; Martin et al. (2017)), but Chukchi Sea polar cod enter their 1st winter at ~50% the size of similarly aged gadids from the Bering Sea (Siddon et al. 2013a, Siddon et al. 2013b) and the Gulf of Alaska (Laurel et al. 2017). Such contrasting energy storage strategies may set the distributional limits for small polar cod to minimize winter energy loss. Based on summer field collections from the Chukchi Sea (De Robertis et al. 2016), age-0 polar cod are the major gadids in the Chukchi Sea, but changing climatic conditions in the summer and winter could disrupt these distribution boundaries and result in a more boreal summer fish assemblage (Levin et al. this report). It remains uncertain whether boreal gadids can successfully overwinter at temperatures routinely <1°C, such as those common to the Chukchi and Beaufort Sea shelves.

Successful overwintering for polar cod will be highly dependent on seasonal conditions in both the winter and summer. The survival trajectories described in this study demonstrate how summer lipid allocation and cold winters theoretically improve overwintering success while also indicating that winter foraging is necessary when fish are in poor pre-winter condition or Arctic winter thermal habitats are warmer. However, the transition from age-0 to age-1 will remain a poorly understood component of population dynamics without increased seasonal observational data during this period (Heintz & Vollenweider 2010, Geoffroy et al. 2016, Boudreau et al. 2017, Geoffroy & Priou 2020). Winter studies on diet will be especially critical, as will information on regional predation pressure that may impact strategies for energy allocation (e.g., growth) or thermal habitat preferences. The survival trajectory models described

here will therefore remain a theoretical framework for field validation studies and models examining population impacts under varying climate projection scenarios.

.

Table 1: Allocation of samples from age-0 polar cod overwintering experiment. Sampled fish and mortalities were processed for condition metrics based on WWT (526), DWT (374) and detailed tissue-specific lipid classes (n=140).

Temperature	-1°C	1°C	3°C	5°C
Replicate tanks	3	3	3	3
Fish per tank	50	50	50	50
Day-0: October 24, 2016	**Number of fish sacrificed per tank**			
Total fish sampled per tank	10	10	10	10

Table 5: The importance of energetic condition and winter temperatures on days of starvation resistance in age-0 polar cod. Lipid concentrations in polar cod from the central Chukchi Sea in 2013 (Copeman et al. 2020) and 2017 (Copeman et al. this report) are used to demonstrate variability in time to starvation for field collected fish of different nutritional status. The equation for lipid loss ($mg.g^{-1}$ WWT).day^{-1} = -0.1879 -0.02122 (T), r^2=0.77 (Fig. 7d) was used to calculate the days to starvation lipid storage levels under the 4 different experimental temperatures. Data are mean ± standard errors of field-collected age-0 polar cod in the Central Chukchi Sea (68.25 - 70.74°N) region as defined in Buckley and Whitehouse (2017). Extrapolated over a continuous temperature range from -2 to 10 °C in Fig. 9.

Year	Lipids concentration in polar cod from the Central Chukchi Sea	Change in lipid concentration (µg.mg^{-1}, WWT) between end of summer and mortality levels	Duration of starvation resistance at -1 °C (days)	Duration of starvation resistance at 1 °C (days)	Duration of starvation resistance at 3 °C (days)	Duration of starvation resistance at 5 °C (days)
2013 (n=30)	34.73 ± 3.42	22.63	136	108	90	77
2017 (n=35)	16.03 ± 1.08	3.93	24	18	16	13
Mortality levels	12.5					

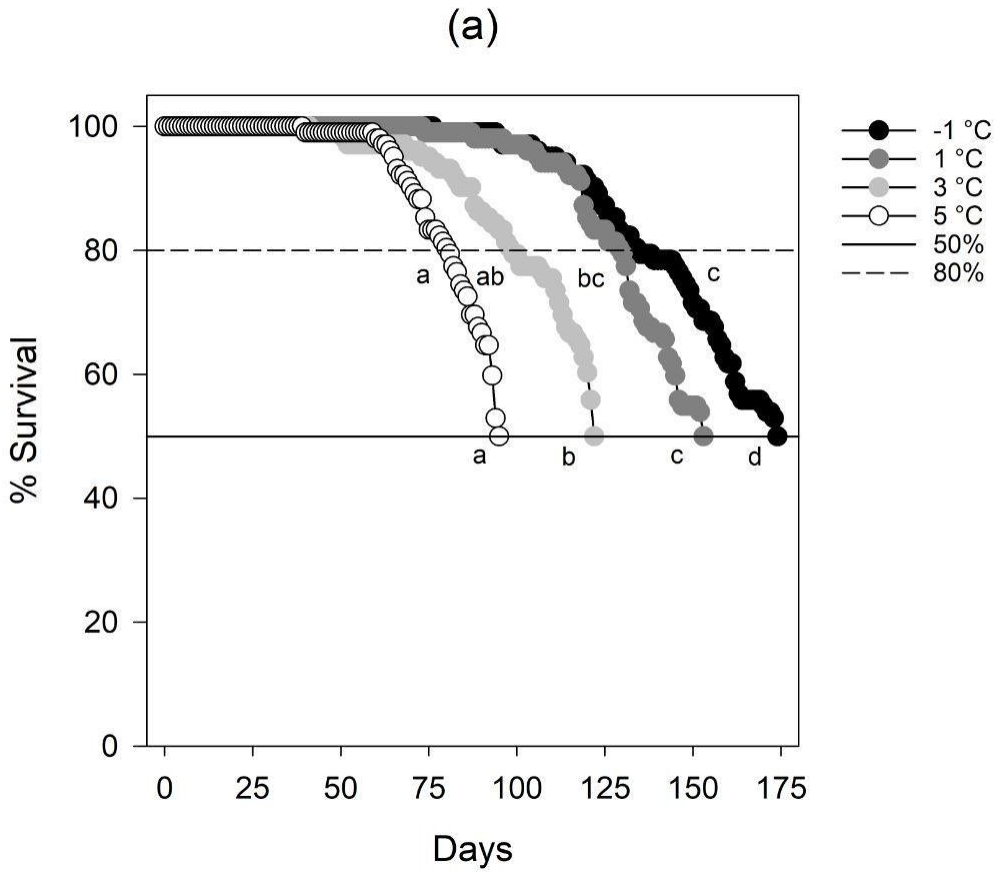

Fig. 1: Temperature-dependent survival of age-0 polar cod during simulated winter conditions in the laboratory. Experiments were run at -1, 1, 3 and 5 °C until 50% population mortality. Dashed and solid lines represent the point at which tank populations dropped to 80% or 50% survival, respectively. Data points represent temperature averages (n=3 tanks) and letters represent significant differences between temperature treatments.

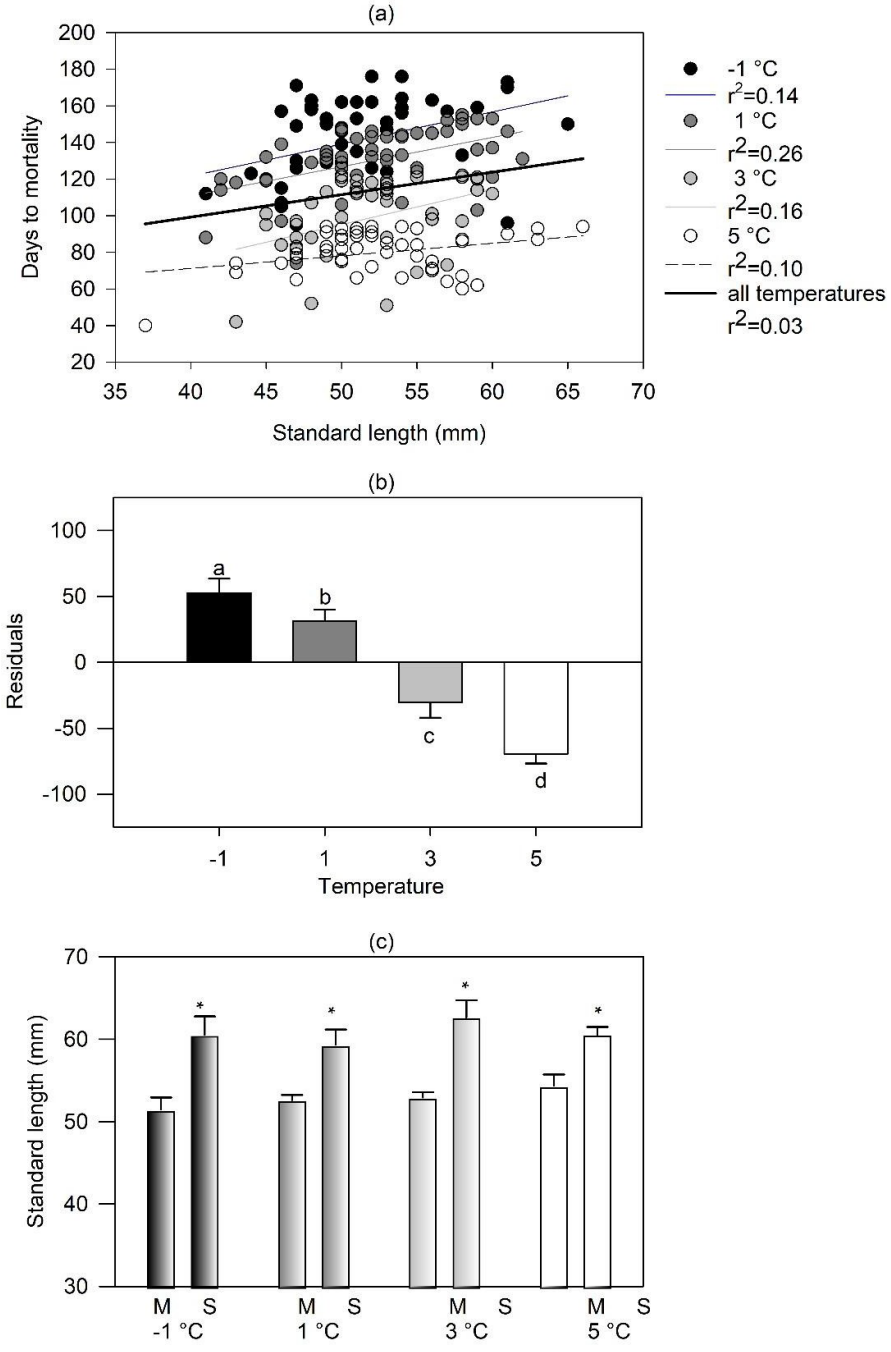

Fig. 2: The effect of temperature and length on age-0 polar cod survival time with (a) days to mortality only weakly affected by standard length with (b) size de-trended residuals showing a significant increase in starvation resistance at low temperatures compared to higher temperatures ($p<0.05$) and (c) fish that experienced mortality before 50% of the population (m) were significantly smaller than fish the survived (s) across all experimental temperatures ($p<0.05$).

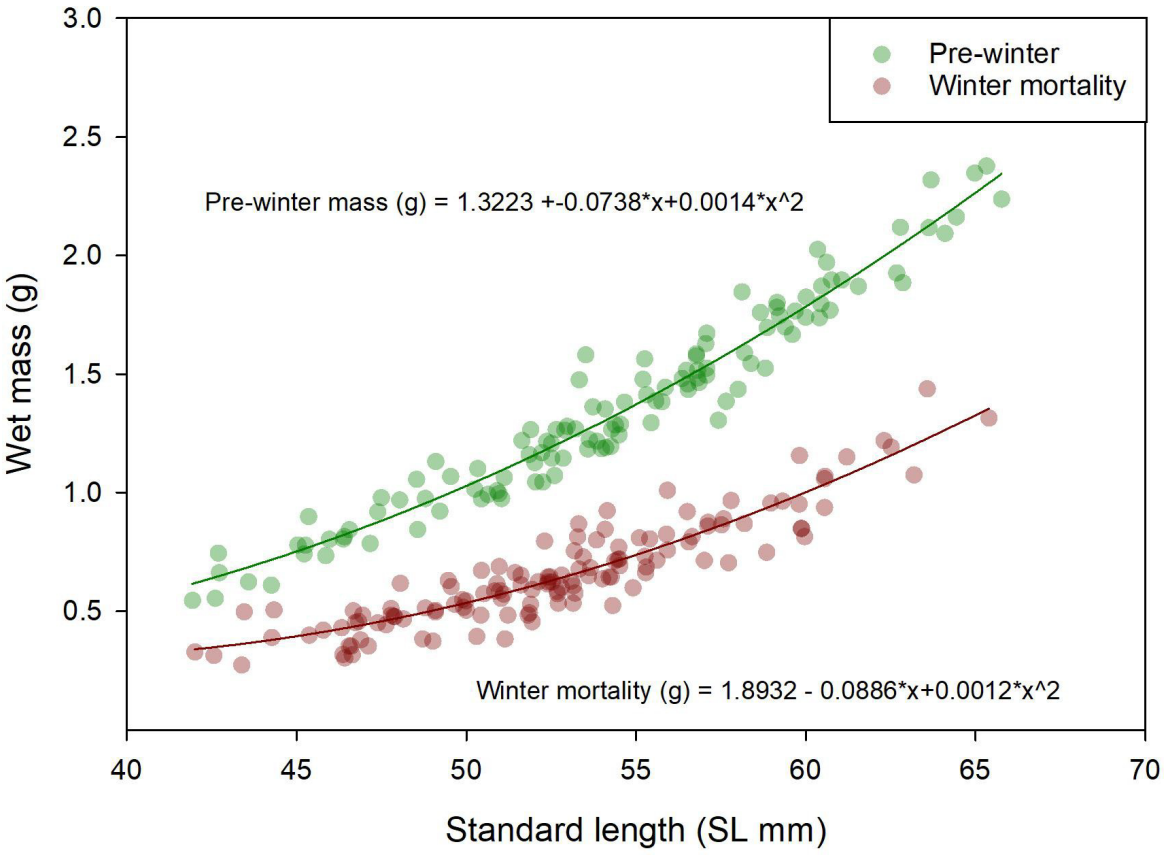

Fig. 3: Length-weight relationships for age-0 polar cod at the beginning of the experiment ('pre-winter') and at the time of mortality during the experiment ('winter mortality'). The winter mortality length-weight model is the theoretical lower weight threshold juvenile fish must maintain for survival during winter. Temperature-dependent growth loss (Fig. 4) was determined using the difference in weight at the time of mortality and length-based weight of the pre-winter model (See Methods).

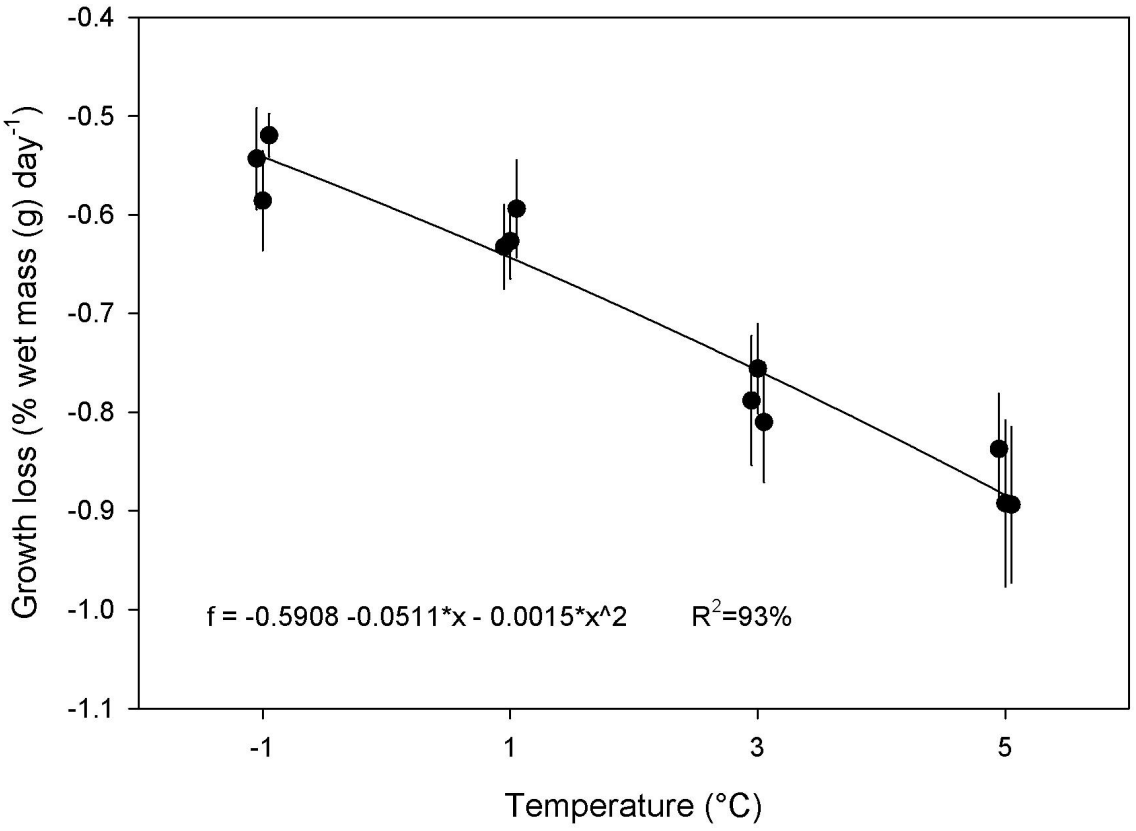

Fig. 4: Rate of temperature-dependent weight loss for age-0 juvenile polar cod during simulated temperature-dependent overwintering laboratory experiments. Experiments were run at -1, 1, 3 and 5 °C until 50% population mortality. Data are tank means (n=3 per temperature) of individual weight loss over time.

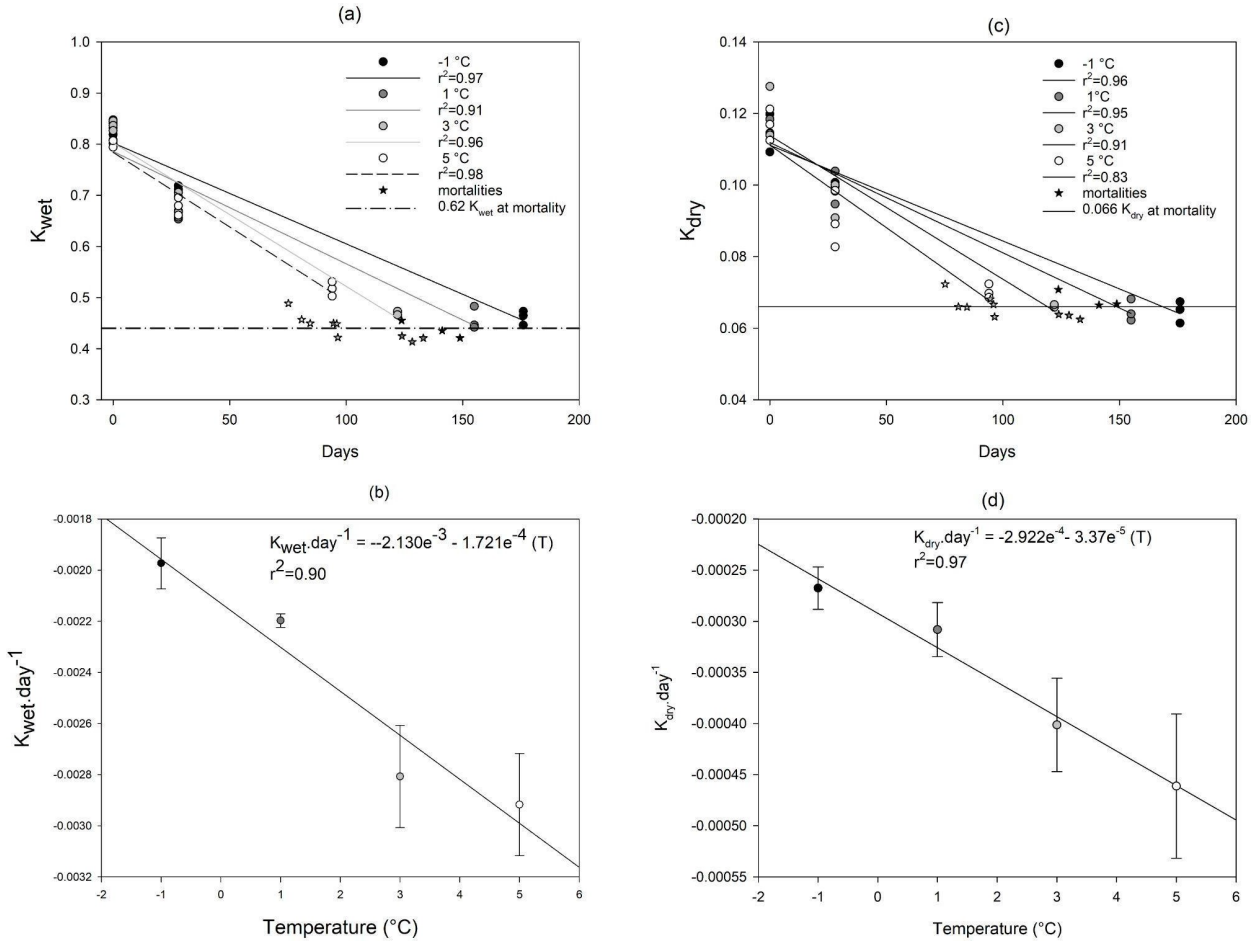

Fig. 5. Fulton's K condition factor per WWT shown (a) over the full overwintering experiment and (b) as a temperature-dependent rate of loss function. Fulton's K condition factor per DWT shown (c) over the full overwintering experiment and (d) as a temperature-dependent rate loss function. Data are the mean of 3 tank values (± 1 SE) for sampled fish (circles) and mortalities (stars) per temperature. Fish that died had an average Fulton's K_{wet} of 0.62 and Fulton's K_{dry} 0.066. Temperature dependent rate of loss functions are shown across four temperature treatments (-1, 1, 3, 5 °C).

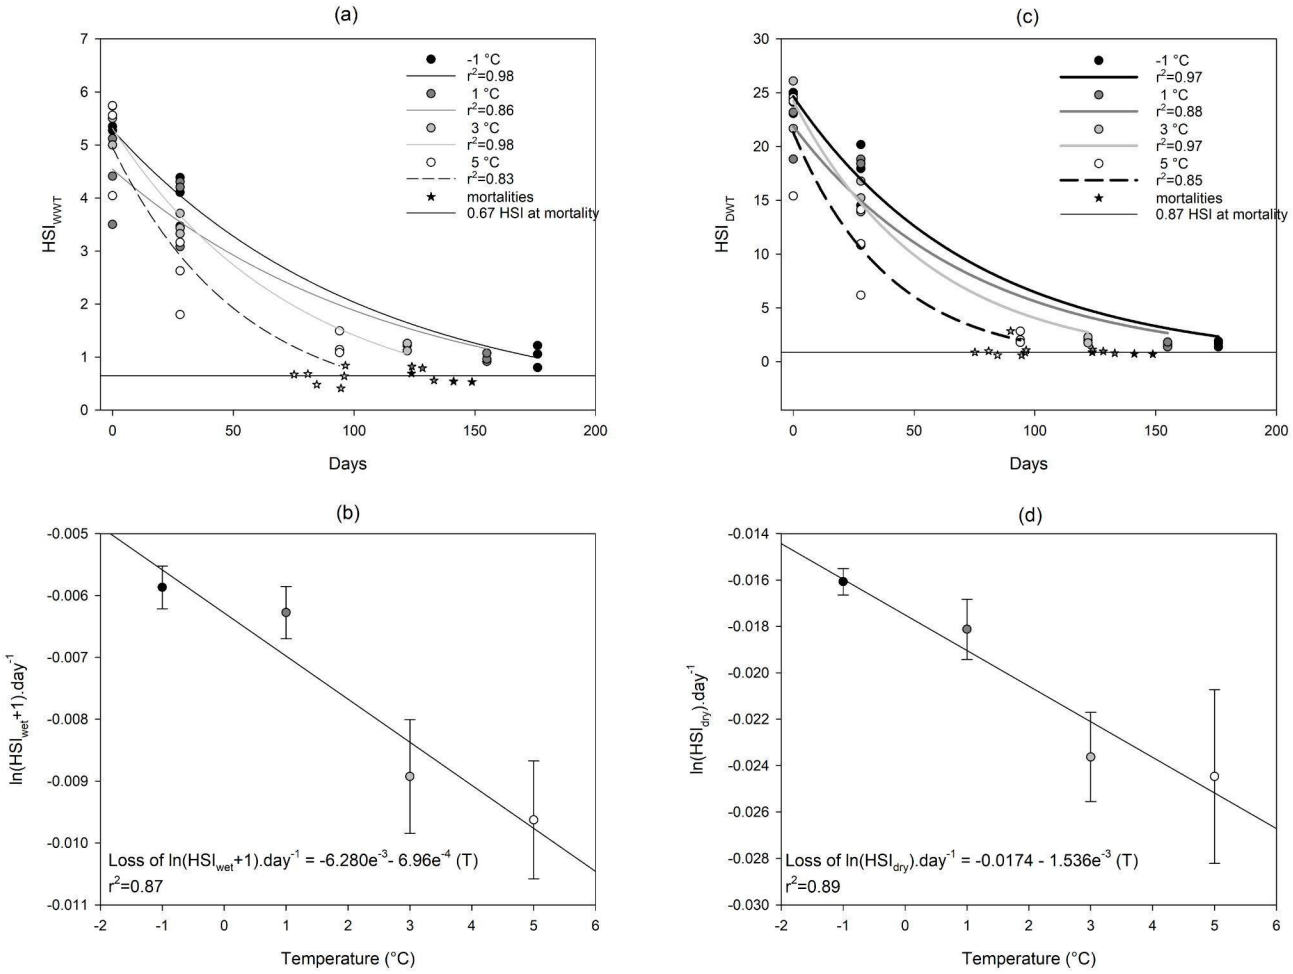

Fig. 6. Hepatosomatic index (HSI) per WWT shown (a) over the full overwintering experiment and (b) as a temperature-dependent rate of loss. HSI per DWT shown (c) over the full overwintering experiment and (d) as a temperature-dependent rate of loss. Data are the mean of 3 tank values (± 1 SE) for sampled fish (circles) and mortalities (stars) per temperature. Fish that died had an average HSI_{wet} of 0.67 and HSI_{dry} of 0.87. Temperature dependent rate of loss functions are shown across four temperature treatments (-1, 1, 3, 5 °C) for the natural log transformed HSI indices.

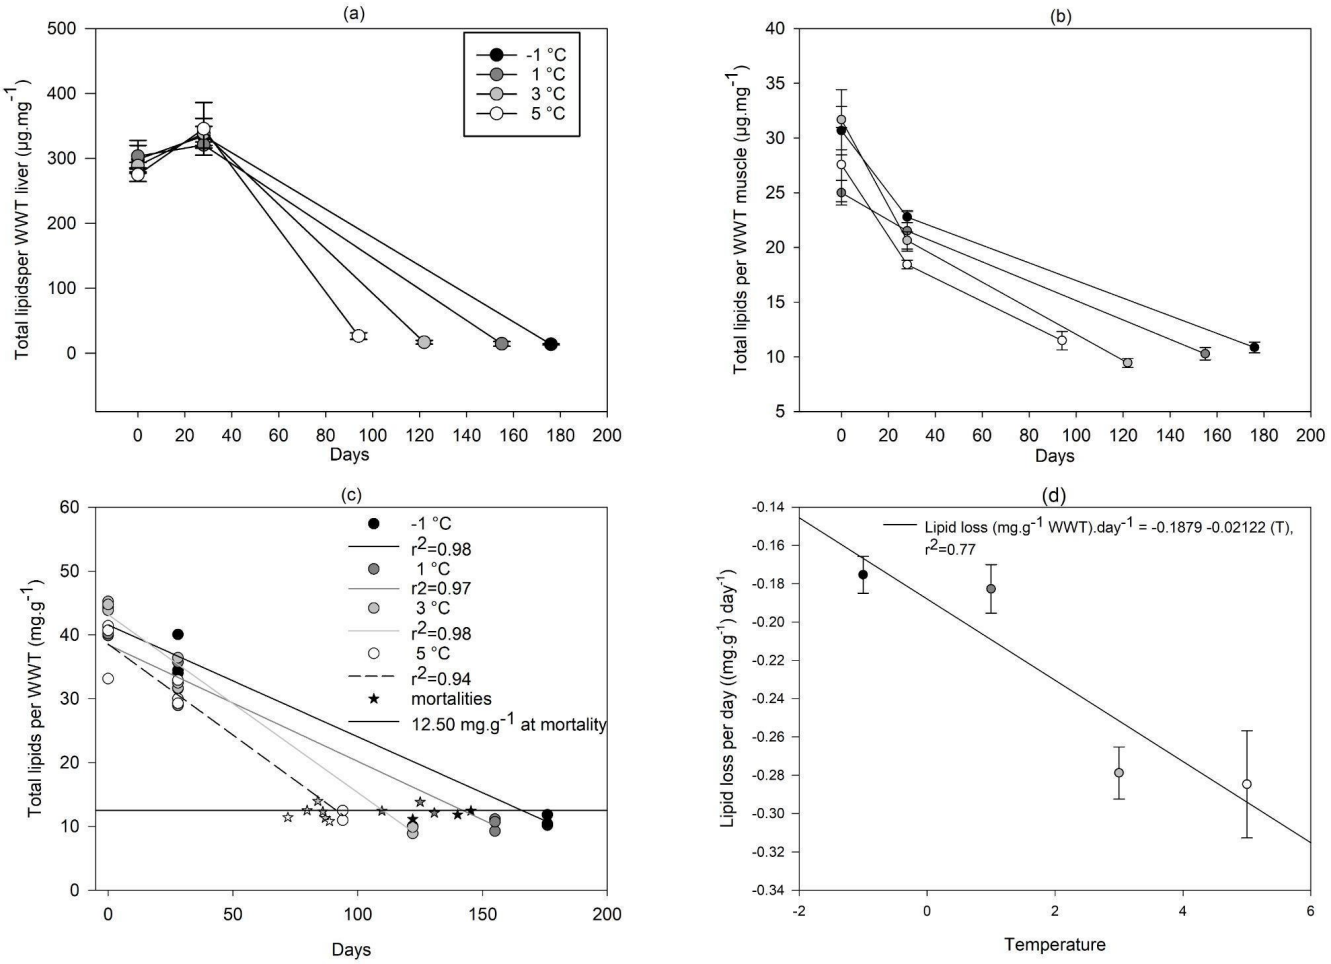

Fig. 7. Total lipids per WWT shown in (a) the liver, (b) muscle tissue and (C) estimated whole bodies of age-0 polar cod over the full overwintering experiment. Temperature dependent rate of lipid loss in whole fish (d) is shown across four temperature treatments (-1, 1, 3, 5 °C). Data are tanks means (n=3) for sampled fish (circles) and mortalities (stars) per temperature. Fish that died had an average whole body total lipid per WWT of 12.50 $mg.g^{-1}$.

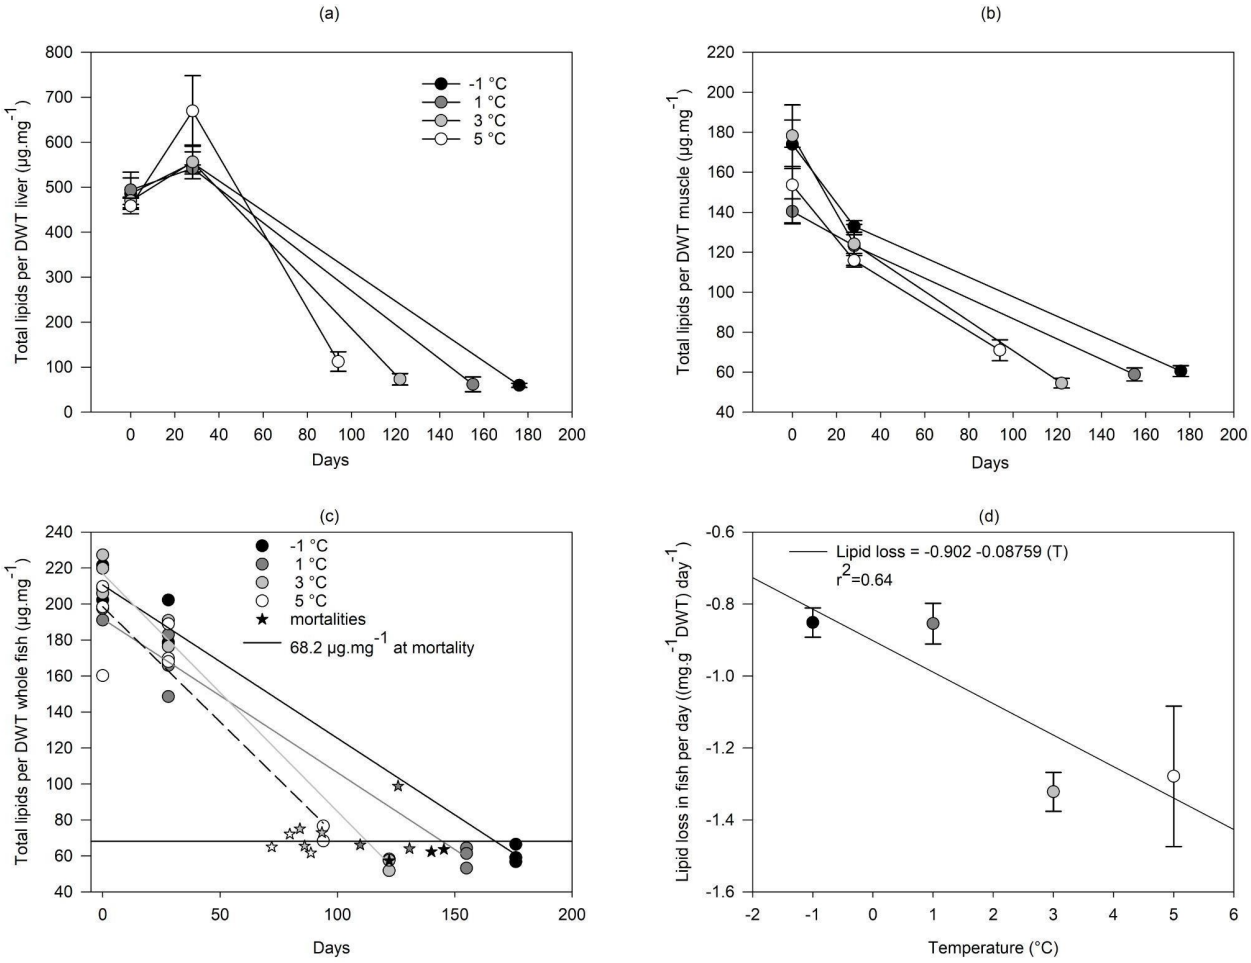

Fig. 8. Total lipids per DWT shown in (a) the liver, (b) muscle tissue and (C) estimated whole bodies of age-0 polar cod over the full overwintering experiment. Temperature-dependent rate of lipid loss in whole fish (d) is shown across four temperature treatments (-1, 1, 3, 5 °C). Data are tanks means (n=3) for sampled fish (circles) and mortalities (stars) per temperature. Fish that died had an average whole body total lipid per WWT of 68.2 $mg.g^{-1}$.

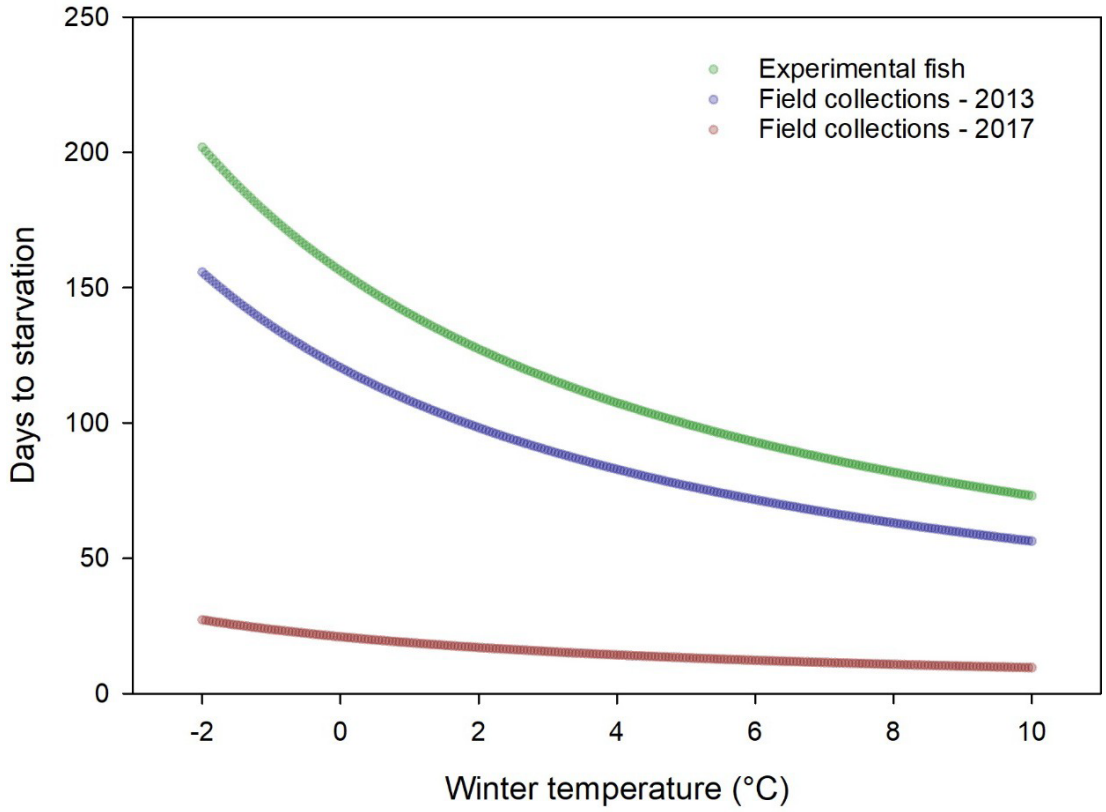

Fig. 9. Days to starvation based on the lab determined temperature-dependent lipid-loss model:

Lipid-loss (mg.g^{-1} WWT).day^{-1} = -0.1879 -0.02122 (T), r^2=0.77 (Fig. 7d).

Scenarios are shown for experimental fish, as well as polar cod from the central Chukchi Sea in a cold year (2013, Copeman et al. 2020) and a warm year (2017, Copeman et al. this report) to demonstrate variability in time to starvation for fish of different nutritional status over a wide range of temperatures. The mean lipid concentration values are given in Table 5 from fish sampled in the Central Chukchi Sea (68.25 - 70.74°N) with latitudinal region defined in Buckley and Whitehouse (2017)

CHAPTER 9 - Variation in Nutritional Quality of Arctic Zooplankton and Fish

Objective 2: Quantify the distribution, abundance, and condition of pelagic marine fishes, in particular young-of-the-year Arctic gadids and other forage fishes

Abstract

One of the quintessential aims of marine science is predicting population productivity. In the newly ice-free areas of the Arctic, benchmark data are limited and traditional stock-assessment techniques cannot be used without knowledge of prior years of population fluctuations on which to build. Bioenergetics models are an ideal alternative tool because they integrate biotic and abiotic effects on organism function that can be extrapolated up to the population level. One of the fundamental inputs into bioenergetic models is the nutritional condition of organisms, which is virtually unquantified in waters of the U.S. Arctic. We measured the nutritional condition of the most abundant fish and zooplankton from seven surveys conducted between 2005 and 2019 across the Chukchi and western Beaufort Seas to maximize spatial and temporal variation. Condition indices included energy, lipid and protein content. We evaluated twenty-seven species of zooplankton from nine orders and forty-one species of fish from twelve families. Lipid was the most variable of the condition indices, differing by 35 times from the most lipid-rich fish species, Bering cisco (*Coregonus laurettae*), to the leanest fish, daubed shanny (*Leptoclinus maculatus*). Similarly, lipid was 28 times higher in the zooplankter *Calanus glacialis* than in *Argis lar.* Interspecific variation occurred within some families of fish and orders of zooplankton. For a given size fish, energy density of Pacific herring (*Clupea pallasii*), Pacific capelin (*Mallotus villosus*), Pacific sand lance (*Ammodytes personatus),* starry flounder (*Platichthys stellatus*), and to a lesser degree, saffron cod (*Eleginus gracilis*) collected during the late summer was lower in the Arctic than in the Gulf of Alaska, illustrating the bias introduced by using condition values from mismatched locations. Consequently, this catalog of fish and zooplankton condition should greatly improve the accuracy of bioenergetic modeling of a host of fish, seabird, and marine mammal populations in the U.S. Arctic. These results increase the capacity for prediction of Arctic species productivity and the Arctic ecosystem as a whole.

Keywords: energy density, lipid, protein, trophic ecology, Chukchi Sea, Beaufort Sea

Introduction

The Arctic is warming disproportionally faster than the rest of the globe from polar amplification and feedback processes associated with melting sea ice (Koenigk et al., 2020; NSIDC, 2020) and the newly, seasonal ice-free areas are gaining interest for transit, oil extraction, infrastructure development, and potential fisheries (Babin et al., 2020; Runge et al., 2020)). Managing the expanding user groups in the newly accessible areas requires a benchmark understanding of the biological communities that may be impacted as well as expectations for how the biological communities will be transformed by their changing habitat in the future. Recent shifts in marine biological community composition in the Arctic have occurred, presumably from changes in the marine environment such as reduced sea ice thickness, extent, and duration, warming ocean temperatures, increased freshwater input, increased storm activity, and variations in ocean currents and stratification (Wassmann et al., 2011).

Environmental forcing on Arctic marine biota is anticipated to be most pronounced in lower trophic levels that are tightly coupled with their environment. Zooplankton exemplify this because they are generally short-lived, limited in mobility, and have narrow physiological tolerances to temperature (Hays et al., 2005). These life history characteristics limit the potential for zooplankton to adapt in response to varying environmental conditions. Furthermore, observed and predicted changes to ocean stratification alter light levels, temperature gradients, and nutrient cycling, all of which are crucial components for plankton productivity (Carmack et al., 2004). Consequently, climate-driven environmental change has already changed zooplankton abundance, distribution, and timing of life-cycle events (Jonkers et al., 2019; Dam and Baumann, 2018; Chiba et al., 2015)).

Reorganization of zooplankton communities will influence community composition of secondary consumers such as fish. Larval and juvenile fish primarily consume zooplankton, and some fish species continue to be planktivores as adults (Gray et al., 2017, 2016; Whitehouse et al., 2017). Alterations in zooplankton community composition and timing of zooplankton production will have consequences for fish survival. Fish can contend with a changing prey base to some degree by relocating to more productive areas (Rose and Leggett, 1989). Similarly, fish move in response to habitat conditions such as temperature. Warming temperatures have facilitated northward range extensions of several fish species from sub-Arctic to Arctic regions (Hollowed et al., 2013, Rand and Logerwell, 2011; Mecklenburg et al., 2007). Alternate habitat is not always available, however, leaving adaptation as the only alternative for survival.

The ability for fish to adapt to changing environmental conditions is highly variable among species. Arctic fish residing in relatively steady-state conditions may be less capable of adaptation than southerly species, which routinely experience much greater swings in their surrounding temperatures, such as seasonal or daily changes. For example, Arctic cod (*Boreogadus saida*) range from the North Pole south to 57 °N in the Bering Sea and have narrow temperature tolerances compared to the eurythermal saffron cod (*Eleginus gracilis*) (Laurel et al., 2016), which range from 71 °N to 37 °N in the Pacific Ocean (Mecklenburg et al., 2016). Their different physiological tolerances have led to the prevailing hypothesis that saffron cod may potentially be more resilient to warming, while Arctic cod will likely struggle once temperatures exceed their threshold (Laurel et al., 2016; Reusser et al., 2013). The varying ability of fish species to adapt, move or perish in response to their changing environment and prey base will structure the abundance and distribution of Arctic fish.

Predicting trophic cascade effects on fishes, seabirds, and marine mammals from climate-induced changes in their prey is complex. The flow of energy is a primary component structuring food webs, and reductions in lipid-dense prey have caused declines of top-level predators in other ecosystems. In the North Sea and near Greenland, populations of lipidrich *Calanus* species were replaced by lower lipid zooplankter species, causing reduced body condition and fewer numbers of their sand eel (*Ammodytes marinus*) predators (Frederiksen et al, 2006). Similarly, low lipid diets correlated with impaired life-

history traits in a variety of seabird species throughout the world, including reduced productivity, slow growth, and reduced fledging fat reserves (Osterblom et al, 2008; Wanless et al, 2005; Romano, 2000). In the Gulf of Alaska, Steller sea lion (*Eumetopias jubatus*) population declines of 49% coincided with a major community reorganization in their prey base, from an abundance of lipid-rich forage fish to one dominated by lean groundfish (Fritz et al., 2005; Trites et al., 2003; Merrick et al., 1997). This phenomenon, coined the "junk food hypothesis," could potentially occur in the Arctic if the relatively high lipid, abundant forage fish, Arctic cod, were out-competed by a lower lipid prey such as saffron cod, reducing quality prey available for their predators.

There are several ways to assess the impacts of a changing prey base on predator health and survival. Laboratory feeding studies show direct impacts of prey quality, though results are restricted to single species that can be accommodated in captivity. A more comprehensive approach to evaluating the effect of a changing prey base is the use of bioenergetic food web models that can assess trophic shifts by computing the mass-balance of energy flow through entire ecosystems. Bioenergetic models rely on accurate quantification of prey condition parameters, which are currently sparse to nonexistent in the Arctic. Evaluations of the nutritional condition of Arctic zooplankton has been quantified for a relatively large number of species, however sampling is focused primarily in Norway and the Canadian-Atlantic (Falk-Petersen et al., 2009, 2000; Auel et al., 2002) and is nonexistent in the US Arctic. Arctic fish condition measurementsare extremely rare and are primarily limited to anadromous species such as Arctic char (*Salvelinus alpinus*) and broad whitefish (*Coregonus nasus*) or limited in geographic scope (Fechhelm et al., 2011; Lawson et al., 1998; Jorgensen et al., 1997; Hop et al., 1995).

Consequently, existing food web modeling efforts in the Chukchi and Beaufort Seas cite prey energetics as a significant data gap and relied on literature values of prey quality from disparate species, locations and sizes (Carroll et al. 2013; Bluhm and Gradinger, 2008; Welch et al., 1992). Using proxy species from other ecosystems is problematic as prey quality of zooplankton and fish is highly variable. Zooplankton species can vary widely in their lipid content, from lipid-rich *Calanus* copepods (>50% lipid of dry mass) to lipid-deplete gelatinous zooplankton (~10% lipid) (Syvaranta and Rautio, 2010; Clarke and Peck, 1991; Reinhardt and Van Vleet, 1986). Similarly, fish species can vary widely in their energetic content and other condition indices. Within an ecosystem, calorific content can vary 10-fold among some of the most abundant fish species (Vollenweider et al., 2011; Anthony et al. 2000) and by two-fold within a family (Tierney et al., 2002), underscoring the importance of using appropriate values of prey quality.

Our goal is to quantify the nutritional condition of the most abundant species of Arctic zooplankton and fish and to test the hypothesis that there is significant interspecific variation thereby conferring unequal quality of prey to their predators. We provide a comprehensive library of the nutritional condition of the most abundant Arctic zooplankton and fish species during the summer feeding season in the US Arctic. Specifically, we quantify the energy, lipid and protein content of Arctic zooplankton and fish species in the Chukchi Sea, western Beaufort Sea and the adjoining Elson Lagoon during the ice-free summer months. Our work fills a large data gap, providing accurate parameters for bioenergetic food web models in the US Arctic and consequently enhancing the predictive capacity for how the Arctic food web will reshuffle in the future.

Methods

Sample collections

Zooplankton and fish were collected from the US waters of the Chukchi Sea, the western Beaufort Sea, Elson Lagoon, and Kotzebue Sound during summer ice-free months (July - September) from 2005 to 2019 from eight different surveys (Figure 1). Sampling time and methods varied by project, which has the benefit of potentially detecting a broader range of species, and the detriment of an unbalanced study design (Table 1). Greater detail on net specifications and fishing methodologies adopted in these surveys

are described in Vollenweider et al. (2018), De Robertis et al. (2017), Pinchuk and Eisner (2017), Goddard et al. (2014), and Norcross et al. (2010). Macrozooplankton were targeted in four surveys (ACES, AFF, ArcticIERP, SHELFZ) with zooplankton nets and were picked opportunistically out of mid-water and bottom trawls from other surveys. Though the focus of this work was zooplankton, several abundant epibenthic invertebrates were collected opportunistically and analyzed for nutritional condition, including several shrimp and isopod species, and an Arctic basket star (*Gorgonocephalus arcticus*). Individual zooplankton and samples consisting of multiple individuals of a given species were blotted dry and frozen at sea. Fish were collected from each of the eight projects. Generally, five to fifteen fish of each species were retained from each haul/station and frozen at sea. Additional fish samples were obtained from subsistence collections made by rod and reel in Kotzebue, Alaska. At times small samples were obtained for species that were encountered infrequently, either because they were in low abundance or due to sampling method biases. Though sample sizes of one are relatively uninformative, they are presented here for several species to provide realistic values rather than borrowing from other species.

Laboratory processing

Zooplankton and fish samples were thawed and processed in the laboratory. Zooplankton were identified to the lowest taxonomic level possible using keys from northern latitudes (Vassilenko, 2009; Kozloff, 1987; Kathman, 1986). Total length (excluding antennae) was measured for most zooplankton except mysids and euphausiids which were measured from the rostrum to the end of the carapace. All lengths are reported to the nearest mm. Weights were measured to the nearest 0.01 g or 0.001 g when total mass < 0.01 g. Laboratory measurements of fish included total length (mm) for all species except the ammodytids, osmerids and salmonids which were measured for fork length (mm). Whole-body mass was measured to the nearest 0.01 g before stomach contents were removed.

In preparation for chemical analysis, individual zooplankton and small fish (< 0.5 g) were dried whole to a constant weight then homogenized, while large fish (≥ 0.5 g) were homogenized wet and an aliquot was dried to a constant weight. Drying occurred in either drying ovens set to 60 ºC or using a LECO Thermogravimetric Analyzer 601 or 701 at 135 ºC. For quality assurance assessment of percent moisture, a replicate sample was included with each batch of samples, not to exceed 1.5 standard deviation. In addition, two replicates of homogenate of Pacific herring (*Clupea pallasii*) from the Gulf of Alaska or Meat1546 from the National Institute of Standards and Technology (NIST) were dried with each group of samples, with percent moisture not to exceed 15% from target values. Dried samples were homogenized to a uniform consistency. When necessary, individual zooplankton and fish weighing less than 0.01 g dry were grouped together by haul to achieve enough mass for subsequent lipid analysis, while those weighing less than 0.04 g were grouped for bomb calorimetry. The moisture content of fish was calculated and used to calculate condition indices (energy density, lipid, and protein) on a wet-mass basis for direct applicability to bioenergetic models. Accurate wet weights of individual zooplankton were difficult to obtain, as water retained among appendages requires time and care in the field to delicately wick moisture from each organism prior to freezing. Therefore, zooplankton condition was presented on a dry mass basis and wet-mass values from the best-preserved specimens were estimated using moisture from individuals of the same species or similar species.

Chemical analysis

Energy density (ED; kJ/g dry mass) of zooplankton of sufficient mass and all fish was measured using bomb calorimetry. Dried homogenates of 30-70 mg or 70-200 mg were pressed into small or large pellets and combusted using a Parr 6725 semi-micro bomb calorimeter[3] using standard instrument operating

[3]Mention of trade names or commercial companies does not imply endorsement by the National Marine Fisheries Service, NOAA.

procedures from the instrument manual. Quality assurance samples included with each batch of samples were 1) duplicate benzoic acid standards, not to exceed 0.5 % coefficient of variance (CV) from each other or 0.5 % error from target values for large pellets (0.07 - 0.20 g dry) and 1.5 % CV and 2.0 % error for small (0.03 -0.07 g dry) pellets, 2) a sample replicate when sample mass permitted, not to exceed 1.5 standard deviation for both large and small pellets, and 3) a tissue reference sample of homogenized Pacific herring or walleye pollock (*Gadus chalcogrammus*) from the Gulf of Alaska (not to exceed 2.75 % or 3.0 % error for large and small pellets, respectively. Measured energy densities were converted to a wet-mass basis using moisture content. The total energy of individual zooplankton and fish (kJ) was calculated as energy density times the whole wet mass of the individual.

Lipid content of dried zooplankton and fish was measured using a sulfo-phospho-vanillin (SPV) colorimetric method (modified from Van Handel, 1985). Briefly, dry sample homogenates were placed in glass centrifuge tubes and 2 mL of 2:1 (v/v) chloroform/methanol was added to the tissue. Samples were sonicated for 30 minutes, diluted further to 1:10, and added to a 96-well plate in a fume hood. The plate was heated to 100 °C for 10 minutes, after which 20 µL of concentrated sulfuric acid was added to each well and heated for 10 more minutes before cooling to room temperature. Subsequently, 280 µL of SPV reagent (1.2 mg/ml vanillin and 80 % v/v phosphoric acid) was added to each well and the plate was vortexed at 500 rpm for 30 minutes. Light absorbance at a wavelength of 490 nm was measured through each sample and total lipid was calculated from a calibration curve. Quality assurance consisted of a Walleye Pollock tissue reference sample (percent lipid not to exceed 15 % from target values), a sample replicate (not to exceed 15 %), and a blank (not to exceed 0.3 % lipid). Percent lipid was converted from dry to wet mass basis using moisture content for use in bioenergetic models.

If more than 0.1 g of dried homogenate was available after completion of other analyses, protein content of fish samples was calculated from measured nitrogen values using a LECO[1] TruSpec CHN following methods in the instruction manual (LECO, 2007). Briefly, samples of approximately 0.1 g of dried homogenate were wrapped in foil and combusted at 950 °C. Expelled nitrogen was quantified and protein content was estimated by multiplying total nitrogen content by the Kjeldahl conversion factor of 6.25 to account for the nitrogen content of protein (AOAC, 1995). Prior to sample analysis, the LECO was calibrated with 1) ethylenediaminetetra-acetic acid (EDTA), 2) a standard reference material of Meat1546 that was not to exceed 6 % error from the target value, and 3) sucrose with zero nitrogen content. Quality assurance samples and their allowable thresholds included with every batch of 21 samples were 1) EDTA with < 1 % error from target protein value, 2) two atmospheric blanks not to exceed 0.1 % protein, and 3) one replicate of a sample varying less than 1.5 standard deviation.

Statistical analysis

Mean condition indices for zooplankton and fish were calculated across all collections for each species. Standard deviations were reported unless sample size was one. Species were ranked by condition indices and ranges of each index were calculated across all zooplankton and fish taxa and within family. Statistical comparisons among species of zooplankton and fish were evaluated using Analysis of Variance with natural log-transformed data to meet required assumptions for the test and a significant p-value of 0.05. Tukey's multiple comparison test was used to evaluate which pairwise comparisons were significantly different and values of Tukey's Honest Significant Difference (HSD) are reported. Relationships between fish length and energy density were evaluated for fourteen species of fish for which larger sample collections spanned multiple ages as inferred by their size ranges (Forster et al., 2018). Local weighted regression (LOWESS) curves with a smoothing span of one was fit to these relationships. As a discussion point, length-energy relationships of Pacific herring, Pacific capelin (*Mallotus villosus*), saffron cod, Pacific sand lance (*Ammodytes personatus)*, and starry flounder

(*Platichthys stellatus*) caught in the Arctic were compared to fishfrom the Gulf of Alaska (Vollenweider[4], Unpublished results) to evaluate regional variation.

Results

Body condition indices were measured for sixteen species of zooplankton from seven families and six orders. Ten species of opportunistically-collected epibenthic invertebrates were also analyzed, comprising five families and three orders. Lipid content was highly variable within the Calanoida and Gymnosomata orders, differinging by as much as 227 times amongst individual animals within the order Gymnosomata, the pteropods (0.09 – 19.7 % lipid wet mass; Figure 2). Mean lipid content also varied by species and was 19 times higher in *Calanus glacialis*, the most lipid-rich zooplankter (22.57 % lipid), than in *Parasagitta elegans*, the most lipid-poor species (0.81 %; Table 2). Interspecific variation in lipid content was less among the epibenthic invertebrates, with the most lipid-rich *Eualus macilentus* (6.02 % lipid) having 7.5 times as much lipid as the most lipid-poor *Argis dentata* (0.81 %). Within the decapods (shrimp) and euphausiids (krill), lipid content correlated highly with energy density (R^2 = 0.81 and 0.65, respectively), consequently, similar patterns occurred in energy content as in lipid (Table 2). Within the isopods, the correlation between lipid and energy density was considerably less strong (R^2 = 0.19).

Body condition indices were measured for forty-one species of fish from twelve families. Lipid content was highly variable among species, and was 35 times as great in Bering cisco (*Coregonus laurettae*) (25.71 % lipid), the most lipid-rich species, compared to daubed shanny (*Leptoclinus maculatus*), the most lipid-poor species (0.71 %). Bering cisco had twice as much lipid as the second most lipid-rich fish, Arctic cisco (11.50 %) while the majority of fish species analyzed for lipid content had <5 % lipid (Table 3).

Energy density of fish was positively correlated with lipid content (R^2 = 0.85), consequently similar patterns were observed between the two indices. The variability among fish species was less than for lipid content, however, with the most energy-rich species, Bering cisco, having 3.4 times greater energy density (11.01 kJ/g wet mass) than the most energy-deplete Alaska plaice (*Pleuronectes quadrituberculatus*) (3.27 kJ/g) (Table 3, Figure 3). Approximately half of the families had variation in energy density among species, including the salmonids, osmerids, gadids, and cottids (Figure 4). Within the salmonids, Bering cisco (11.01kJ/g) had 53% greater energy density than the other five species that were similarly low (4.98–7.59 kJ/g). Within the gadids, Arctic cod (4.66 kJ/g) had 16% higher energy density than saffron cod and walleye pollock that were similar (3.99–4.24 kJ/g) (Figure 4). Cottids ranged 42% amongst the most energy-rich hamecon (*Artediellus scaber*; 4.94 kJ/g) and energy-deplete species shorthorn sculpin (3.48 kJ/g). Within the osmerids, zoarcids and pleuronectids, there was no difference in energy density amongst species ($p > 0.05$). Species variability could not be assessed for stichaeids that had limited sample sizes.

Correlations between energy density and length could be evaluated for fourteen species that spanned relatively large size ranges with ample sample sizes. Four general patterns of energy accumulation with size were apparent. Pacific herring, Pacific capelin and Arctic cod gained relatively more energy with size initially, followed by a decrease (Figure 5). Both species of salmonids, humpback whitefish and least cisco, as well as Arctic flounder and Bering flounder, maintained consistent increases in energy density with size. Saffron cod and starry flounder reached an asymptotic energy densities at larger sizes. In contrast, the three cottid species decreased in energy density with size, though fourhorn may have a slight uptick at the largest sizes. Finally, energy density of slender eelblennies and Pacific sand lance were generally invariant with size.

[4] Vollenweider J, Unpublished data, 2020

Total energy content (kJ) of individual fish integrates size with energy density. Salmonids ranked as the top six species with the greatest energy content (1,161 – 10,027 kJ) and were the only species with individuals large enough to have greater than 1,000 total kJ (Figure 6). Due to their large size (20 - 163 g), multiple species of flatfishes moved higher in their ranking for total energy content than their rankings for energy density (Table 3). In particular, the Alaska plaice (*Pleuronectes quadrituberculatus*) which was the most energy-deplete species in terms of energy density, had the ninth greatest total energy content (496 kJ) though this observation is limited to a single fish. Within families, the ranking of species by total energy content differed from a ranking according to energy density. For example, on a gram-for-gram comparison, Arctic cod had 10% more energy than walleye pollock or 17% more energy than saffron cod.; When energy density is scaled up to total energy content of a whole fish, however, saffron cod (333 kJ) had ten times more total energy than the other gadids (33 kJ and 27 kJ for Arctic cod and walleye pollock, respectively) kJ) as the mass of an individual saffron cod was an order of magnitude greater than Arctic cod or walleye pollock sampled here (Figure 8.

Protein content was the least variable condition index measured, only ranging two-fold between the highest and lowest protein contents (Table 3). Salmonids were the top five species with the greatest protein content (18.15–19.30 %), whereas ribbed sculpin (9.55 %) had the least. Two-thirds of the species analyzed had protein contents higher than 15 %.

Discussion

This research has significantly expanded the library of body condition analyses of Arctic zooplankton and fish by enlarging the number of species analyzed as well as the spatial coverage to include the Chukchi and western Beaufort Seas. We highlight how size and location can have dramatic consequences on animal body condition and consequently the importance of using appropriate condition measures. We expound on the bioenergetics consequences of prey switching. Finally, we put forth this work as a foundational piece in supporting bioenergetics models to predict Arctic ecosystem communities in the future.

Of the zooplankton species previously reported from the Svalbard region off the coast of Norway and adjacent to Baffin Island, Canada (Mayzaud et al., 2016; Scott et al., 2000; Percy and Fife, 1981), species-specific lipid values generally fall within the ranges measured here. Euphausiids, however, had higher lipid in other regions than observed here, including the adjacent Bering Sea and more distant Arctic locations by Baffin Island and Svalbard (Harvey et al., 2012; Hopkins et al., 1978; Percy and Fife, 1981;). In contrast, energy densities of zooplankton measured in this study are consistently higher than those collected in the Norwegian Arctic near Svalbard (Westlawski 1994).

Changes in availability or timing of high quality zooplankton prey could have drastic effects on their zooplanktivore predators whose life cycle events are tightly paired to these events. For example, the time when juvenile fish such as Arctic Cod have exhausted their lipid sacs and begin their first feeding coincides with high spring zooplankton production, particularly lipid-rich calanoid copepods (Rand et al., 2013; Gray et al., 2016). Another example of a critical energetic event is in the summer when bowhead whales feed on ephemeral euphausiid aggregations caused from summer upwelling (Okkonen et al., 2011). Should these high quality prey resources be replaced with alternative prey, cascading effects could proliferate up the food chain. This phenomenon has been observed in the North Sea where warming ocean temperatures resulted in shifts from high lipid *Calanus finmarchicus* to a lower quality *Calanus helgolandicus*, causing reduced condition and abundance in their Sandeel (*Ammodytes marinus*) predators and subsequently declines in productivity of multiple species of seabirds feeding upon the Sandeels (Frederiksen et al., 2006). To evaluate bottom-up regulation of marine ecosystems as observed in the North Sea, accurate measures of zooplankton body condition are a foundational component.

Fish energy density variation of 267 % among the 41 evaluated species could potentially have large consequences for piscivorous predators. .. For example, for a seal to intake equal calories from a diet solely composed of Bering cisco, the most energy-rich fish, the seal would need to consume 3.4 times the biomass of Alaska plaice, the least energy-rich species. Bering cisco weigh approximately four times more than Alaska plaice meaning a seal would need to consume twelve Alaska plaice to equate to one Bering cisco. Similarly, eighty-seven shorthorn sculpin, the second-least energy-rich species, would be required to equate to one Bering cisco. These simple comparisons contrasting monospecific diets of prey of both extremely different quality and size show that consuming greater quantities of low-quality prey may not be possible. This has been demonstrated by Steller sea lions, which could not compensate for a low quality diet of walleye pollock by consuming sufficient biomass to maintain their body mass (Rosen and Trites, 2000). Furthermore, the comparison of monospecific diets is oversimplified as there are a host of additional complicating factors playing into predator foraging strategy, including abundance, distribution and timing of available prey species, as well as species-specific behavior of prey commensurate with particular feeding methods of predators, i.e., gulp feeding versus single fish selection (Petrov et al., 2020).

A more pertinent situation is that Arctic cod, which is relatively averse to warming temperatures, may be outcompeted in the Arctic by saffron cod which can tolerate warmer temperatures, or by invading temperate gadids such as walleye pollock (Laurel et al, 2016; Logerwell et al., 2015; Hollowed et al., 2013). With saffron cod as the dominant prey fish, predators would need to consume 17 % more biomass of it than of Arctic cod for equivalent ingested energy. However, saffron cod are significantly larger than Arctic cod, thus provide more energy per fish and consequently a single saffron cod provides the same the total energy as ten Arctic cod. If Arctic Cod are displaced by the juvenile walleye pollock caught in this study, a predator would need to consume 10 % more biomass of walleye pollock which equates to 1.2 individual pollock.. The different energy content of fish can have profound effects on their predators. Consider the grey seal (*Halichoerus grypus*), one of the few Arctic phocids whose energetic demands have been measured but inhabits the North Atlantic. Grey seals require 1,006 kJ/d for resting metabolism (Ronald et al. 1984).To meet daily energy requirements, a seal would need to consume 6 saffron cod, 33 Arctic cod, or 41 walleye pollock. In terms of biomass, this would equate to 287 g of saffron cod, 200 g of Arctic aod, or 245 g of walleye pollock. These discrepancies would be less pronounced for smaller phocids inhabiting the Chukchi Sea such as ringed seals (*Phoca hispida*), but significantly more pronounced for bearded seals (*Erignathus barbatus*) that can be twice as large as grey seals. This comparison has direct bearing for the Chukchi ecosystem as both phocids are known to consume all three gadid species (Crawford et al., 2015).

Predicting future changes in the biological community composition in the Arctic is considerably more complicated than comparisons of energy content. The comparison of gadids is complicated by different habitat preferences of the species. While Arctic cod and potentially walleye pollock have broader distributions across the Chukchi and Beaufort Seas, saffron cod prefer nearshore, shallow habitats (Vollenweider et al., 2018; De Robertis et al., 2017, Logerwell et al., 2015). Additionally, the most energy rich species were not highly abundant nor widespread. For example, Pacific herring was caught in relatively low abundance north of Norton Sound. Similarly, Pacific sand lance, Arctic staghorn sculpin, and rainbow smelt and anadromous species such as ciscos were caught more frequently in nearshore habitats than offshore (Vollenweider et al., 2018; De Robertis et al., 2017; Logerwell et al. 2015). Additional caveats of our energetic-based comparisons are the size and age of fish used for analysis. Though samples analyzed are probably relatively reflective of the most abundant size and ages of fish present, samples were derived from multiple studies with somewhat dissimilar sampling methods that would skew this, such as somewhat unbalanced sampling of pelagic versus benthic habitats and offshore versus nearshore. It is scenarios such as these in which spatially-explicit bioenergetic models can integrate prey quality, abundance, and distribution to predict biological community composition in the Arctic under future environmental scenarios.

There are some similarities and stark differences between the summertime energetics of the 41 Arctic species examined here compared to more southerly species in Alaska. In a similar study in the Gulf of Alaska (GOA), energy content was measured for 16 of the most abundant marine fish species, 5 of which also caught in this study study (Vollenweider et al. 2011). The average energy density of the fish species examined in these studies were very similar, ranging from 3.27–7.98 kJ/g wet mass in the Arctic versus 3.64–9.78 kJ/g in the GOA. In contrast, the range of average total energy of individual fish confounded by fish mass in the GOA was 14 times greater than Arctic fish (Arctic fish: 1–10,027 kJ; GOA: 30-30,624 kJ). This stark difference is due to the large size discrepancy of abundant fish between the two regions, with the Arctic comprised of many juveniles such as Arctic cod, walleye pollock, yellowfin sole, (Forster et al., 2018; De Robertis et al., 2017) as well as adult fish of diminutive size (Forster et al., 2020). Size and ontogenetic differences (Wuenschel et al., 2011; Post and Parkinson, 2001) of fishes illustrate the need for appropriate measures of energy content.

Five species of fish spanning large size ranges and sampled in relatively large numbers could be directly compared between the Arctic study and the GOA study. From the energy density-length relationships, energy accumulation with size was slower in the Arctic than in the GOA for both species of fish (Figure 6). Juvenile fish have rapid growth during significantly shorter summer growing seasons at high latitude which could tax their energy reserves relative to their southerly counterparts (Conover and Present, 1990). Though juveniles require large energy stores in the fall to sustain themselves during winter conditions with low food availability (Sewall et al., In Review; Sogard and Olla, 2000), Arctic fish in colder water may have significantly reduced metabolic rates and may therefore require less energy to sustain themselves through the winter (Bystrom et al 2006; Garvey et al., 2004). At higher latitudes fish are older at a given length, therefore lower energy content of mature fish may be associated with gonad development that commences earlier at higher latitudes in some species of fish (Garvey and Marschall, 2003). In addition, Pacific capelin may preferentially allocate energy to maturation and maximum gonad production over adult survival (Carscadden et al. 1997).

Foundation for bioenergetics modeling

Summer is an important feeding period in the Arctic as sea ice melts and habitat becomes seasonally available. Many species of seabirds and marine mammals migrate annually to the Arctic to feed during the ice-free season to take advantage of the high productivity. In the US Arctic, ocean currents transport large nutrient loads from the Bering Sea into the Chukchi Sea and then onto the Beaufort Sea Shelf through upwelling from the Arctic Basin (Tremblay et al., 2011; Danielson et al., 2017). The majority of the ~15,000 individuals of the Western Arctic stock of bowhead whales (*Balaena mysticetus*) migrates from the Bering Sea through the Chukchi and western Beaufort Seas each spring and fall to these feeding grounds (IWC 2018). Similarly, migration from the Bering Sea to the coast of the Chukchi Sea and to the eastern Beaufort Sea is performed annually by thousands of Beluga whales (*Delphinapterus leucas*) to calve and molt (Barber et al., 2001). Humpback (*Megaptera novaeangliae*), Fin (*Balaenoptera physalus*) and Minke whale (*Balaenoptera bonaerensis*) sightings are increasingly more common in the Chukchi Sea in the summer (Clarke et al., 2013). Millions of seabirds congregate in the Chukchi and Beaufort Seas to feed and breed during the summer (Kuletz et al., 2015; Smith, 2010). With such an immense seasonal influx of foraging animals to the Arctic, the quality of their zooplankton and fish prey in the summer is foundational to the region's food web. Understanding trophic linkages and predicting future ecosystem community composition under anticipated climatic changes can be evaluated using bioenergetic models with prey nutrition indices described here.

Though the summer period of Arctic productivity is generally the focal period of trophic analysis, winter may be of interest for non-migrating species that remain in the Arctic year- round. Winter prey quality descriptors of zooplankton and fish are nonexistent in the US Arctic due to substantial logistic constraints imposed by sea ice and perpetual darkness. Some zooplankton and fish, particularly those inhabiting pelagic habitats, undergo significant seasonal cycles in energy content in relation to their ontogenetic

development, food availability and maturation state (Vollenweider et al., 2011; Syvaranta and Rautio, 2010; Clarke and Peck, 1991; Hislop et al., 1991). Zooplankton in the water column also tend to fluctuate significantly likely due to high metabolic costs incurred in that habitat (Clarke and Peck, 1991; Syvaranta and Rautio, 2010; Falk-Petersen et al., 2009, 2000). This is especially true of pelagic species that rely most heavily on seasonal production. Ice algae has an important role in the phenology and energetics of some Arctic zooplankton species, and consequently, loss of sea ice will likely impact zooplankton condition and potentially survival of some species. Similar seasonal variation occurs in fish condition, generally with an increase in energy content during productive summer conditions, followed by a decrease in energy over winter when food is scarce and gonad development may concurrently take place in preparation for spawning (Paul and Paul, 1999; Robards et al., 1999). In the Gulf of Alaska, the most extreme seasonal energetic cycling occurs in Pacific Herring, for which energy density can nearly double from spring minima to fall maxima. Demersal species cycle less, likely due to a more steady-state conditions near the sea floor. To what degree the prey quality of Arctic zooplankton and fish species fluctuates seasonally warrants investigation.

Conclusions

This is the most thorough library of Arctic zooplankton and fish condition to date. Comparisons of prey quality illustrate that climate-induced changes in zooplankton and fish communities could result in a vastly different nutritional value of available prey for fish, seabirds and marine mammal predators. Specific effects on health and survival of upper-level trophic consumers can be ascertained using body condition of fish and zooplankton characterized here to parameterize bioenergetic models that take prey quality into account. These data provide critical prey quality indices that can be used in these models. As Arctic zooplankton and fish species have different energetic strategies than their congeners at lower latitudes, having location-specific condition values is critical for the accuracy of bioenergetic models. Inclusion of prey quality values in Arctic food webs will significantly enhance predictions and understanding of how the Arctic marine ecosystem will fare in the future.

Acknowledgements

A project of this size is not possible without the support of countless people! We thank our critical funding sources, including NPRB, BOEM, NSB, and the Wildlife Conservation Society/Arctic Beringia Program. People that proposed and secured funding for these projects include Ed Farley (NOAA), Franz Meuter (UAF), Kevin Boswell (FIU), Craig George (NSB) and Seth Danielson (UAF). Many, many people were critical in the collection of samples, notably Kris Cieciel (NOAA), Alex Andrews (NOAA), John Moran (NOAA), Wyatt Fournier (NOAA Affiliate), Scott Johnson (NOAA), John Thedinga (NOAA), and Alex Whiting (Native Village of Kotzebue). Ann Robertson, Mark Barton, and Brian Haggerty-Perrault led the collection and preservation of the nearshore samples. A fleet of boats and crewmen kept us safe and helped us achieve our goals, including the R/V Ocean Star, R/V Ukpik, and R/V Annika Marie. The people of Utqiagvik and Kotzebue were foundational in supporting nearshore project activities. An army of people in the laboratory provided biological processing and chemical analysis of the samples. Ann Robertson and Brian Haggerty-Perrault oversaw sample processing of the majority of fish, and large contributions were made by Matt Callahan, Kevin Heffern, Courtney Weiss, Corey Fugate, and Lawrence Schaufler.

Figure 1. Station design of the projects from which samples were obtained, including The Arctic Coastal Ecosystem Survey (ACES), Arctic Lagoon Ecology of Forage Fishes in the Arctic Nearshore (AFF), ArcticEis, Arctic Integrated Research Project (IERP), Coastal Arctic Lagoons, Arctic Shelf Growth, Advection, Respiration and Deposition (ASGARD), Shelf Habitat and EcoLogy of Fish and Zooplankton (SHELFZ), and opportunistic samples from subsistence collections.

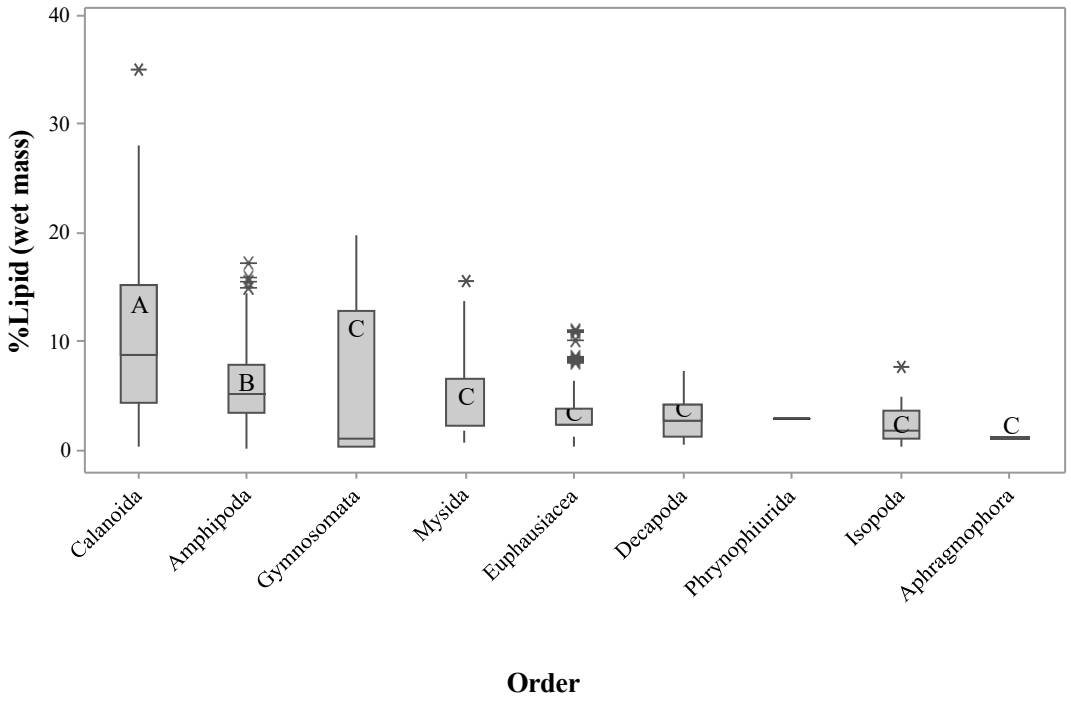

Figure 2. Lipid content (% wet mass) of zooplankton orders shown as boxplots, where the solid bars depict the interquartile range, the horizontal lines within the bars depict the median, vertical lines depict the range, and asterisks depict outliers. Like letters indicate statistical similarity.

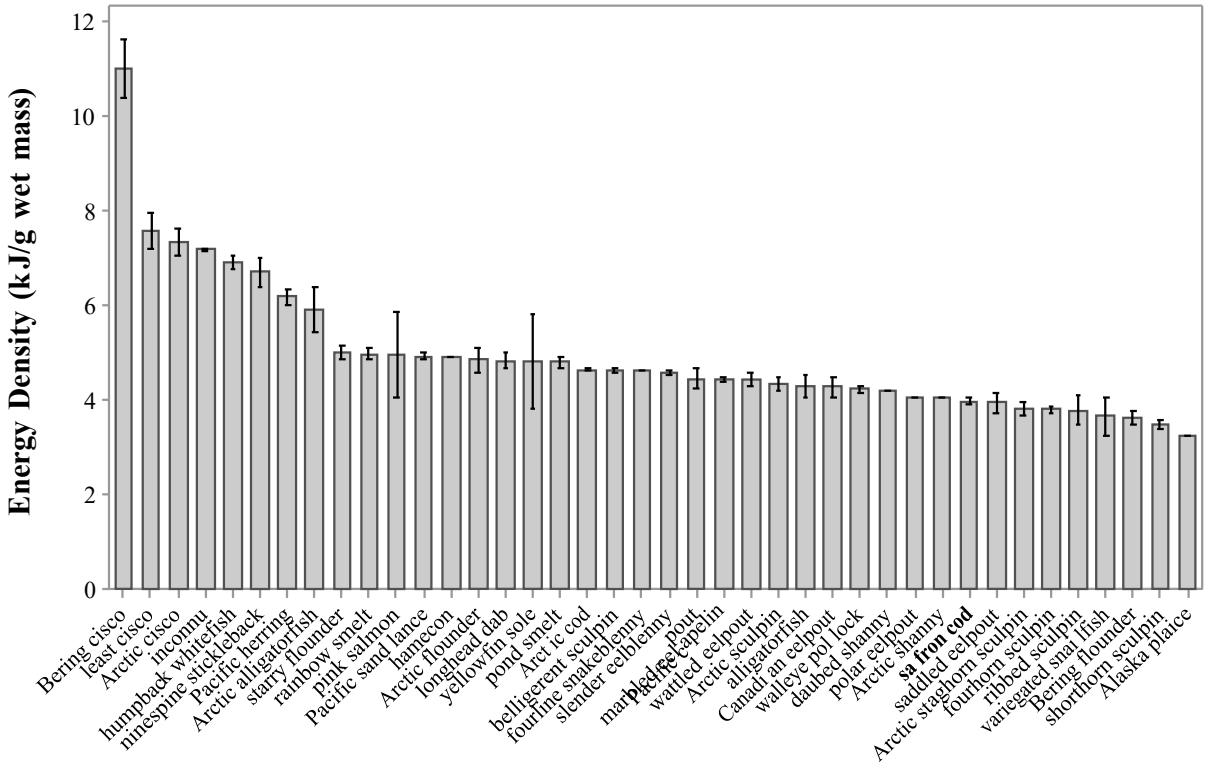

Figure 3. Mean energy density (kJ/g wet mass; ± standard error) of Arctic fish species. Lack of error bars indicates a sample size of one.

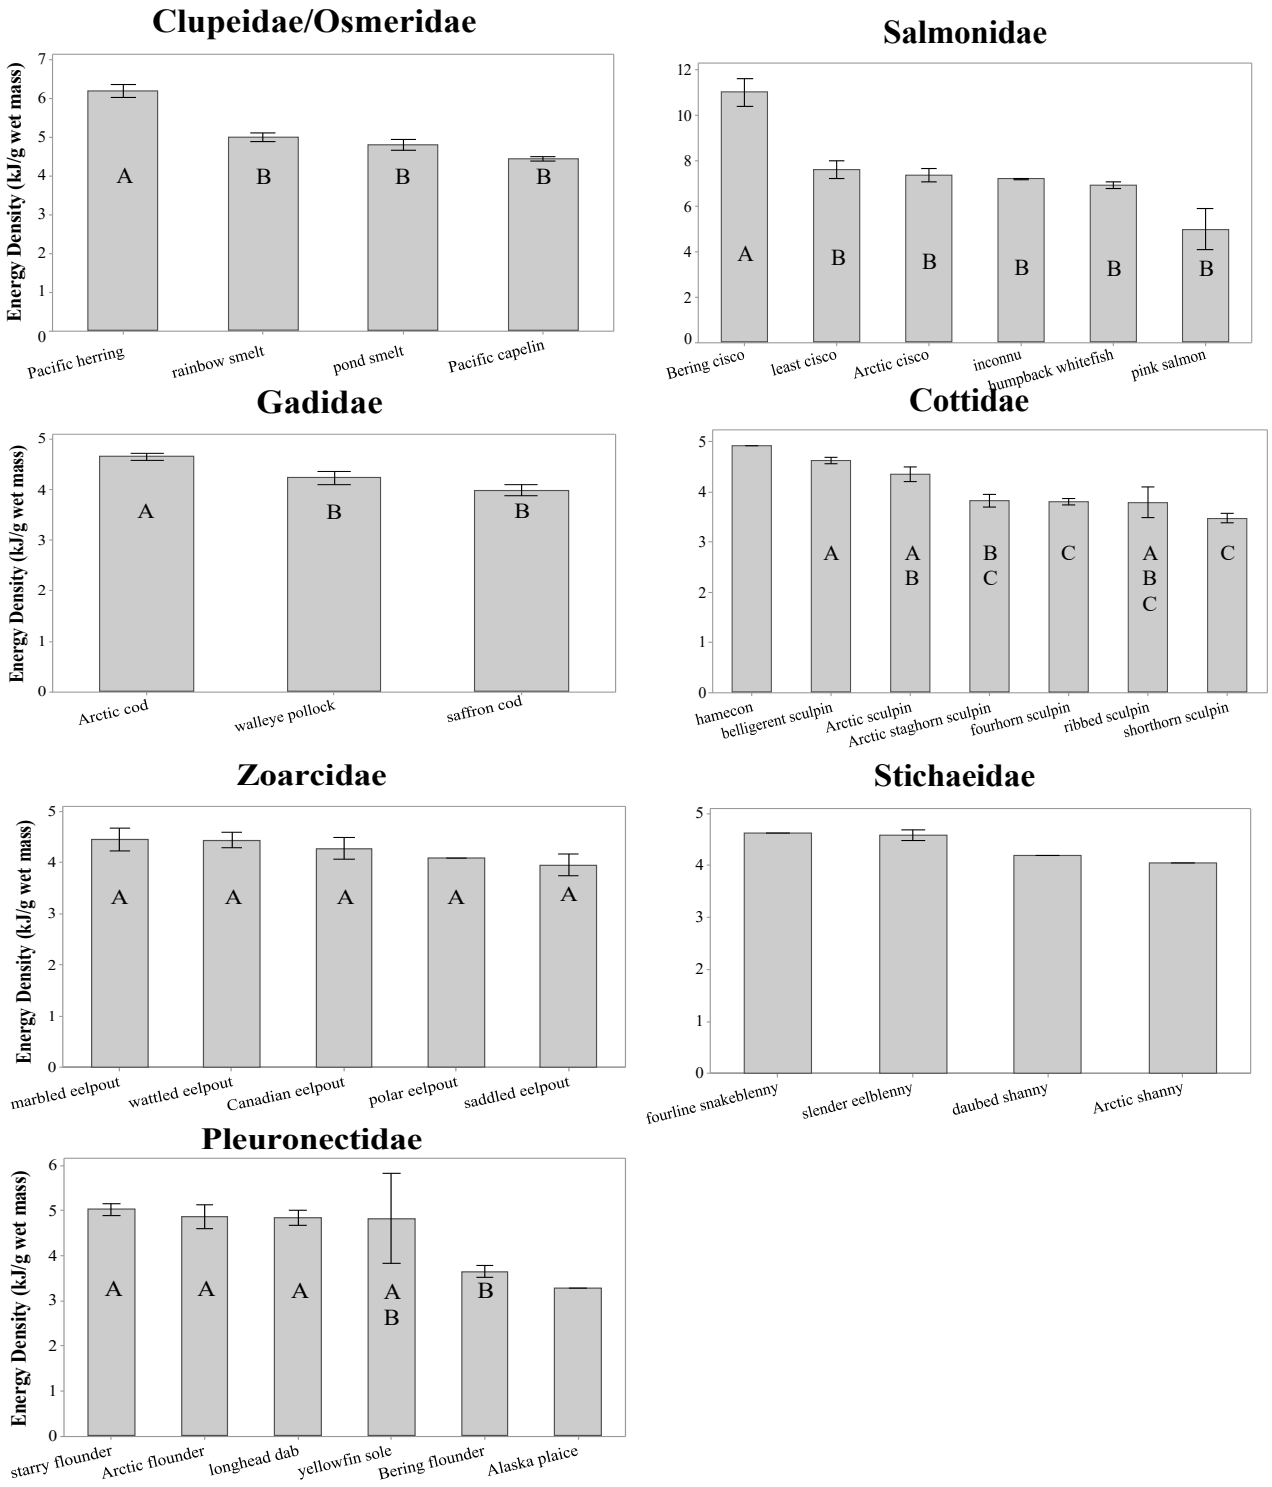

Figure 4. Mean energy density (kJ/g wet mass; ± standard error) of Arctic fish species by family. Like letters indicate statistical similarity. Lack of letters and error bars indicates a sample size of one.

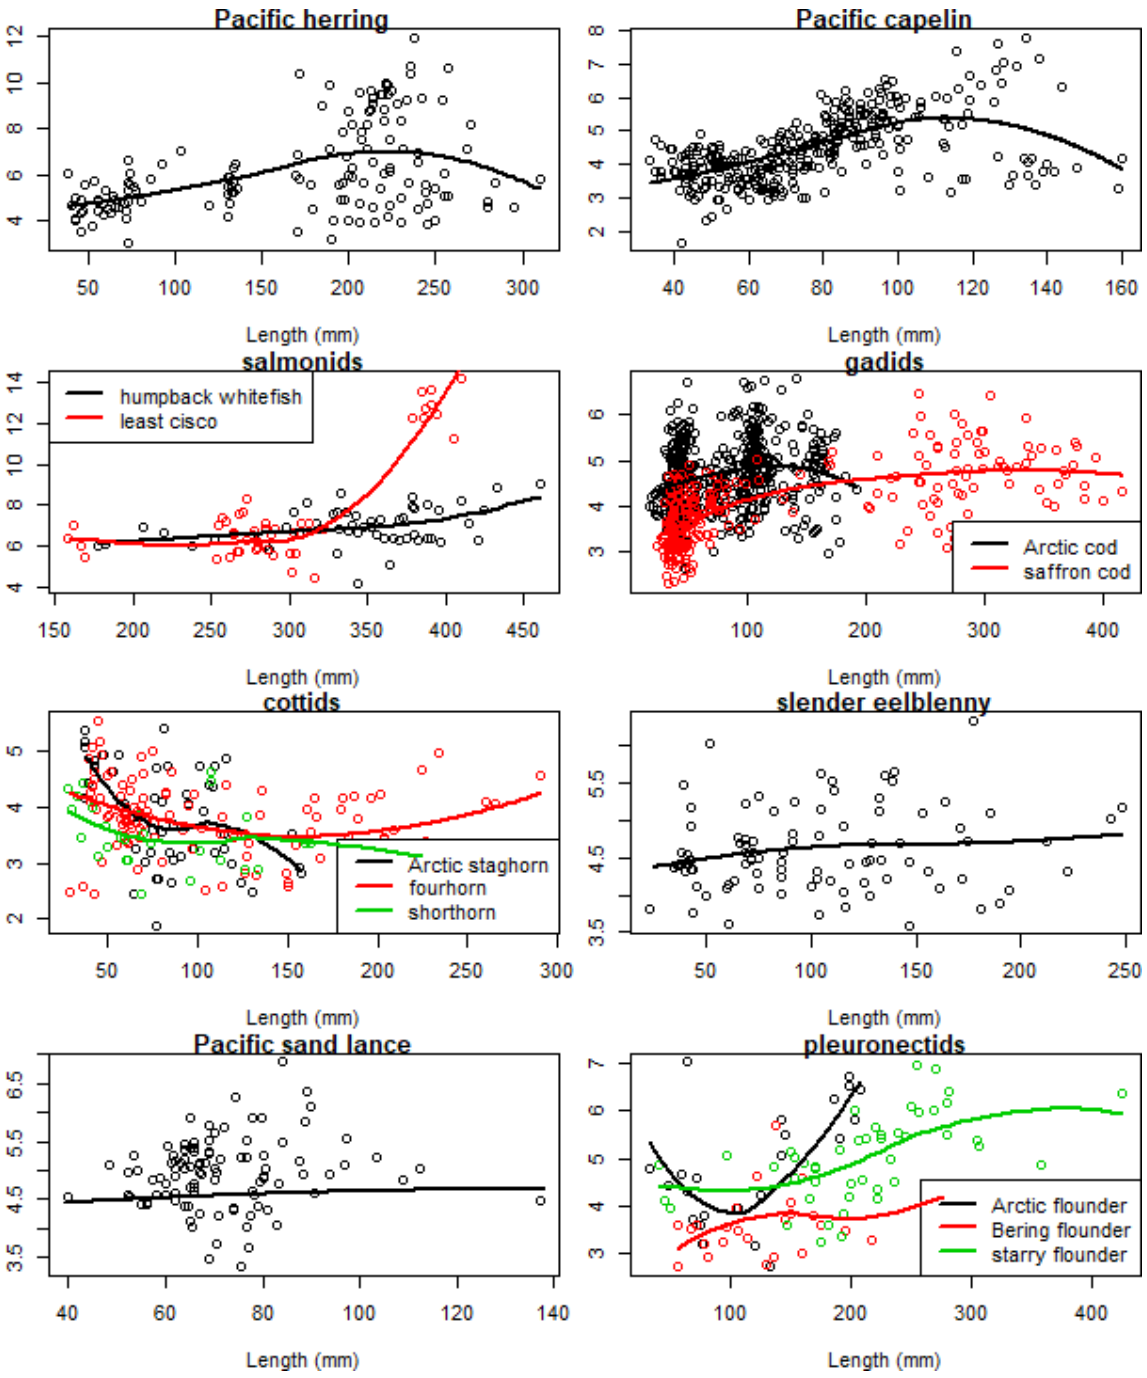

Figure 5. Length-energy density relationship of Arctic fish, where length is measured as fork length for Pacific herring, Pacific capelin, salmonids and Pacific sand lance and total length otherwise.

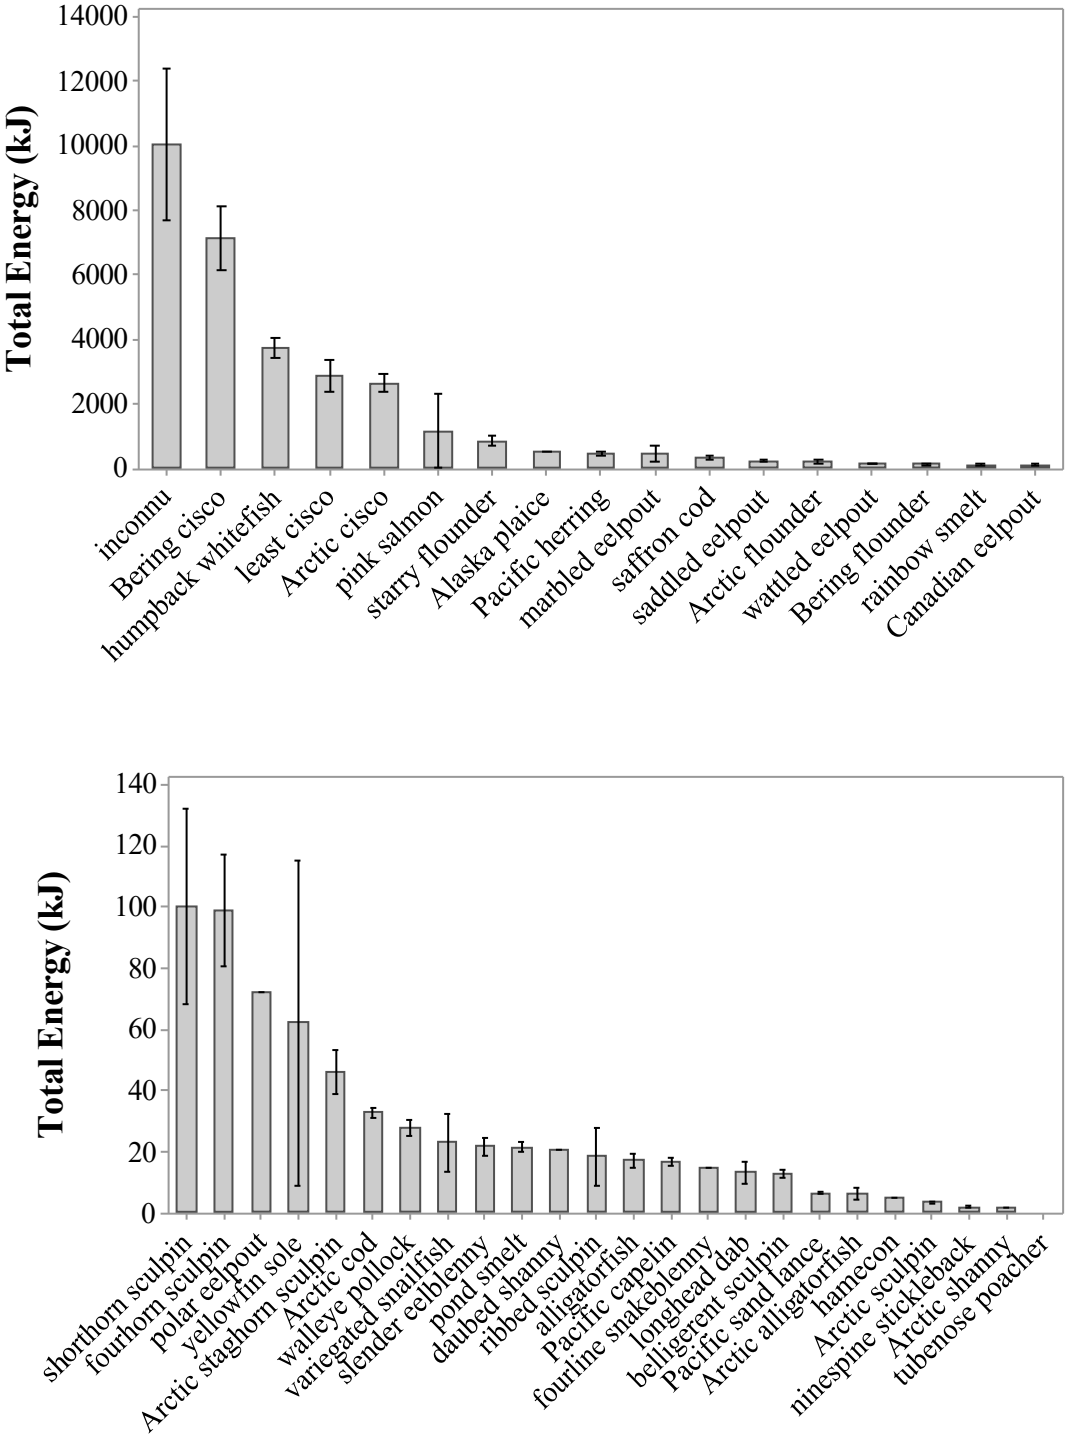

Figure 6. Average total energy content (kJ; ± standard error) of Arctic fish species. The top panel includes the species for which total energy exceeds 100 kJ while the bottom panel are those less than 100 kJ.

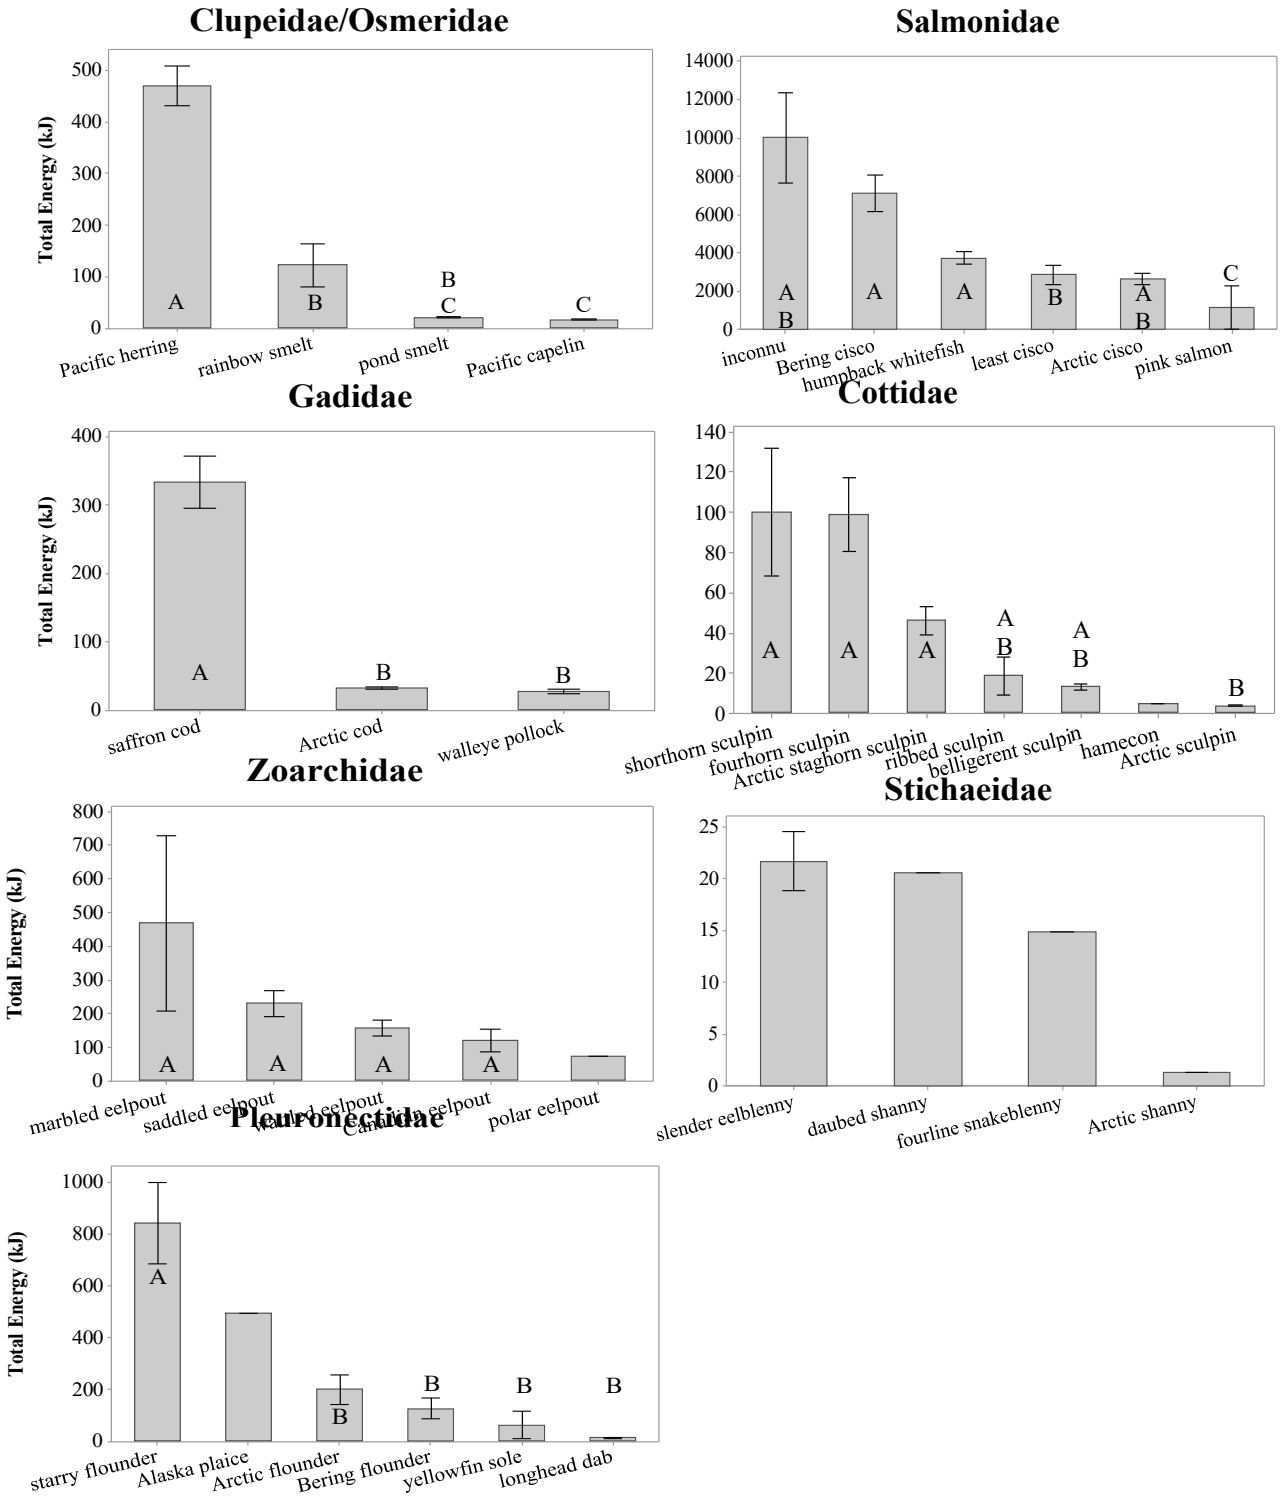

Figure 7. Average total energy content (kJ; ± standard error) of Arctic fish species. Like letters indicate statistical similarity. Lack of letters and error bars indicates a sample size of one.

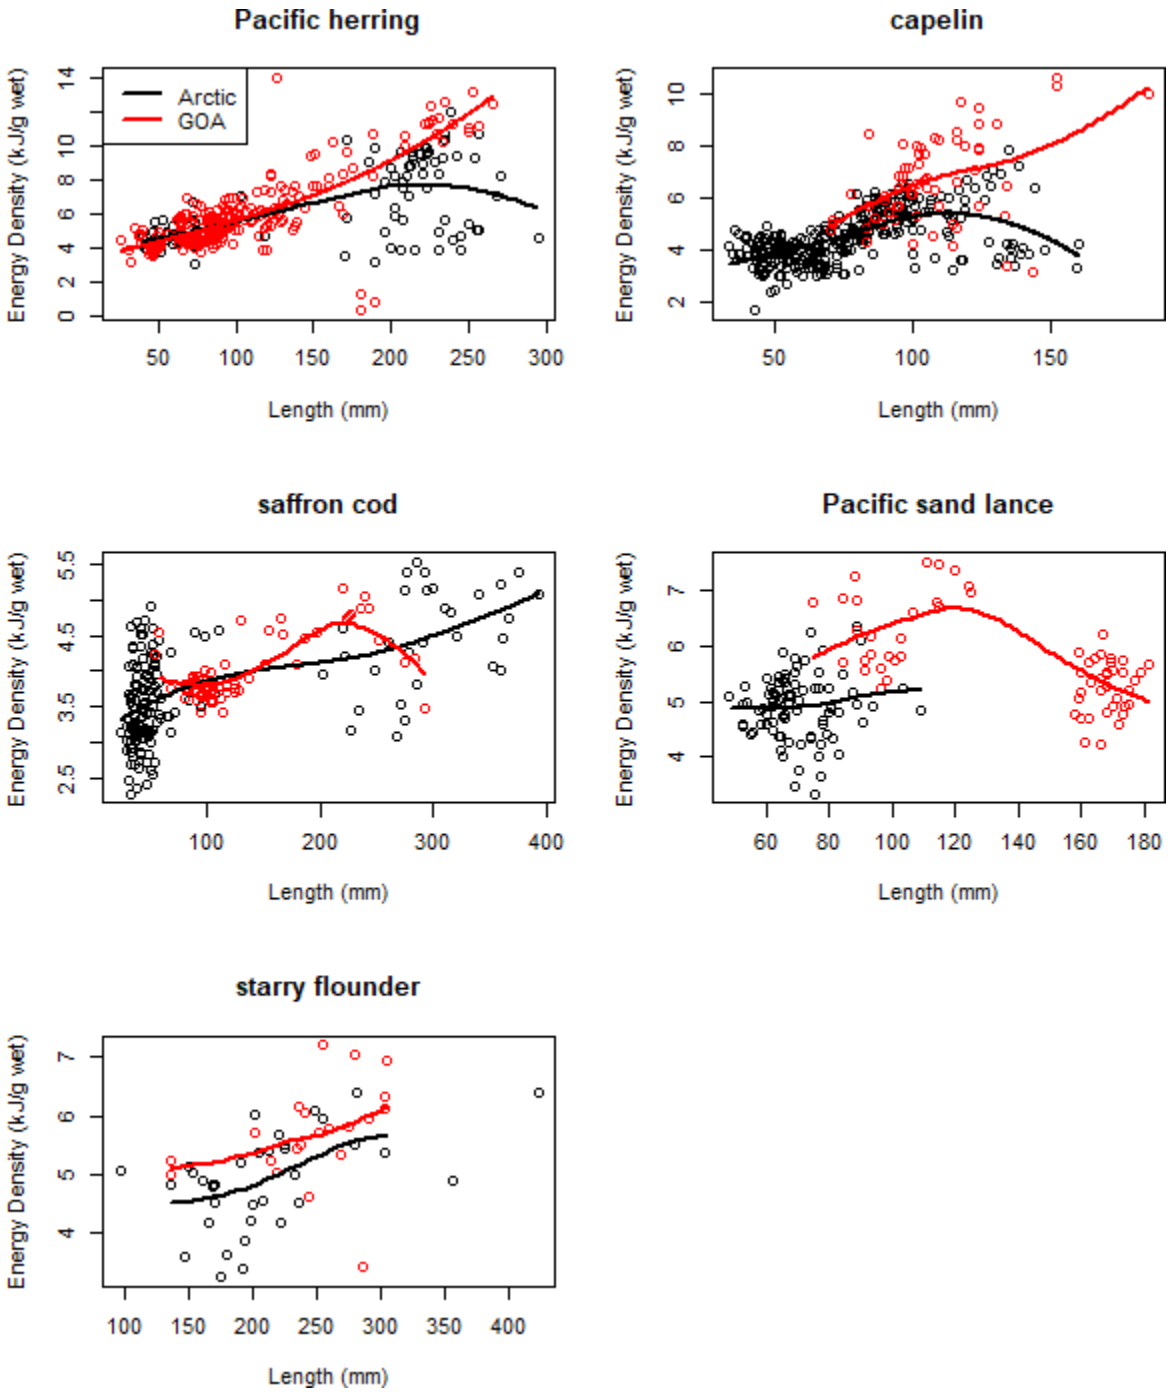

Figure 8. Length-energy density relationship of fish collected in the summer (July–September) from two Large Marine Ecosystems, the Arctic and the Gulf of Alaska.

Table 1. Survey details of the projects from which samples were obtained, including 1) The Arctic Coastal Ecosystem Survey (ACES), 2) Arctic Lagoon Ecology of Forage Fishes in the Arctic Nearshore (AFF), 3) ArcticEis, 4) Arctic Integrated Research Project (IERP) 5) Coastal Arctic Lagoons (ArcticLag), 6) Arctic Shelf Growth, Advection, Respiration and Deposition (ASGARD), 7) Shelf Habitat and EcoLogy of Fish and Zooplankton (SHELFZ), and 8) opportunistic samples from subsistence collections (Opp). Sample sizes (n) of zooplankton (Zoop) and Fish analyzed for prey quality are reported for each project.

Project	Years	Months	Zoop n	Fish n	Sampling Method
ACES	2005, 2007, 2012-2014	July-August	98	370	• 37 m variable mesh beach seine • 2.6 x 1.2 m otter trawl • 50 cm 333 µm mesh ring net
AFF	2015	July-September	220	684	• 37 m variable mesh beach seine • 5 x 3.5 m Aluette mid-water trawl • 4.7 m plumb staff beam trawl • 2.6 x 1.2 m otter trawl • 1^2 m 505 µm Tucker trawl • 50 cm 333 µm mesh ring net
ArcticEis	2012-2013	August-September	0	443	• 122 m CanTrawl 400/601 surface trawl • 6.1 x 6.1 m Marinovich mid-water trawl • 4.7 m plumb staff beam trawl • 34.1 m 83-112 Eastern otter trawl • 60 cm 505 µm bongo net
ArcticIERP	2015	August-September	81	291	• 122 m CanTrawl 400/601 surface trawl • 6.1 x 6.1 m Marinovich mid-water trawl • 60 cm 505 µm bongo net
ArcticLag	2016-2017	June-September	0	379	• variable mesh gillnet • fyke net • beach seine • rod and reel
ASGARD	2017-2018	June	0	17	• 4.7 m plumb staff beam trawl
SHELFZ	2013	August-September	54	146	• 5 x 3.5 m Aluette mid-water trawl • 6.1 x 6.1 m Aluette mid-water trawl • 4.7 m plumb staff beam trawl • 34.1 m 83-112 Eastern otter trawl • 37 m variable mesh beach seine • 1^2 m 505 µm Tucker trawl net

CHAPTER 10 - Trade-offs among sampling designs for monitoring biodiversity and abundance of marine organisms in the Chukchi Sea

Objective 3: Combine results from previous Arctic surveys (Arctic EIS, Phase 1, BASIS) and planned surveys (Arctic IES Phase 2) to assess variability in pelagic and demersal fish ecology over time relative to ocean conditions.

Abstract

Assessing and quantifying biodiversity at multiple levels is a key component of monitoring and understanding changes in marine ecosystems. Adequate monitoring is particularly challenging in remote, high-latitude regions such as the Chukchi Sea, an Arctic inflow shelf that is undergoing rapid environmental changes. Current monitoring efforts in the Chukchi Sea rely on opportunistic sampling in recognized 'hot spots' (the Distributed Biological Observatory, DBO) or dedicated, but typically short-term, monitoring programs. The relatively extensive sampling design used during Arctic Marine Biodiversity Observing Network (AMBON) surveys in the northeast Chukchi Sea in 2015 and 2017 and by the Arctic Integrated Ecosystem Survey (AIES) in 2017 provide an opportunity to evaluate the effectiveness of different sampling designs for quantifying biodiversity. We evaluated how common diversity measures and their uncertainty vary across a set of reduced survey designs that were pragmatic subsets of the stations sampled by the full AMBON and AIES designs. As a case study, we estimated the power to detect changes in diversity of the demersal fish community resulting from the expansion of new or rare species into the study region. A framework was developed to simulate changes from the 2017 baseline using temperature-dependent changes in the probability of occurrence of new or otherwise undetected species. Results suggest no apparent bias in diversity estimates for any of the reduced designs, including those with spatially restricted sampling such as the Distributed Biological Observatory (DBO), but substantial increases in uncertainty as sample sizes decrease. This high uncertainty contributed to the poor performance of most sampling designs in terms of detecting changes in the presence of relatively rare species from baseline conditions. Our study provides a general framework for evaluating alternative sampling designs in the context of monitoring biodiversity that can easily be adapted to other regions and communities and can be used to test a variety of hypotheses about the nature of possible changes.

Introduction

Monitoring trends in species occurrences and abundances is critical to the management and conservation of ecosystems and their components (Duffy *et al.*, 2013). Consequently, measures of biodiversity have been identified as key variables for monitoring ecosystems. Global monitoring efforts include terrestrial and marine biodiversity observing networks (BONs) that have been established in an effort to standardize biodiversity measurements through the development of Essential Biodiversity Variables (EBVs) (Proença *et al.*, 2017). Measures of diversity are relatively simple to interpret and are critical to ecosystem function, stability and productivity (Tilman *et al.*, 1994, 2012). However, monitoring biodiversity across multiple functional groups is costly, especially in remote marine regions like the Arctic (Iken *et al.*, 2019). Given

limited resources, there are clearly trade-offs among the extent of geographic coverage, sampling effort per site, the frequency of sampling, the number of functional groups monitored, and other costs associated with different sampling designs (Couvet *et al.*, 2011). While these trade-offs have been acknowledged, few studies have systematically evaluated trade-offs among sampling designs. Here we examine some of these trade-offs using data from the Arctic Marine Biodiversity Observing Network (Iken *et al.*, 2019).

The Arctic-Subarctic transition zone is characterized by rapid changes in ice conditions and ocean temperatures (Danielson *et al.*, 2020) with the potential to transform the Pacific Arctic ecosystem (Huntington *et al.*, 2020). These physical changes are associated with changing distributions of marine organisms from benthic macrofauna (Waga *et al.*, 2019) to fish (Stevenson and Lauth, 2019; Thorson *et al.*, 2019) and whales (Moore and Reeves, 2018). Projections based on an ensemble of species distribution models suggest increases in species richness and functional redundancy in the Chukchi Sea under continued warming as opportunistic subarctic species expand northward into the Arctic (Alabia *et al.*, 2020), a process that has been referred to as borealization (Carmack and Wassmann, 2006; Fossheim *et al.*, 2015). Thus, there is a need for continued monitoring in the Pacific Arctic to detect changes in biodiversity associated with changes in the abundances of common species as well as changes in the occurrence of rare species or of new, previously unrecorded species. Sampling effort in this region has been limited by logistical constraints and the high costs associated with remoteness and harsh environmental conditions, making it all the more important to optimize field sampling designs (Iken *et al.*, 2019).

A number of short-term field efforts have sampled the biological components of the Pacific Arctic in recent decades and two ongoing observational programs, AMBON and the Distributed Biological Observatory (DBO, Grebmeier *et al.*, 2019), continue to sample multiple trophic levels. Of these, the DBO reflects a minimal design focused on selected hot spots with three sampling transects in the Chukchi Sea, while AMBON includes two of these transects as part of a more extensive network of transects sampled in 2015 and 2017 (Fig. 1). In addition to these transect-based monitoring programs, gridded ecosystem surveys have been conducted in 2012 and 2013 (Mueter *et al.*, 2017), as well as in 2017 and 2019 during the Arctic Integrated Ecosystem Survey (AIES)[5]. The AMBON and AIES surveys conducted in 2017 (Fig. 1) overlapped in time and space, thereby providing an opportunity to assess the efficiency of different sampling designs for quantifying biodiversity at a regional scale that encompasses most of the US portion of the Chukchi Sea shelf.

Designing a biodiversity monitoring program requires a series of choices including the geographic extent of the study region, the target assemblages for monitoring, the sampling methodology (net sampling, visual surveys, acoustic surveys, environmental DNA, etc.), the frequency of sampling, the number of locations to sample (e.g. station density), the spatial arrangement of samples (random sampling, gridded survey, transects, etc) and many others. The AMBON program is part of a national effort to develop marine observing networks focusing on biodiversity (Duffy et al., 2013). The program samples multiple ecosystem components including microbes (eDNA), microalgal biomass (chlorophyll a); zooplankton (plankton net), meiobenthos and macrobenthos (van Veen grab), epibenthos and demersal fish (bottom trawl), as well as seabirds and marine mammals (visual observations) (Iken *et al.*, 2019). A long-term goal for the monitoring program is to serve as a change-detection array for biological resources in the region. Further borealization associated with the loss of sea ice and potential increases in northward advection through Bering Strait (Woodgate, 2018) are expected for this region, therefore detecting expansions of boreal species into the northern Chukchi Sea, or changes in abundance of key species, are important objectives. To meet these goals, the AMBON sampling design was a pragmatic choice that incorporates previous observational programs to extend existing time series (Iken *et al.*, 2019) and uses established methodologies for the selected target communities that are consistent with historical sampling efforts, while also adding new approaches such as eDNA to assess the microbial community.

[5] https://www.nprb.org/arctic-program

Our goal in this study was to assess the efficiency of different sampling designs and different amounts of sampling effort to quantify biodiversity for selected marine assemblages, using data from the 2017 AMBON and AIES surveys and simulated changes in diversity. Specific objectives were (1) to assess bias and uncertainty in three diversity measures estimated for 5 different assemblages from zooplankton to seabirds using a range of survey designs and station densities, and (2) to assess the sensitivity of these diversity measures to simulated changes in species diversity. The first objective aims to inform the choice of sampling design for ongoing and future monitoring programs in the Pacific Arctic to help identify an efficient sampling design for achieving biodiversity-related sampling goals, The second objective addresses our ability to detect changes in regional biodiversity associated with the ongoing borealization of Arctic communities. Finally, we hope that the approach presented here serves as a flexible template for assessing sampling designs for other biodiversity monitoring programs.

Methods

Study region

The shallow inflow shelf of the Chukchi Sea is strongly influenced by waters entering from the Bering Sea through Bering Strait, advecting heat, nutrients, and organisms from the Pacific to the Arctic (Coachman *et al.*, 1975; Hunt Jr *et al.*, 2016). The flow through Bering Strait transports about 0.8 Sv northward with stronger flow in the summer than in winter (Roach *et al.*, 1995; Woodgate *et al.*, 2006), but has increased over recent decades (Woodgate, 2018). The Bering Strait region and the Chukchi Sea are a transition zone between subarctic and arctic communities and as such are characterized by strong gradients in species composition, diversity, and abundance of fish and invertebrates (Stevenson and Lauth, 2012; Sigler *et al.*, 2017). The shallow Chukchi Sea shelf is characterized by high levels of primary production fueled by both advected and regenerated nutrients that support high standing stocks of zooplankton and a rich community of benthic invertebrates. The combination of advected zooplankton combined with high local production attract large numbers of seabirds and marine mammals that seasonally migrate to the Chukchi Sea to take advantage of abundant prey (Hunt *et al.*, 2013).

The Pacific water signature extends into the Northeast Chukchi Sea but varies in spatial extent from year to year. During summer, a frontal zone separates Pacific waters extending northward from Bering Strait from Arctic waters that typically consist of a bottom water mass from the previous winter and meltwater at the surface (Weingartner, 1997). The position of the front varies among year, resulting in interannual variations in the distribution of zooplankton and their predators (Day *et al.*, 2013).

For our analyses, we divided the study region into the central Chukchi Sea (CCS) and northern Chukchi Sea (NCS) at 71°N (Fig. 1). This division was selected for oceanographic, biological and pragmatic reasons. First, 71°N is the approximate location of the frontal zone between Pacific and Arctic water masses (Day *et al.*, 2013), although it's location is highly variable. Second, a biogeographic boundary near 71 °N separates northern Chukchi shelf (Arctic) communities from communities with stronger Pacific affinities (Day *et al.*, 2013; Pinchuk and Eisner, 2017; Sigler *et al.*, 2017). Finally, a division at 71 °N result in an approximate even distribution of stations between the CCS and NCS to facilitate comparisons of biodiversity.

Data collection

Data from two cruises conducted in 2017 were used in these analyses. The AMBON cruise occupied 81 stations in the central and northeast Chukchi Sea between August 6 and August 22, 2017, along a series of 6 cross shelf transects and two along-shelf transects (Fig. 1). Bottom depths at the sampling stations ranged from 15 m to 57 m with an average of 42 m. While the original AMBON design had five cross-shelf transects including the DBO3 and DBO4 lines (Iken *et al.*, 2019), a sixth transect was added opportunistically in 2017 to cover the previously under-sampled region between Cape Lisburne and Point Lay. At each station, water column properties were profiled using a CTD (Seabird SBE911), water samples were collected at discrete depths for nutrient, chlorophyll *a* and eDNA analyses; zooplankton

were collected using 150 µm and 305 µm plankton nets; surface sediment samples were collected for assessing surface chlorophyll, grain size and benthic infauna, and a plumb-staff beam trawl was deployed to collect demersal fish and epibenthic invertebrates. In addition, seabirds and marine mammals were assessed using visual sampling methods along the ship's track during daylight hours.

For these initial analyses, we focus on the demersal fish community to illustrate the simulation approach. Although both demersal fish and epibenthic invertebrates are benthic ecosystem components and are caught with the same gear, we considered them separately for this analysis following Iken et al. (2019). Demersal fish are generally more motile and have a strong association with water mass characteristics (Hunt *et al.*, 2013), while epifaunal invertebrates are more closely related to substrate characteristics (Bluhm *et al.*, 2009). Therefore, demersal fish are expected to respond more directly to changes in ice cover, temperature conditions and advection associated with climate change. The modified plumb-staff beam trawl (Abookire and Rose, 2005) effectively samples small demersal fish that characterize the Chukchi Sea benthic community (Norcross *et al.*, 2013; Kotwicki *et al.*, 2017) and had a 2.26 m opening and a 7-mm mesh net with a 4-mm cod end liner. Trawls were conducted for 2–5 min duration at approximately 1.5 knots, resulting in area swept estimates ranging from 113 to 1138 m^2 with an average of 507 m^2. Catches were sorted on board to the lowest taxonomic level possible at the species or genus level. Pelagic juvenile fishes (mostly gadids) were excluded from the analysis because they were likely collected in the water column while the trawl was retrieved. Trawl distance for area swept calculations was estimated by multiplying average trawling speed by the time the trawl was in contact with the bottom. Bottom contact was assessed based on depth recordings by a time-depth recorder (TDR, Star Oddi, Gardabaer, Iceland) attached to the net opening. Numerical abundance for all taxa were quantified for each haul as catch per unit effort (CPUE), where effort was computed as trawl distance multiplied by the estimated width of the net opening (= area swept).

The Arctic Integrated Ecosystem Survey sampled a total of 58 stations throughout the US portion of the Chukchi Sea between August 10 and September 26 with identical sampling gear and a similar sampling protocol, but using a gridded survey design. Of these sampling stations, 45 stations overlapped with the AMBON survey area and were included in this analysis (Fig. 1). Bottom depths at these stations ranged from 20 m to 58 m, comparable to the AMBON survey stations (15-57 m). Area swept estimates for CPUE calculations ranged from 128 m^2 to 1079 m^2 with an average of 602 m^2. As for the AMBON survey, catches were sorted on board to the lowest taxonomic level possible at the species or genus level and pelagic juveniles were excluded from the analysis.

Measuring diversity

Ecologists generally agree that the preferred measure of diversity in ecological applications should be Hill numbers (Ellison, 2010). Most commonly, Hill numbers of orders q = 0, 1 and 2 are used, corresponding to simple species richness, Shannon diversity and Simpson diversity, respectively (Chao *et al.*, 2014). Simple species richness disregards relative abundances, thereby emphasizing each species equally and effectively highlighting rare species in an assemblage. Because the focus in this study is on the possible northward expansion of species into the study region, which at least initially may occur at a low frequency, we highlight estimates of species richness to avoid an over-emphasis on small species with high numerical abundances. However, borealization may involve both an expansion of rare species as well as an expansion or a local increase of highly abundant species (Stevenson and Lauth, 2019), thus we also present Hill numbers of order q > 0, which measure the "effective" number of species. Specifically, we present Shannon diversity (q = 1), which can be interpreted as the equivalent number of "common" species, and Simpson diversity (q = 2), which corresponds to the equivalent number of the dominant species, as it discounts rare or less abundant species (Chao *et al.*, 2014).

It is well known that any measure of diversity strongly depends on sampling effort, therefore we standardize diversity to the same number of sampling units (number of hauls) for comparisons among regions and among different sampling designs. Effort also varied among hauls due to differences in area

swept. However, we found no relationship (linear or non-linear) between measures of diversity recorded in each haul and area swept ($p > 0.4$), therefore biodiversity metrics for each haul were assumed to provide standardized estimates of local species richness at a spatial scale of approximately 500 m^2. The occurrence or incidence of species at this local scale are then used to estimate biodiversity and its uncertainty at regional scales corresponding to the CCS, NCS and the total survey region (Fig. 1). Input data for the analyses therefore consists of a species by station matrix of occurrences with values of 1 if a species was present at a given station 0 otherwise. As a metric for comparison, we used occurrence-based measures evaluated within the rarefaction and extrapolation framework proposed by Colwell et al. (2012) and Chao et al. (2014), which interpolates diversity measures for cases where sample sizes are less than the observed number of samples (rarefaction) and extrapolates measures for sample sizes larger than the observed number of samples. Because the number of samples, and hence the expected number of species detected, differed among the sampling designs considered (see next section), all comparisons were based on the expected number of species caught in 30 hauls, with one haul sampled per station. Estimates were obtained by interpolating (rarefying) diversity if more than 30 stations were sampled and extrapolating to 30 stations if fewer stations were sampled. The number of samples used to standardize metrics for comparison (n=30) was selected to ensure that the number of stations sampled over the entire survey region under any given sampling design was no smaller than ~50% of the number used for standardization (minimum of n=14 for DBO). For estimating species richness, extrapolation is reliable for up to two times the number of samples, while higher-order indices can be reliably extrapolated to infinity (Chao *et al.*, 2014).

To assess spatial patterns in diversity and possible relationships between local species diversity and environmental characteristics, we used a generalized additive modeling approach. Samples from both the 2017 AMBON and 2017 AIES surveys were pooled for this analysis. First, we modeled local diversity metrics, for example species richness by haul, as a smooth function of latitude and longitude using a tensor product interaction between latitude and longitude (Wood, 2017). Predicted diversity over the survey region was then mapped to visually assess spatial patterns in diversity. Second, we modeled local diversity as additive smooth functions of temperature, salinity and Julian day to identify potential drivers of diversity. The GAM analyses and predictions were conducted using the *mgcv* package version 1.8.33 (Wood, 2017) in the R statistical programming language, version 4.0.3 (R Core Team, 2020).

Finally, we compare diversity accumulation curves based on Hill numbers between 2015 and 2017 using a reduced set of taxa that were identified to the same taxonomic level in both years. For each year, the full set of stations sampled in each year was included, rather than a common set of stations sampled in both years, to compare diversity at a given sample size.

Simulation framework to compare sampling designs

To assess the power of different sampling designs to detect changes in species diversity, we developed a simulation framework based on the existing gridded and transect-based designs. Specifically, we compared the relative performance of a range of sampling designs from the full AIES and AMBON 2017 designs to a minimal design based on the two DBO transects off Point Hope (DBO 3) and off Wainwright (DBO 4) (Fig. 2, Table 1). Alternative designs were based on the full gridded and transect-based designs and either reduced the number of transects without changing station density along transects or reduced the station density of the gridded design or along the 6 cross-shelf transects of the 'xShelf.6t' design (Table 1). We compared the performance of alternative sampling designs in two ways. Both approaches assume that the 2017 observed species occurrences provide a representative and unbiased estimate of the fish communities in the three regions considered. That is, they represent the "true" diversity against which reduced sampling designs or simulated changes in diversity are compared. To assess if the full survey designs provides an adequate assessment of diversity in the fish community, we constructed species accumulation curves separately for the two surveys and calculated asymptotic estimates for the three Hill numbers (the number of species or equivalent species that would be expected to be collected in a very large number of samples). In addition we assessed sample coverage, which is the fraction of the total

number of individuals in an assemblage that belong to species represented in the sample (Good, 1953; Good and Toulmin, 1956).

Our first approach to assessing the performance of different sampling designs simply asked: How does our perception of species richness and its uncertainty change under alternative sampling designs? Specifically, we were interested in comparing metrics between the two full designs (gridded vs transect-based), identifying potential biases of reduced designs relative to the full designs, and comparing uncertainty across designs. We estimated Hill numbers for each of the alternative designs, which were standardized to a sample size of 30 hauls using interpolation or extrapolation depending on the observed sample size, and constructed 95% confidence intervals for each estimate using a bootstrap approach (Chao *et al.*, 2014) as implemented in the iNEXT package version 2.0.20 (Hsieh *et al.*, 2016) in R version 4.0.3 (R Core Team, 2020).

The second approach assesses the performance of alternative sampling designs by quantifying their statistical power to detect simulated changes in species composition under selected scenarios. Our approach does not simulate "true" diversity but starts with species occurrences as estimated by the 2017 survey and assesses the performance of different designs by repeatedly simulating changes in species diversity from the 2017 baseline. Statistical power for a given sampling design was estimated by computing the fraction of simulations that correctly rejected the null hypothesis that diversity as quantified by Hill numbers were not significantly different from the 2017 baseline.

Scenarios for the simulations were developed under the assumption that ongoing and future reductions in sea ice, ocean warming, and advection are likely to result in the expansion of new or previously unsampled species (i.e. species not sampled in the 2017 surveys) into the northeast Chukchi Sea. Our analyses suggested that local diversity of the demersal fish community tends to decreases with bottom temperatures, therefore we simulated a temperature-dependent expansion of one or more Pacific-origin species into the northeast Chukchi Sea. Catches of these species were generated for each sampling design by randomly simulating their presence or absence based on station-specific probabilities of occurrence. The probability of a between one and five additional species being sampled in a given haul was scaled to the smoothed spatial pattern of the 2017 observed bottom temperatures, such that the probability of occurrence was highest at stations with the warmest temperatures and declined linearly with temperature to zero in areas with the coldest bottom temperatures (Fig. 3). For the base case, we assumed a mean probability of occurrence across the study region of 1%, implying that on average the species is "observed" at 1 in 100 stations. The assumed temperature dependent probabilities ranged from 0 at the coldest stations on the northern shelf to 2.25% at the warmest stations off Point Hope (Fig. 3). Simulations were repeated for different mean probabilities by multiplying the probabilities at each station by a value ranging from 1-10, hence the average probability of occurrence was 10% (maximum 22.5%) under the most extreme scenario. In addition, for each multiplier we simulated between one and five new species. The simulated occurrences of the new species were appended to the 2017 species-by-station matrix for computing changes in diversity relative to the 2017 baseline.

The power of different sampling designs to detect a resulting change in biodiversity due to the expansion of new species into the survey area was assessed for each combination of the number of new species and the multiplier for scaling the average probability of occurrence. We note that this is one possible and idealized scenario of change, and is unlikely to reflect true changes as the entire community composition is likely to change when environmental conditions change and as a result of increases in subarctic species. However, our goal was to compare the relative performance of different sampling designs in terms of their power to detect change rather than assessing absolute changes in diversity. As a sensitivity analyses we repeated the simulations using a latitudinal gradient in probability of occurrence, rather than a temperature-dependent gradient, as well as a constant probability of occurrence across the entire study area. For comparing sampling designs, we calculated the power to detect a change in diversity as the probability of concluding that a change of a given magnitude in each Hill number could be detected at a 95% or 99% confidence level. To simplify presentation of results, we show statistical power for different

scenarios (number of species, probability multiplier) by geographic region and by sampling design based on species richness (Hill number of order 0), temperature-dependent probabilities of occurrence, and a 95% significance level only. Results from other choices are discussed only if they may lead to different conclusions.

In addition to quantifying the power to detect changes in the probability of occurrence of relatively rare species, we assessed the power of alternative designs to detect changes in the individual abundances of two common species, Arctic cod and Arctic staghorn sculpin (Table 2). The same sampling designs were evaluated with respect to their power to detect differences in mean abundance across the entire study region or across either sub-region. We simulated changes in abundance ranging from a 50% decrease to a 50% increase in steps of 10% as follows: First, to estimate mean densities (fish per unit area) across the study region, we modeled the 2017 observed abundances using a generalized additive model with a negative binomial distribution to account for the large number of zeros and for apparent overdispersion in the data. Observed counts were used as the response variable and an offset was included to account for differences in effort (area swept) across hauls (base model). Changes in mean density under a given scenario (e.g. 10% increase) were then simulated by decreasing or increasing the overall mean density estimated by the base model and randomly drawing 'observed' counts at each station from the base model using the new mean and assuming that effort for each simulated haul was equal to the mean observed effort in 2017. This approach also assumes the same spatial pattern of distribution across simulations. Using the simulated data, mean densities by region (CCS and NCS) and overall were then estimated by fitting the same model to the simulated data, separately for each sampling design, i.e. only using the stations included in a given sampling design to fit the model. The estimated mean densities were then compared between each model that was fit to the simulated data and the mean density from the 2017 base model. The statistical power of each sampling design to detect changes in mean density was estimated over 1000 simulations by calculating the proportion of simulations that correctly rejected the null hypothesis of no change in mean density. All simulations were conducted in R version 4.0.3 (R Core Team, 2020).

Results

The demersal fish community in the Chukchi Sea had a relatively low number of taxa with 36 and 37 different taxa identified by the AMBON and AIES surveys, respectively, for a total of 43 unique fish taxa (Table 2) sampled across 125 stations (Fig. 1). Species diversity accumulated quickly with the higher-order Hill numbers approaching an asymptote at 40-60 stations sampled (Fig. 4), while species richness accumulated more slowly, especially at the scale of the entire study region. Due to spatial heterogeneity and a much higher species diversity in the CCS, this sub-region had a higher species richness for a given number of samples and accumulated species at a more rapid rate than when the number of samples was spread over a larger region (Fig. 4). The gridded AIES sampling design accumulated diversity more rapidly, particularly in the northern Chukchi Sea where the gridded stations encompass a somewhat broader geographic area, but the trade-off is a much broader confidence band around the point estimates for all three Hill numbers (Fig. 1).

Spatial patterns in species richness (Fig. 5), as well as the other diversity measures (not shown), show strong latitudinal and cross-shelf gradients in diversity. These gradients were significantly ($p < 0.001$) and positively related to temperature variability (Fig. 5); however, the smoothed spatial pattern and the temperature relationship explained only a small portion of the overall variability in species richness ($R^2 = 0.19$ and $R^2 = 0.12$, respectively). The spatial pattern primarily reflects higher species richness in warmer waters of Pacific origin, including both coastal waters that extend into the northeast Chukchi Sea and Bering shelf water.

Comparing sampling designs based on the 2017 data alone found no evidence of systematic biases as all but two of the 95% confidence intervals included the 2017 best estimates of diversity (Fig. 6). However, the trade-off between the number of stations sampled and uncertainty in diversity metrics is clearly

evident with the minimal DBO design resulting in a 95% confidence interval for the number of species expected to be caught in 30 hauls ranging from 28.4 to 44.6 species (mean = 36.5), corresponding to a coefficient of variation (CV) of 11.3%. While the DBO regions are known hotpots of high benthic productivity, the standard DBO stations do not observe fish at a higher rate than the survey overall or other reduced designs. In the northeast Chukchi Sea, the estimates of species richness and Shannon diversity expected in 30 hauls were lower than for any other design, but increased notably (and significantly, $p < 0.05$) in the 'DBO.plus' design, which extends the standard DBO line to include a larger cross-shelf gradient and estimated higher diversities than most other designs, although these differences were not significant ($p > 0.05$, Fig. 6). In the CCS, both the DBO and, in particular, the DBO.plus design estimated a higher diversity than other designs, suggesting that the DBO line is well placed to sample biodiversity in this region. We note, however, that estimating the number of species expected in 30 hauls involves considerable extrapolation beyond the number of observed stations (14 and 22 stations, respectively, Table 1), which accounts for the large uncertainty in the diversity estimates and poor performance in simulations.

The power of different sampling designs to detect changes in diversity resulting from simulated increases in up to 5 species was small under most scenarios and for most sampling designs (Fig. 7). Initial simulations were limited to increases in up to two species (approximately 5% of the observed number of species), but none of the sampling designs were able to detect a resulting change in diversity even at the highest level of probability of occurrence (mean probability = 10%, range 0-22.5%). Simulations were therefore extended to include increases in up to 5 species. The power of most sampling designs to detect changes within one of the sub-regions was less than 75% over the range of scenarios tested, with the exception of the full AMBON design (AMBON17) and the slightly reduced, 6-transect design (xShelf.6t). The opportunistic transect added to the orginal AMBON design in 2017, which was only included in these two designs, was critical to detecting changes in diversity within the CCS sub-region. The power to detect changes was generally highest when evaluating changes over the entire survey region, except for AMBON 15, which had a higher power to detect changes in the NCS under most scenarios due to the higher station density in the area. The full gridded survey was unable to detect changes within either of the sub-regions under any scenario, but performed similar to AMBON 15 when considering the entire survey area (Fig. 7).

Despite the poor power of most sampling designs to detect increases in diversity, comparison of the demersal fish communities between 2015 and 2017 showed substantially and significantly higher diversities over the survey region (Fig. 8) for all three diversity measures and for all sample sizes over 5. These differences were evident for diversity measures calculated over the entire area (Fig. 8) and for each sub-region (not shown).

Results from sensitivity analyses using a latitudinal gradient for the probability of occurrence of new species, or a uniform probability over the entire survey regions, showed very similar results and did not affect the relative rankings of different sampling designs in terms of their power to detect differences. The power to detect differences increased considerably when a lower (90%) or higher (99%) significance level was used for comparisons, but patterns across areas and sampling designs were identical. At a 99% significance level, only the full AMBON design detected changes under any scenario with a more than 75% probability.

Discussion and conclusions

The simulation framework presented here allows for an evaluation of sampling designs for the purposes of estimating changes in biodiversity of a community of interest. We focused on assessing the power to detect the expansion of new or previously rare species into an area using data from the Chukchi Sea and simulating changes from an observed baseline. This contrasts with approaches that use simulated data for the entire community based on an assumed species distribution model. An advantage of our approach is that it makes fewer assumptions about community structure and accounts for the observed spatial

heterogeneity in the region of interest in the comparisons. However, the approach requires more subjective choices about how species compositions may change. Here we assume that the addition of or increased probability of occurrence of rare species does not affect the relative species composition of the existing community, which may be the case initially but is clearly not realistic over longer time frames.

We found that a substantial change in the presence of rare species is required before recently employed sampling designs such as the transect-based AMBON design or the gridded AIES survey in the Chukchi Sea will detect the resulting changes in diversity based on Hill numbers. In contrast, most of the sampling designs had substantial power for detecting changes in abundance of common species, but not the resulting changes in diversity based on preliminary results. Thus, while the performance of such large-scale monitoring programs may be adequate for monitoring changes in relatively abundant species based on effort-adjusted catches, or in species composition based on multivariate analyses, they may not be very sensitive to changes in simple diversity measures such as species richness or other Hill numbers.

This study provides a general framework for evaluating alternative sampling designs in the context of monitoring biodiversity that can easily be adapted to other regions and communities. We are in the process of applying the framework to other communities sampled during AMBON, including zooplankton, benthic macrofauna, epibenthic invertebrates and seabirds. Relevant results and conclusions will be incorporated into this draft manuscript for comparing performance of sampling designs across multiple communities.

Table 1: Alternative survey designs considered for analyses and simulations, showing sample sizes (=number of hauls = number of stations sampled) by region and a rationale for including the design in the analysis.

Survey	Design	Stations			Rationale
		total	CCS	NCS	
AIES	fullGrid	45	17	28	gridded design for comparison with transect-based designs
	halfGrid	25	9	16	reduced gridded design to assess effects of sampling density
AMBON	AMBON17	81	41	40	extensive transect-based design including new transect in previously undersampled region
	AMBON15	69	29	40	original AMBON design to maximize overlap with previous sampling efforts (Iken et al. 2019)
	xShelf.6t	65	34	31	cross-shelf transect design that drops alongshore transects for improved sampling efficiency
	xShelf.4t	39	19	20	reduced effort cross-shelf transect design that maintains sampling density along transects
	DBO.plus	22	11	11	extended DBO design to better capture cross-shelf gradients from nearshore to offshore
	DBO	14	8	6	established DBO design
	xShelf67	44	24	20	reduced sampling density along fixed number of transects (~2/3 of 'xShelf.6t' stations)
	xShelf50	33	18	15	reduced sampling density along fixed number of transects (~1/2 of 'xShelf.6t' stations)
	xShelf33	24	13	11	reduced sampling density along fixed number of transects (~1/3 of 'xShelf.6t' stations)

Table 2: Species caught in the Chukchi Sea during the Arctic Integrated Ecosystem Survey (AIES) and the Arctic Marine Biodiversity Observing Network (AMBON) surveys in 2015 and the number of occurrences (number of stations at which a species was caught) for each species by survey.

Species caught in within overlapping region		Occurrences	
Scientific name	**Common name**	**AIES**	**AMBON**
Boreogadus saida	Arctic cod	40	70
Lumpenus fabricii	slender eelblenny	34	59
Gymnocanthus tricuspis	Arctic staghorn sculpin	32	52
Aspidophoroides olrikii	veteran poacher	21	51
Myoxocephalus scorpius	shorthorn sculpin	27	44
Liparis sp.	Liparis	23	46
Anisarchus medius	stout eelblenny	24	45
Artediellus scaber	hamecon	14	42
Hippoglossoides robustus	Bering flounder	20	36
Lycodes polaris	Canadian eelpout	14	33
Icelus spatula	spatulate sculpin	8	19
Podothecus sp.	poacher	3	23
Eleginus gracilis	saffron cod	10	14
Gymnelus hemifasciatus	halfbarred pout	11	13
Stichaeus punctatus	Arctic shanny	7	17
Triglops pingelii	ribbed sculpin	5	19
Leptoclinus maculatus	daubed shanny	10	13
Gymnelus viridis	fish doctor		16
Limanda aspera	yellowfin sole	3	11
Lycodes raridens	marbled eelpout	12	
Trichocottus brashnikovi	bullhorn sculpin	1	10
Gadus chalcogrammus	walleye pollock	9	1
Lycodes palearis	wattled eelpout	8	2
Ammodytes hexapterus	Arctic sandlance	4	5
Nautichthys pribilovius	eyeshade sculpin	9	
Aspidophoroides monopterygius	Alligatorfish	3	5
Eumesogrammus praecisus	fourline snakeblenny	2	6
Gadus macrocephalus	Pacific cod	7	
Lycodes mucosus	saddled eelpout	2	5
Limanda proboscidea	longhead dab	4	2
Chirolophis snyderi	bearded warbonnet	1	3
Hexagrammos stelleri	whitespotted greenling	2	2
Hypsagonus quadricornis	fourhorn poacher	2	2
Melletes papilio	butterfly sculpin		4
Myoxocephalus polyacanthocephalus	great sculpin	4	
Lycodes turneri	polar eelpout	3	
Myoxocephalus jaok	plain sculpin		3
Gymnocanthus pistilliger	threaded sculpin	2	

Limanda sakhalinensis	Sakhalin sole	1	1
Acantholumpenus mackayi	pighead prickleback		1
Enophrys diceraus			1
Enophrys lucasi	leister sculpin	1	
Pallasina barbata	tubenose poacher		1

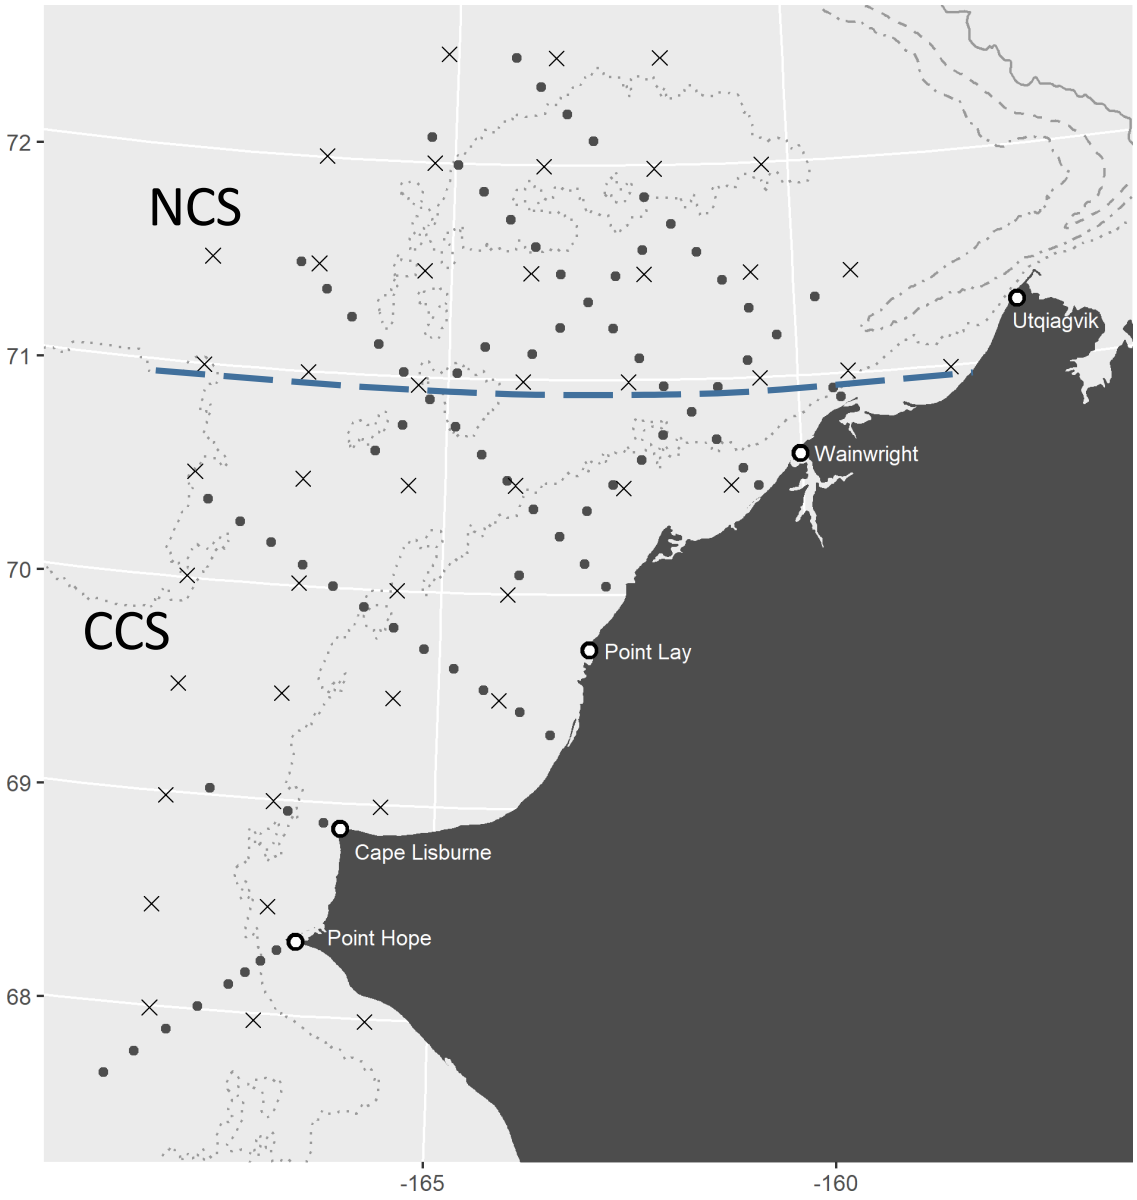

Figure 1: Stations sampled during the Arctic Marine Biodiversity Observing Network (AMBON) survey (filled circles along transects) and during the gridded Arctic Integrated Ecosystem Survey (AIES) in 2017. Heavy dashed line at 69.9 °N divides the central Chukchi Sea (CCS) and northern Chukchi Sea (NCS) subregions.

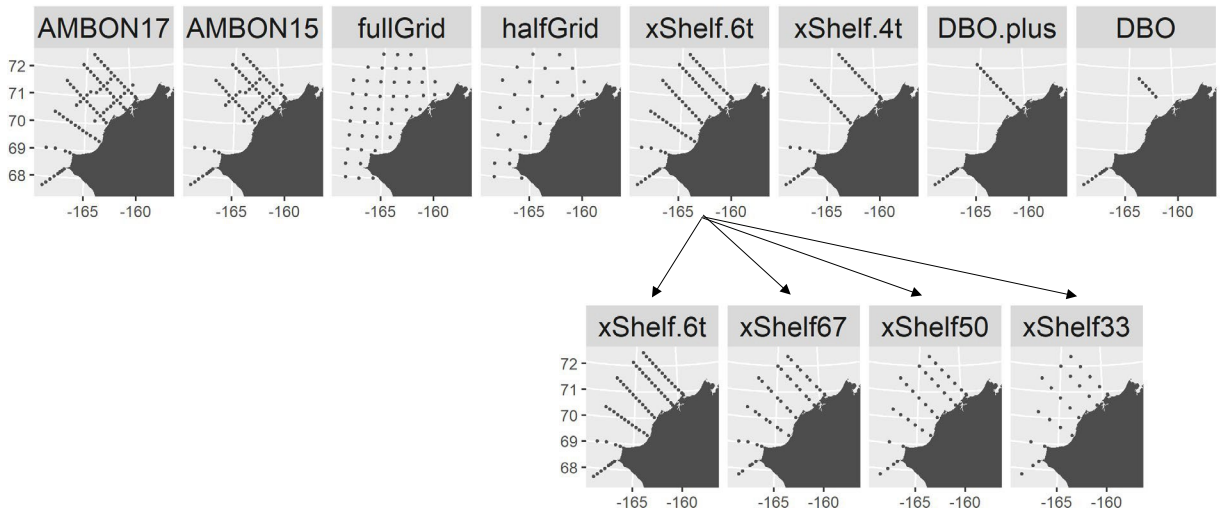

Figure 2: Alternative sampling designs considered in the analysis of their relative performance for quantifying and detecting changes in biodiversity of demersal fishes.

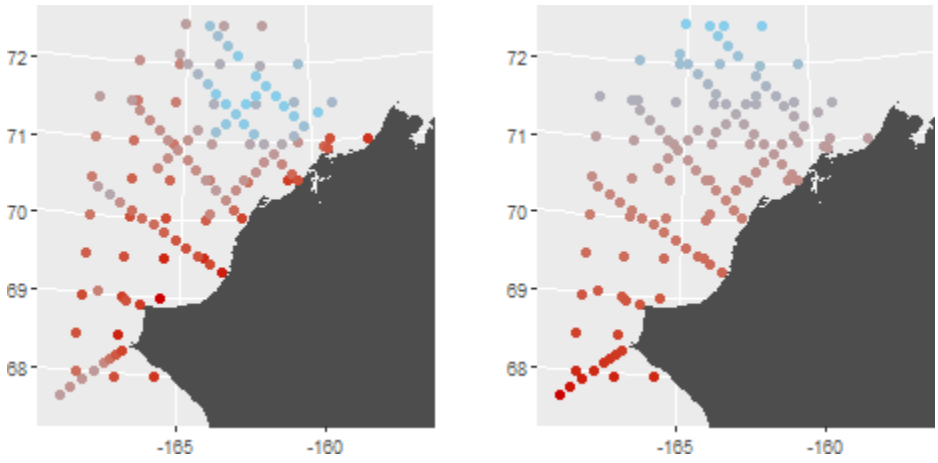

Figure 3: Temperature-dependent (left) and latitudinal gradients (right) in assumed probability of occurrence for simulating expansion of species into the northeast Chukchi Sea. Probabilities range from zero (blue) in the north to a maximum (red) in the south, scaled such that the mean across stations has a specified value.

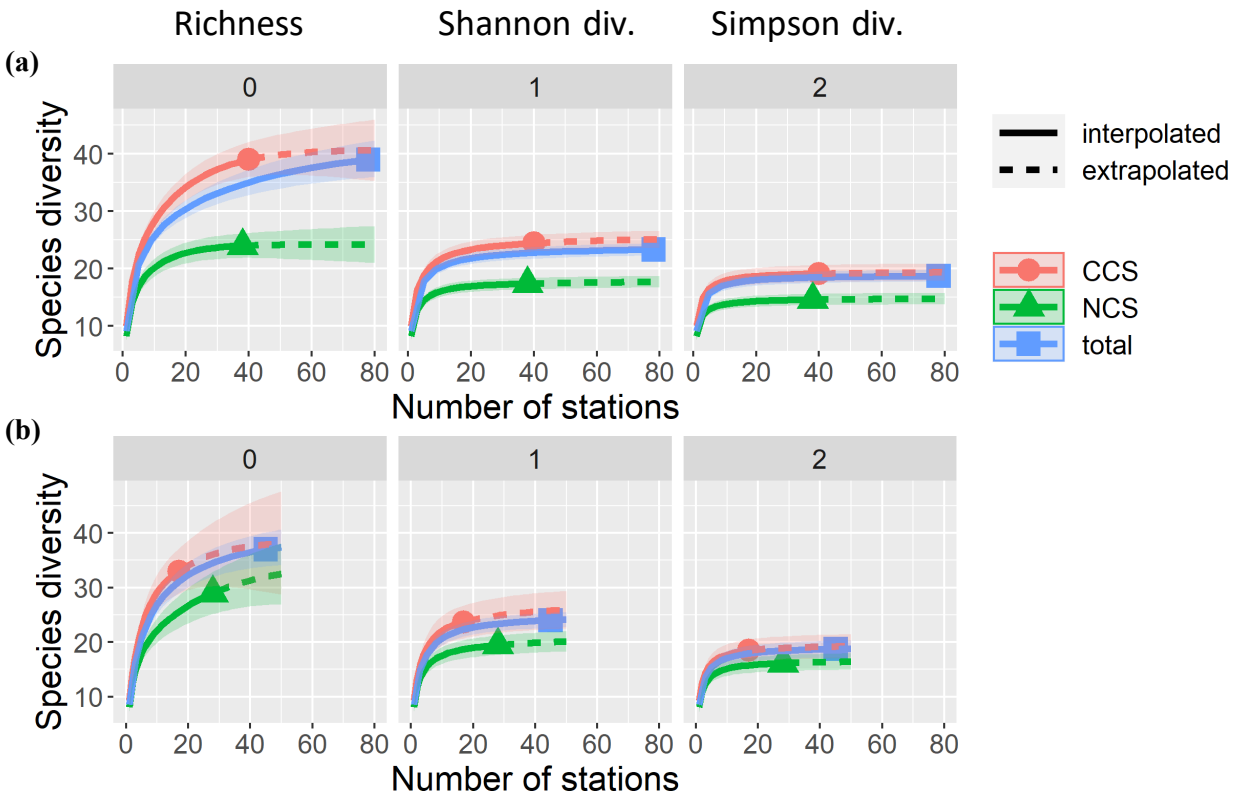

Figure 4: Diversity accumulation curves for three Hill numbers: species richness (q=0, left panels), Simpson diversity (q=1) and Shannon diversity (q=2) by geographic region (CCS = Central Chukchi Sea, NCS = Northern Chukchi Sea, total = total survey region). Diversity was estimated separately based on the 2017 AMBON survey (a) and based on the 2017 Arctic Integrated Ecosystem Survey (b). Symbols indicate estimated diversity for the observed number of stations; diversity is interpolated using a bootstrap approach for smaller sample sizes (solid lines) and extrapolated for larger sample sizes (dashed lines).

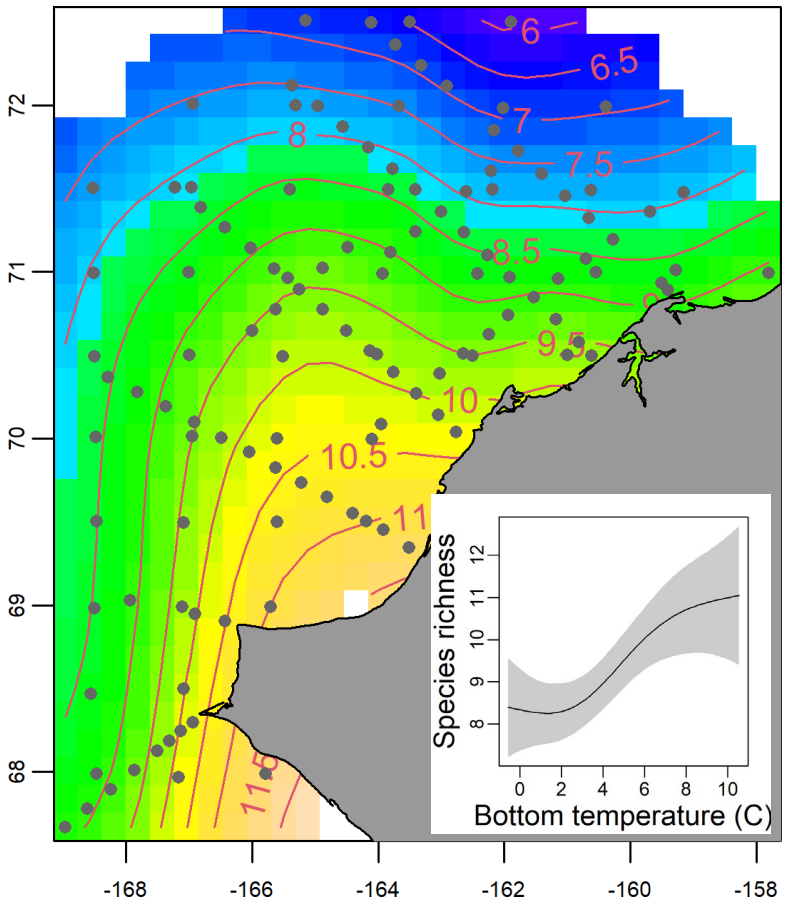

Figure 5: Spatial patterns of species richness estimated by fitting a smoothed surface to observed number of species by station using a tensor-product smoother. Inset shows estimated relationship between species richness and bottom temperature.

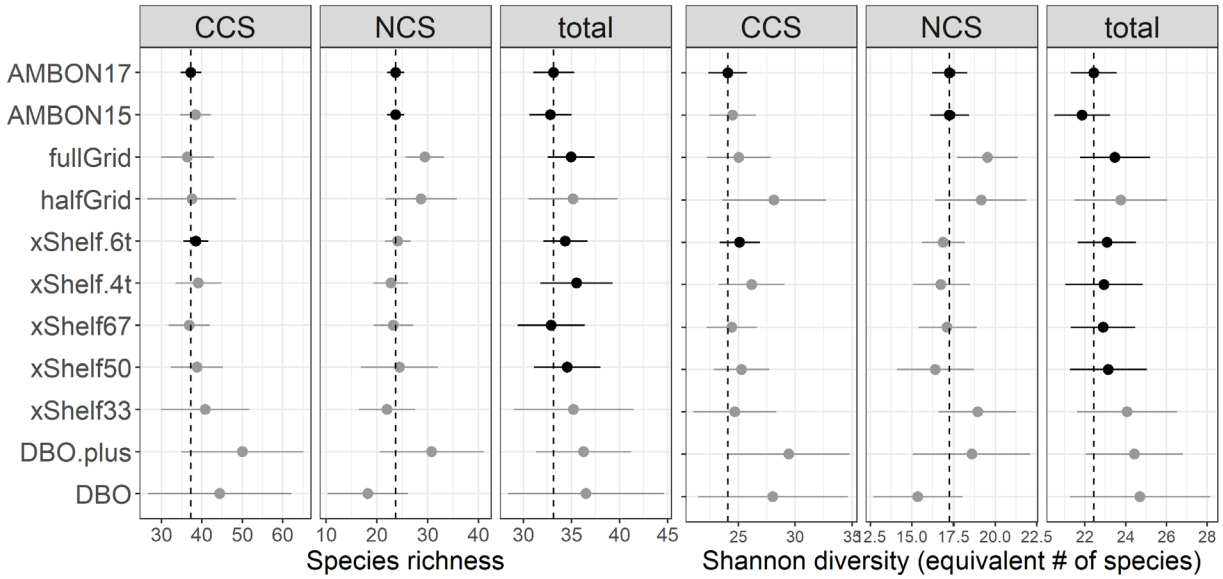

Figure 6: Comparison of species richness and Shannon diversity with 95% confidence intervals estimated from different sampling designs and standardized to the (equivalent) number of species expected to be caught in 30 hauls. Sample designs are based on subsets of the two full surveys ('AMBON17' and 'fullGrid') as shown in Fig. 2 and described in Table 1. Black dots denote interpolated estimates, while grey indicates extrapolation (< 30 stations sampled). Vertical bars show best estimates of diversity from the full AMBON 2017 survey (N = 81 stations).

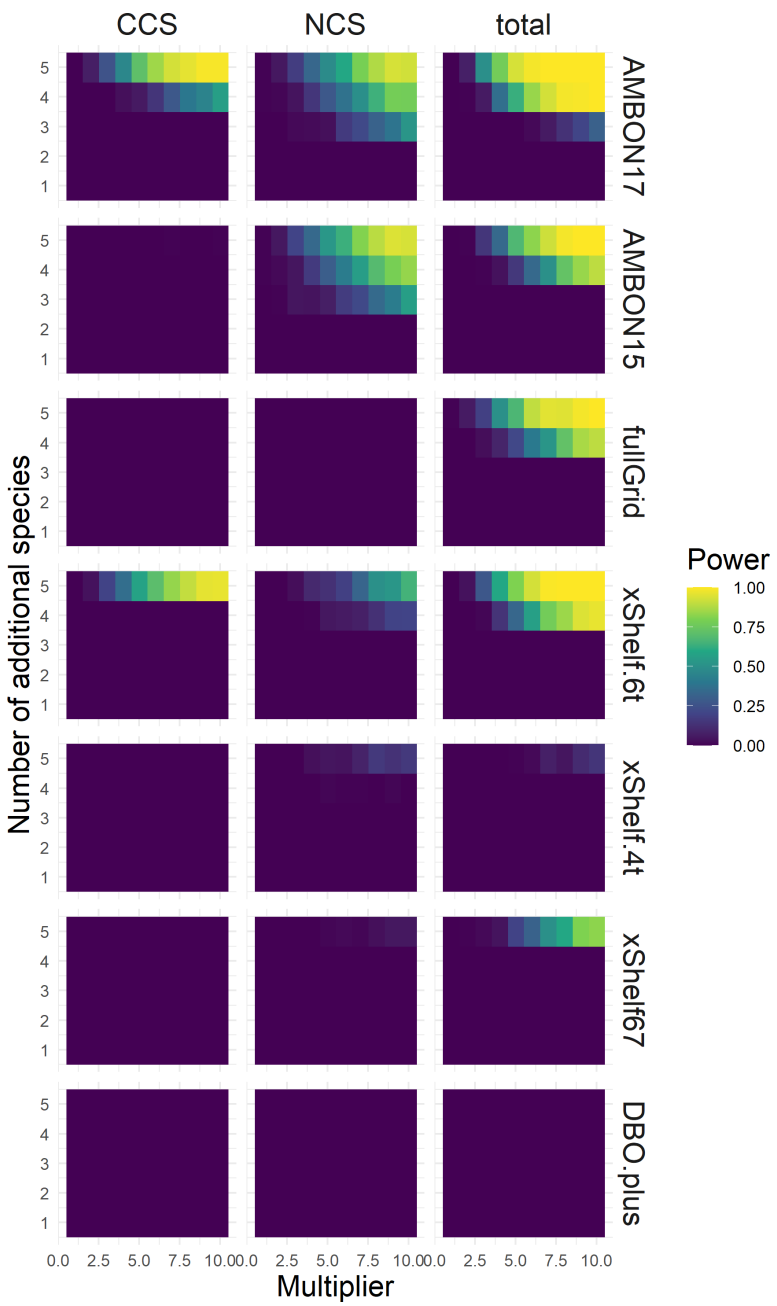

Figure 7: Estimated statistical power of different sampling designs for detecting a simulated increase in diversity due to temperature-dependent increases in the probability of occurrence of new or rare species within the survey area. Except for 'DBO.plus', designs whose power was less than 25% for all scenarios are not shown.

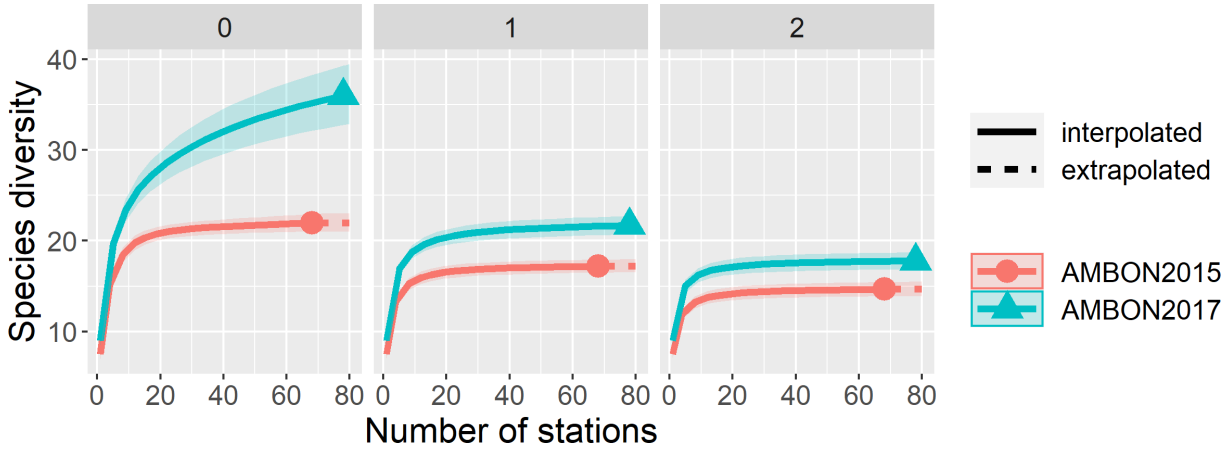

Figure 8: Diversity accumulation curves for three Hill numbers: species richness (q=0, left panels), Simpson diversity (q=1) and Shannon diversity (q=2) by year for 2015 and 2017 AMBON surveys. Diversity was estimated based on the full set of stations sampled in each year. Symbols indicate estimated diversity for the observed number of stations; diversity is interpolated using a bootstrap approach for smaller sample sizes (solid lines) and extrapolated for larger sample sizes (dashed lines).

CHAPTER 11 - Annual and spatial variation in the condition and lipid biomarkers of four juvenile gadid species from the Chukchi Sea during a recent period of dramatic warming (2012 to 2019).

Objective 3: Combine results from previous Arctic surveys (Arctic EIS, Phase 1, BASIS) and planned surveys (Arctic IES Phase 2) to assess variability in pelagic and demersal fish ecology over time relative to ocean conditions.

Louise Copeman, Carlissa Salant, Michelle Stowell, Mara Spencer, et al. (in preparation)

Abstract

The Arctic is undergoing dramatic environmental change with decreasing sea ice extent and increasing summer temperatures. The late summers of 2017 and 2019 on the Chukchi Sea were anomalously warm, nearly 4°C warmer than the previous 30-year average. Increased ocean temperatures are affecting North Pacific fish both via direct thermal effects on their physiology as well as through indirect changes to their diet quality. Here we describe the total lipids as well as fatty acid trophic markers in two Arctic juvenile gadids (polar cod, *Boreogadus saida* and saffron cod, *Eleginus gracilis*) as well as two invading boreal gadids (walleye pollock, *Gadus chalcogrammus* and Pacific cod, *Gadus macrocephalus*) collected on recent ecosystem surveys of the north Bering and Chukchi Seas. Allometric relationships between length and lipid storage revealed a unique high-lipid strategy in polar cod when compared to other Chukchi Sea congeners. Further, during 2017 both polar cod and saffron cod showed region-specific decreases in lipid storage compared to fish from 2013 and 2012, respectively. This reduction in total lipid, triacylglycerols, diatom- (16:1n-7/16:0) and *Calanus*-sourced fatty acids ($\sum C_{20}+C_{22}$) was particularly significant in polar cod collected over the Central Chukchi shelf in 2017. Age-0 juvenile gadids showed interspecific differences in the spatial distribution of high condition individuals, with polar cod having the highest lipid-based condition in the northern ice-associated regions of the Chukchi Sea. In 2019, polar cod were only abundant in the northern Chukchi Sea where they maintained higher region-specific lipid storage than in 2017. These data will be discussed in relation to the importance of lipids to overwintering survival in the Arctic. Data from laboratory experiments combined with evidence of declining lipid storage during warming events, may indicate that the southern and central Chukchi Sea are warming beyond the thermal limits of polar cod. If lower-fat fish such as walleye pollock or Pacific cod displace polar cod, Arctic predators will need to consume more fish to meet their energy requirements.

Introduction

There are four ecologically important species of gadids in Alaskan waters. These traditionally included the 'boreal gadids', walleye pollock (*Gadus chalcogrammus*) and Pacific cod (*Gadus macrocephalus*) in the Bering Sea and Gulf of Alaska and the 'Arctic gadids' saffron cod (*Eleginus gracilis*) and polar cod (*Boreogadus saida)* in the Chukchi and Beaufort Seas. Adult gadids occupy a range of habitats with polar cod and walleye pollock generally using pelagic and offshore habitats while saffron cod and Pacific cod are generally more demersal and often reside in both the nearshore and offshore regions, respectively (Laurel et al. 2007, Hurst et al. 2015, Logerwell et al. 2015). Conversely, pelagic habitats are important during the early life history stages of all four gadids where these cod species facilitate energetic transfer between zooplankton and upper trophic levels (Frost & Lowry 1981, Craig et al. 1982, Springer et al. 1996). Recent extreme warming and increased current flows from Bering Straits has resulted in the co-occurrence of all four juvenile gadids in pelagic waters of the South Eastern Chukchi Sea (SECS, Wildes et al., this report) with movement of boreal congeners as far north as the North Eastern Chukchi Sea (NECS) (Cooper et al., this report, Levine et al., this report).

In the last ten years, unprecedented warming of the Chukchi Sea (Danielson et al. 2020, Huntington et al.

2020) and record low sea ice in the Bering Sea (Stabeno & Bell 2019) have been noted. Concurrent with these oceanographic changes, Kimmel & Spear (Lower AIERP report) have measured a reduction in *Calanus glacialis* abundance throughout the Chukchi Sea with small copepods (i.e. *Pseudocalanus* spp.) increasing, particularly in the warm waters of the north Bering and SECS. In the most recent survey years (2017 & 2019), *C. glacialis* was an order of magnitude lower than in the previous decade (Kimmel & Spear). Small-bodied pelagic fish species are already well-recognized as being important biological indicators of climate-driven changes by way of direct temperature-dependent effects on their growth (Peck et al. 2013, Laurel et al. 2016) and lipid storage (Copeman et al. 2017). The direct effects of temperature on early survival and growth of gadids are now known to be dependent on ontogeny and also be species-specific ((Laurel et al. 2016, Laurel et al. 2017, Laurel et al. 2018)). However, the indirect effects of climate change on juvenile gadid survival and growth, such as through variable food quantity (Hurst et al. 2017, Koenker et al. 2018b) and quality (Copeman & Laurel 2010, Jonsson et al. 2013) are less well understood.

Previous studies in Alaska have shown that species-specific and ontogenetic differences in energy allocation should be considered when quantifying fish condition in cohorts of variable size individuals (Heintz et al. 2013, Martin et al. 2017, Copeman et al. 2020). This information will be vitally important in the Alaskan Arctic as temperatures continue to rise faster than in more southern regions (Renaud et al. 2015, Timmermans et al. 2017, Huntington et al. 2020). For many specialized Arctic species, temperatures throughout the SECS and CECS are already above or approaching their thermal limits (Pörtner & Farrell 2008, Laurel et al. 2017, Koenker et al. 2018a) with many species now projected to lose or gain habitat in future decades, depending on their thermal preferences (Frainer et al. 2017, Dahlke et al. 2018, Steiner et al. 2019) Logerwell et al. this report).

Measurement of lipids and fatty acids in juvenile fish provide temporally-integrated (weeks) information on both trophic relationships and energetic status (St John & Lund 1996, Copeman et al. 2008, Budge et al. 2012, Copeman et al. 2013). Trophic biomarkers such as fatty acids (FA) are produced at low trophic levels and are moved through the food web in a somewhat conservative manner, thus providing information about dietary origins when analyzed in consumers (Budge & Parrish 1998, Dalsgaard et al. 2003, Budge et al. 2006). Two specific fatty acid trophic markers are important in polar and upwelling food webs: diatom indicator fatty acids (16:1n-7/16:0) and long chain monounsaturated fatty acids (MUFA) indicative of calanoid copepod wax storage ($\sum C_{20+C22}$ MUFA) (Viso & Marty 1993, Lee et al. 2006, Kattner et al. 2007, Galloway & Winder 2015). Previous studies on polar cod and saffron cod have used these fatty acid trophic markers to show the degree of reliance on a diatom-*Calanus* sp. based food webs (Budge et al. 2008, Graham et al. 2014, Copeman et al. 2016, Kohlbach et al. 2017, Brewster et al. 2018, Dissen et al. 2018).

The goal of our study was to characterize size-dependent lipid allocation in four gadid species from the Alaskan Arctic in order to better understand spatial differences in fish condition as well as tissue lipids. Our approach was to 1) describe the species-specific relationships between length-weight and length-lipid storage using data from four survey years, 2) understand annual variation in gadid energetics by comparing region- and species-specific morphometric and lipid-based condition metrics, 3) use fatty acid trophic markers for diatoms (16:1n-7/16:0) and *Calanus*-sourced fatty acids ($\sum C_{20}+C_{22}$ MUFA) to explore interspecific and annual differences in fish food webs, 4) use lipid 'condition metrics' to explore annual and spatial variation in 'hot spots' for polar cod and walleye pollock across the Chukchi Sea, and 5) to discuss variable patterns in lipid storage in relation to overwintering survival on the Chukchi Sea shelf.

Methods

Field fish sampling and tissue collections

Juvenile gadids for this study were collected using a variety of gear types with methods with annual cruises, sample numbers, and gear types as shown in Table 1 and Figure 1 (Gunderson & Ellis 1986), De Robertis et al. (2016), (Marsh et al. 2017, Logerwell et al. 2018)). Collection methods, fish handling

techniques, and oceanographic temperatures for earlier years of saffron cod and polar cod sampling have previously been detailed as in Copeman et al. (2016) and (Copeman et al. 2020). Details on water column temperatures for 2017 and 2019 are detailed in Danielson et al. (AIERP final report).

Juvenile gadids from 2017 and 2019 surveys were sorted from the catch and were immediately placed on ice and frozen at < -20 °C within 6 hours of capture. Samples were stored at -80 °C in Juneau, AFSC-NOAA laboratories following the surveys and were later sorted and shipped frozen overnight from Alaska to the Marine Lipid Ecology Laboratory at the Hatfield Marine Science Center (HMSC) in Newport, OR, USA.

Samples from the 2019 survey were delayed in Juneau, AK and were not received in Newport until after the time that Covid 19 had closed our Newport, NOAA laboratories (February 2020). This delay was due to sampling of all juvenile gadids for species determination using genetic methods (Wildes et al., this report). All of our chemical analyses are based on fume hood work in laboratories so this significantly delayed our project and has made the Arctic IERP deadlines extremely difficult to manage. Newport laboratories have remained in phase "0", with only brief periods of phase "1" opening since our original closure in winter of 2020.

At the time of tissue sampling, standard length (SL, ± 0.1 mm) and wet weight (WWT, ± 0.0001 g) were recorded. During dissections, fish were washed with filtered seawater, blotted dry, stomachs and intestinal tracts were removed and heads were frozen for later annual incremental otolith analysis. All the remaining fish tissues, containing both muscle and liver, were re-weighed, placed in chloroform under nitrogen and frozen at -20 °C until lipid extraction, within 2 months of sampling.

Lipid extraction and analysis

All lipid analyses on field and laboratory collected fish were conducted at the Marine Lipids Ecology Laboratory at the HMSC in Newport, OR, USA. Tissues were homogenized in chloroform and methanol and total lipids were extracted according to Parrish (1987) using a modified Folch procedure (Folch et al. 1956).

Total lipids and lipid classes were determined using thin layer chromatography with flame ionization detection (TLC/FID) with a MARK V Iatroscan (Iatron Labratories, Tokyo, Japan) as described by Lu et al. (2008), Copeman et al. (2016) and Copeman et al. (2017). Extracts were spotted on duplicate silica-gel-coated Chromarods, and a three-stage development system was used to separate wax esters, triacylglycerols, free fatty acids, sterols and polar lipids. Polar lipid is mostly comprised of phospholipids with minor amounts of other acetone mobile polar lipids. The first rod development was in a chloroform: methanol: water solution (5:4:1 by volume) until the leading edge of the solvent phase reached 1 cm above the spotting origin. The rods were then developed in hexane: diethyl ether: formic acid solution (99:1:0.05) for 48 min, and finally rods were developed in a hexane: diethyl ether: formic acid solution (80:20:0.1) for 38 min. After each solvent development, rods were dried (5 min) and conditioned (5 min) in a constant humidity chamber (~32%) that was saturated with aqueous $CaCl_2$. Following the last development, rods were scanned using Peak Simple software (ver. 3.67, SRI Inc.) and the signal detected in millivolts was quantified with calibration curves using the following standards from Sigma (St Louis, MO, USA): palmitic acid (free fatty acids), cholesterol (sterols), L-alpha-phosphatidylcholine (polar lipids). Specialized standards were purified by column chromatography to use for triacylglycerols (from *Boreogadus saida* liver) following methods from Ohman (1997). Calibrated relationships between lipid class areas and standard lipid amounts (μg) had correlations with an r^2 >0.98 for all classes.

Following total lipid and lipid class analyses of fish tissues, samples were processed for fatty acid analyses. An internal standard (23:0 methyl ester) was added at approximately 10% of the total fatty acids

to all samples and total lipid extracts were derivatized into their fatty acid methyl esters (FAMEs) using sulphuric acid-catalyzed transesterification (Budge et al. 2006). Resulting FAMEs were analyzed on an HP 7890 GC FID equipped with an autosampler and a DB wax+ GC column (Agilent Technologies, Inc., U.S.A.). The column was 30 m in length, with an internal diameter of 0.25 mm and film thickness of 0.25 µm. The column temperature began at 65 °C and held this temperature for 0.5 min. Temperature was increased to 195 °C (40 °C min^{-1}), held for 15 min then increased again (2 °C min^{-1}) to a final temperature of 220 °C. Final temperature was held for 1 min. The carrier gas was hydrogen, flowing at a rate of 2 ml min^{-1}. Injector temperature was set at 250 °C and the detector temperature was constant at 250 °C. Peaks were identified using retention times based upon standards purchased from Supelco (37 component FAME, BAME, PUFA 1, PUFA 3) and in consultation with retention index maps performed under similar chromatographic conditions as our GC-FID (Wasta & Mjøs 2013). Column function was checked by comparing chromatographic peak areas to empirical response areas using a quantitative FA mixed standard, GLC 487 (NuCheck Prep). Chromatograms were integrated using Chem Station (version A.01.02, Agilent).

Data analysis of fish lipids

For each of the four juvenile gadid species, we examined length-weight and length-fatty acid (total fatty acids per animal, mg) relationships using a power function ($Y = a * X^b$) with an approximate value of *b* equal to 3 indicating isometric growth (Sigma plot 14.0).

Due to unequal spatial and temporal sampling and significant interactive effects of region and year on fish condition, we explored annual variability in fish condition separately for each species in a given region (one-way ANOVA). We divided the survey area into Southern (SECS), Central (CECS) and Northern (NECS) Chukchi Sea, areas of approximately equal latitudinal range as described in Buckley and Whitehouse (2017) (Fig. 1). We calculated one morphometric condition measurement, Fulton's condition index ($K = 100 * ((WWT, g) / (SL, cm)^3)$) and used multiple lipid-based condition indices: total lipid concentration per WWT ($mg.g^{-1}$), total fatty acid per WWT ($mg.g^{-1}$), % triacylglycerols (TAG), and finally the calanoid-specific fatty acid markers ($\sum C_{20} + C_{22}$) per WWT ($mg.g^{-1}$), an indicator of large lipid-rich copepods in juvenile fish diets.

Statistical differences among the fatty acid parameters of juvenile gadids were compared using individual FAs present at >1% in all samples as well as the percentage of bacterial FAs (∑odd and branched chains) and *Calanus* FAs ($\sum C_{20}+C_{22}$MUFA) using PRIMER v.7 (Primer-E) with a Permutational ANOVA, PERMANOVA add-on package. We were not able to perform tissue-specific fatty acid analyses, however, the inclusion of fatty acid concentration per WWT allowed us to determine FAs that were proportionally associated with higher total fatty acids in juvenile fish. Data (% total FA) was square-root transformed prior to analyses and were then used to calculate a triangular matrix of similarities (Bray-Curtis similarity) between each pair of samples. Non-metric multidimensional scaling (*n*MDS), an iterative process that uses ranks of similarities, was utilized to explore the effect of species and year of sampling on the FA composition of juvenile gadids ($p<0.05$).

To visually show region-specific differences in polar cod lipid composition from 2013, 2017 and 2019 we used bootstrap averages (60 per grouping, Primer v. 7) with 95% confidence intervals in metric multidimensional space. Distances between centroids of polar cod groups as a function of region and year of sampling were calculated in PCO space based on Bray-Curtis similarity matrix.

Empirical Bayesian kriging (Krivoruchko & Gribov 2019) was used to visualize spatial patterns in surface temperatures and lipid parameters by interpolating data from survey sample stations (ArcGIS Desktop 10.7). For symbology, interpolated data values were stretched along a color ramp using the standard deviations stretch type.

Results

Species-specific length-weight and length-lipid storage

The exponential regression coefficient *b*, for the relationship between length (mm) and WWT per fish (g) for all four species of juvenile gadids ranged between 2.85 and 3.22 (Fig. 2, 20-85 mm), indicating isometric growth. Analyses of log transformed length-weight relationships indicated that both length ($p<0.001$) and species (ANCOVA, species $F_{3,710}=49.62$, $p<0.001$) had a significant effect on the WWT of juvenile gadids. For a given length, Pacific cod and saffron cod were significantly heavier than walleye pollock and polar cod had the lowest weight-at-length for all gadid species (untransformed data, Fig. 2a & 2b, $p<0.05$).

The exponential coefficient *b* for the relationship between length (mm) and total fatty acids per fish (mg) ranged from a high of 3.85 in polar cod to a low of 2.19 in juvenile saffron cod, indicating allometric and alternative species-specific lipid allocation (Fig. 2c & 2d). Analyses of log transformed length-fatty acid data indicated that both length ($p<0.001$) and species (ANCOVA, species $F_{3,710}=53$, $p<0.001$) had a significant effect on the fatty acid storage (mg) in juvenile gadids. For a given length, polar cod had significantly higher fatty acid storage, followed by walleye pollock, Pacific cod and saffron cod had the lowest lipid storage of all gadids (untransformed data, Fig. 2d, $p<0.05$).

Region- and species-specific annual differences in condition

Due to variable catches, we were not able to analyzed all species across all regions and years for morphometric and lipid-based condition. Pacific cod, were only captured in 2017 and are discussed in detail in Cooper et al. (this report). Therefore, we have focused on annual differences within broad geographical regions for combinations where we obtained adequate samples.

Relative to lipid-based condition metrics, Fulton's K morphometric condition factor was fairly insensitive to annual changes in juvenile gadid condition (Fig. 3, 4 & 5). In the CECS we noted a significant decrease in all lipid-based condition factors from the earlier collections during a cold year (2013) to fish collected in 2017 (i.e. ANOVA %TAG $F_{1,63}=51.5$, $p<0.001$, Fig 3a). Further, a significant decline in calanoid copepod fatty acids was found in 2017, indicating that polar cod were storing less energy from large lipid-rich copepods than measured in 2013 (ANOVA $F_{1,75}=33.6$, $p<0.001$, Fig 3a).

In 2019, the distribution of polar cod retracted northward and fish were only available across all 3 survey years in the NECS. Comparison of the condition for polar cod in the NECS between 2013 and two contemporary warm years (2017 and 2019) showed that polar cod were generally in low lipid-based condition in 2017. During 2017, polar cod were abundant and caught throughout the whole latitudinal range of the Chukchi Sea (Levine et al. this report) but our data shows they were in poor lipid-based condition throughout much of the survey area. Lipid metrics for polar cod in 2019 were similar to those measured in an earlier cold year (2013), while fish were generally heavier at a given length in 2017 than in the other two years (ANOVA, $F_{2,195}=19.28$, $p<0.001$, Fig 3b). This could indicate that fish sampled in the late summer of 2017 were prioritizing growth over lipid storage (Fig 3b). Further, levels of calanoid copepod lipids in fish from the NECS were similar in 2013 and 2019 but were significantly lower in 2017 (ANOVA, $F_{2,200}=4.06$, $p<0.019$).

We were able to make annual comparisons of saffron cod condition between 2012 and 2017 in the SECS and the CECS, but relatively low abundances of this species in contemporary survey years (2017, 2019, Levine et al, this report) precluded other annual and spatial comparisons. We found significant region-specific declines in most lipid-based condition factors in saffron cod from both regions from 2012 to 2017 (Fig. 4). In the SECS, total lipids per WWT dropped more than 50% from 2012 (24.2 ± 2.3 mg.g^{-1}) to 2017 (9.6 ± 0.26 mg.g^{-1}, Fig 4a). This pattern was similar for the proportion of storage lipids, %TAG, as well as storage of total calanoid fatty acids (Fig. 4a). Trends of decreasing lipid-based condition metrics

in 2017 were also significant for saffron cod in the CECS but were less extreme than in the SECS (Fig 4b). We measured no change in Fulton's K morphometric condition for saffron cod in either region between years (i.e. CECS, ANOVA, $F_{1,63}=0.01$, $p=0.91$), despite dramatically declines in lipid-based condition (i.e. CECS, total lipid ANOVA, $F_{1,64}=16.39$, $p<0.001$).

Pollock from the SECS and CECS were analyzed in both contemporary warm years (2017 & 2019). In the SECS, pollock showed significantly higher Fulton's K in 2017 compared to 2019, while lipid-based condition metrics indicated an opposite trend with fish in 2019 having significantly higher total fatty acids per WWT and calanoid copepod storage lipids (Fig. 5a). In the CECS walleye pollock were in better lipid-based condition in 2019 for all lipid metrics, however, there was not significant difference in Fulton's K during the two contemporary sampling years (Fig 5b). In 2019, walleye pollock were also sampled in the NECS due to their range expansion further north (Wildes et al. and Levine et al. this report). However, our results indicate that pollock in the NECS were in poor morphometric and lipid-based condition compared to pollock in more southern areas of the Chukchi Sea (Fig 5b).

Species-specific differences in lipid composition

Across years and regions, polar cod had a unique lipid storage strategy compared to other Chukchi Sea gadids (Table 2, Fig. 2). Polar cod had twice the lipid concentration (total lipids per WWT, 20-35 $\mu g.mg^{-1}$) in their tissues compared to other juvenile gadids (Table 2). Elevated lipids in polar cod were typified by increased proportions of triacylglycerols (TAG, 27-57%) and very high monounsaturated fatty acids (MUFA, 38-50%, Table 2) relative to other species. MUFA in polar cod were likely accumulated from specialized predation on calanoid copepods, which in turn have high levels of the C_{20}+C_{22} MUFA originating from their unique seasonal wax ester storage. Polar cod had more than 5X the fatty acids per WWT originating from calanoid copepods (4 to 6.5 $mg.g^{-1}$) compared to all other gadid species (0.2 to 1.2 $mg.g^{-1}$, Table 2). The diatom indicator ratio (16:1n-7/16:0) was also elevated in polar cod tissues compared to other gadids. This gives further support to the theory that polar cod nutrition is highly dependent on specialized feeding in cold nutrient-rich waters that support diatom-*Calanus* based food webs. Both saffron cod and polar cod had relatively low diatom indicator fatty acids in warm contemporary years of sampling (2017, 2019), compared to fish from colder reference years (2012, 2013, Table 2).

Multivariate analyses of gadid lipid parameters from contemporary and historic years (Table 2, Fig. 6) illustrate the large relative variation in polar cod multivariate lipid composition compared to other species. Polar cod were spatially segregated due to their high lipid content (fatty acids per WWT) and their *Calanus*- and diatom-sourced lipid storage. Conversely, Pacific cod and saffron cod in 2017 were characterized by very low total fatty acids and elevated proportion levels of fatty acids indicative of membrane phospholipids rather than energy storage (22:6n-3, 18:0). It was evident that saffron cod and polar cod had a significant shift in their lipid composition from earlier cold years (2012, 2013) to warm conditions in 2017, with declining total and diatom sourced lipids (Fig. 6). Walleye pollock had an intermediate lipid storage level that was higher in 2019 than 2017. Pollock had relatively elevated proportions of fatty acids associated with flagellates (18:4n-3, 18:2n-6, phytoplankton marker as discussed in Nielsen et al, lower trophic AIERP report) compared to polar cod, which could indicate feeding on smaller copepods that are not as dependent on diatom production (Fig. 6). The largest species-specific variation in lipid composition was seen in polar cod. Investigation of the differences in polar cod multivariate lipid composition as a function of year and region (Fig. 7), showed the most extreme regional multivariate change in lipid composition in the CECS between 2013 and 2017. Less annual variation in the lipid composition of polar cod was measured annually in the NECS.

Hot-spots for juvenile gadid condition

Spatial trends for polar cod lipid-based condition (total fatty acids per WWT) reflected tissue levels of total *Calanus* copepod lipid storage, indicating the importance of *Calanus* lipids to juvenile polar cod

energetics (Fig. 8). In 2013 and 2017, polar cod had the highest fatty acid storage in the <5 ºC waters of the NECS, specifically surrounding Hanna Shoal, near the mouth of Barrow Canyon and in coastal regions off Icy Cape (Fig. 8). In southern waters with temperatures > 8 °C, polar cod had reduced abundance (Levine et al. this report), but also lower lipid-based condition and reduced *Calanus* lipid storage (Fig 8). In 2019, polar cod were still in high condition near the entrance to Barrow Canyon and in the ice-associated regions east of Hanna Shoal and north of Herald Shoal, but they had reduced lipid storage to the south of Hanna Shoal compared to 2013 and 2017.

In 2019, the regional distribution of polar cod and walleye pollock only overlapped at a few stations to the south and west of Hanna Shoal (Fig. 9), where polar cod were in high condition but walleye pollock were in relatively poor condition. Average surface water temperatures at polar cod stations in 2019 were 6.67 ± 0.16 °C while walleye pollock stations were 8.86 ± 0.8 °C. Polar cod lipids ranged between 14 and 34 $mg.g^{-1}$ throughout the Chukchi while walleye pollock ranged between 9 and 29 $mg.g^{-1}$. For walleye pollock, high condition patterns were also associated with *Calanus*-sourced lipid storage, but at a much lower absolute level of fatty acid storage. Walleye pollock generally had higher total fatty acids and *Calanus* indicators in the SECS.

Discussion

Lipids are the most variable component of juvenile fish energetic storage and their fluctuation in fish tissues have previously been linked to oscillations in overwinter survival and recruitment (Grant & Brown 1999, Heintz & Vollenweider 2010, Siddon et al. 2013). In highly seasonal environments, consumers must rapidly store lipids during times of high productivity to survival prolonged periods of low food availability (Hurst 2007, Copeman et al. 2016, Copeman et al. 2021). Lipids are the densest and therefore most efficient form of energy storage, providing at least two-thirds more energy per gram than proteins or carbohydrates (Parrish 2013). Examples of this polar lipid-rich energetic strategy are evidenced by the large wax ester-filled oil sacs of *Calanus* copepods or the triacylglycerol- enriched livers of cold water cod species (Kattner et al. 2007, Falk-Petersen et al. 2009, Copeman et al. 2017, Kohlbach et al. 2017, Renaud et al. 2018). As polar systems continue to warm, dramatic and complex changes to the structure, function and resulting energetic flow of Arctic marine food webs are likely to occur (Grebmeier 2012, Christiansen 2017). We present some of the first data on changes to juvenile gadid lipid storage and condition during a recent period of rapid warming across the Chukchi Sea.

Interspecific and intraspecific variation in the lipid and fatty acid biomarkers were evident in four co-occuring juvenile gadids. Specifically, we found significant species-specific difference in their length-weight and length-lipid relationships, with polar cod demonstrating a unique high lipid storage strategy. This points to the importance of ontogeny- and species-specific condition metrics for accessing the relative survival potential of field-collected juvenile fish (Suthers 1998, Martin et al. 2017). Secondly, we measured region-specific declines in Arctic gadid lipid storage during recent warming (2017) events compared to earlier cold survey years. However, the northward distributional shift of polar cod and the extremely low catches of saffron cod in 2019 limited our region-specific annual comparisons. In 2019, NECS polar cod maintained relatively high lipid storage compared to polar cod from other regions and years. Pacific cod had very low lipid storage compared to other gadids and in comparison to Pacific cod from more southern regions (discussed in Cooper et al., this AIERP report). Lipid storage in Walleye pollock was generally low, with fish in better condition in 2019 and in southern regions compared to the NECS.

Overwintering and summer lipid storage

Recent laboratory studies on the winter survival of juvenile polar cod (Copeman et al. this report) indicate that lipid content has an important bearing on survival potential. The magnitude of annual differences in lipid content of field collected polar cod from the CECS (2013: 34.7 ± 18.7 versus 2017: 16.0 ± 6.4) were particularly striking despite being similar in size (2013: 43.4 ± 3.9 versus 2017: 47.2 ± 10.3). Copeman et

al (this report) note that the lipid-loss models illustrate how winter thermal conditions are either highly important following summers that support fish in good condition (e.g., NECS 2013, 2019) or are potentially irrelevant when the preceding summer conditions result in a poor energetic state for age-0 juveniles e.g., 2017, 'dead fish swimming'. They also note that small changes in fall/winter temperature between -1 and 2°C have important implications for the survival of fish entering winter in a high energetic state. The importance of summer-fall prey availability and pre-winter condition are important processes regulating winter survival and thus recruitment of walleye Pollock (*Gadus chalcogramma*) in the Eastern Bering Sea (Hunt Jr et al. 2011, Mueter et al. 2011, Heintz et al. 2013). Regardless, the high prioritization for energy storage observed in small-bodied juvenile polar cod suggest there is high winter mortality risk in the Arctic and that this risk is more likely due to starvation than predation (Ivan et al. 2015).

The late summer/fall energetic storage of both Chukchi Sea Pacific cod and walleye pollock was low (2017 & 2019). Cooper et al. (this AIERP report) compared the length-weight and length-fatty acid residuals of Pacific cod captured in the Chukchi Sea to those from the Gulf of Alaska (2017). Pacific cod were significantly larger in August in the Gulf of Alaska than in September in the Chukchi Sea. Further, at a given length, Pacific cod from the Gulf of Alaska were heavier and had higher total fatty acids per WWT than fish from the Chukchi Sea. Similarly, walleye pollock from the Chukchi Sea contained very low lipids per WWT (~16 mg. g^{-1}) compared to pollock from both the south eastern Bering Sea (~34 mg. g^{-1}, calculated from Siddon et al. (2013)) and Gulf of Alaska (20-28 mg.g^{-1} , Heintz and Vollenweider (2010). Given the low lipid storage we found in both species of boreal gadids captured in the Chukchi Sea, it seems unlikely that these new invading juveniles can successfully overwinter in cold, low productivity Arctic winter environments found on the Chukchi Shelf.

Direct and indirect effects of warming

The direct effects of warming on juvenile fish vary with early life history stage (Rijnsdorp et al. 2009). Polar cod have the narrowest thermal tolerance during the egg (-1.5 to 3.0 ºC) and early larval (-1 to 5 ºC) stages that becomes much broader during the late pelagic juvenile stage (-1 to 11 ºC) (Laurel et al. 2017, Koenker et al. 2018b, Laurel et al. 2018). In recent years, the Chukchi Sea region has been generally ice-free for much of the spring-summer and has surface waters that in areas are already warming beyond the thermal limits of many early life history stages of polar cod (Laurel et al. 2017, Laurel et al. 2018, Danielson et al. 2020). Long term ecosystem surveys both in the Barents Sea and in the Canadian Arctic have reported decadal scale increases in size-at-age of juvenile polar cod (Bouchard et al. 2017, Dupont et al. 2020) concurrent with reductions in sea ice concentrations and earlier spring ice retreat. As a result, Bouchard et al. (2017) predicted that warming would cause a temporary increase in polar cod biomass but that with increased borealization of the Arctic, that polar cod would be replaced by less specialized subarctic fish. Laboratory studies on polar cod have shown that they hold an energetic advantage (higher lipid per WWT) over boreal cogeners only at temperatures < 5 ºC (Copeman et al. 2017). These laboratory data combined with evidence of declining lipid storage and abundance during warming events (> 8°C), may indicate that the SECS and CECS are currently warming beyond the thermal limits of polar cod.

Continued warming may have negative impacts on polar cod via changes in the quantity, quality and phenology of zooplankton production and thus the nutrition status of juvenile fish in the summer (Bouchard et al. 2017, Bouchard & Fortier 2020). Large Arctic zooplankton have elevated lipid storage that is dependent on both sympagic and open-water diatom lipid production, that is seasonally elevated in cold nutrient rich waters (Kattner et al. 2007, Kohlbach et al. 2017). Shifts in zooplankton dynamics during recent warming, such as increased abundance of small southern species concurrent with decreases in large Arctic zooplankton (e.g. *Calanus glacialis*), has likely resulted in lower zooplankton lipids available in the diet of juvenile Chukchi Sea fish (Kimmel et al. this AIERP). Previous studies have

found a higher degree of reliance of juvenile polar cod than saffron cod on calanoid-copepod lipids (Copeman et al. 2020). Here we measured large variability in polar cod lipid storage that was highly spatially associated with tissue storage of *Calanus*- and diatom-sourced fatty acid biomarkers (Fig. 6, 8, 9). We do not yet know what portion of the lipid storage in Chukchi Sea polar cod and Arctic zooplankton that originates from ice-algae (Graham et al. 2014, Wang et al. 2015) but it is likely lower than in other high Arctic ecosystems (Kohlbach et al. 2017).

Future work

Models that link polar cod lipid storage to oceanographic parameters, phytoplankton indicators as well as zooplankton abundance are still under development. Specifically, synthesis efforts should focus on 1) understanding spatial and annual links between temperature, phytoplankton quantity/quality and zooplankton abundance/lipids to understand observed changes in zooplankton quality and 2) combining newly generated species-specific Arctic zooplankton lipid values (Copeman et al. this IERP) with climate-driven changes in zooplankton species abundance (Kimmelet al. this IERP) to better forecast changing prey quality available to fish in a rapidly warming Chukchi Sea. Due to the high lipid storage strategy of polar cod relative to other Alaskan congers, it is likely that they are more sensitive to changes in prey quality and particularly to decreases in *Calanus*-sourced lipid storage.

Finally, in contrast to long-term ecosystem surveys available from the Canadian and Norwegian Arctic (Bouchard et al. 2017, Dupont et al. 2020), the pelagic Chukchi Sea is woefully under surveyed. Continued ecosystem monitoring of the Chukchi Sea shelf is needed to understand annual variability and forecast the abundances and nutritional condition of key-stone Arctic species. Increased annual replication would help us better understand climate mediated mechanisms that lead to observed changes in juvenile fish energetics and improve our ability to predict overwinter survival potential and resulting recruitment variability of polar cod in this rapidly warming ecosystem.

Table 1: Four species of juvenile gadids were collected over the Chukchi and northern Bering Sea from seven different Arctic surveys during 2012, 2013, 2017 and 2019. Below are samples sizes, gear types and filed collection citations as well as biochemical analyses performed to assess fish condition.

	Ecosystem Survey	Year	Age	Number of fish for lipid classes	Number of fish for fatty acids	Number of fish for morpho-metrics	Gear type	Region	Reference to collection methods
Polar cod	EIS	2013	0	38	67	66	Midwater/surface trawls	Chukchi Sea	(De Robertis et al. 2016, Copeman et al. 2020, Farley et al. 2020)

	Arctic IERP	2019	0	111	111	111	Midwater/surface/ beam trawls	Chukchi Sea	(De Robertis et al. 2016, Logerwell et al. 2018, Copeman et al. 2020, Farley et al. 2020)

Table 2: Summary of lipid parameters for juvenile saffron cod (*Eleginus gracilis*), polar cod (*Boreogadus saida*), walleye pollock (*Gadus chalcogrammus*) and Pacific cod (*Gadus macrocephalus*) collected on ecosystem surveys during 2012, 2013, 2017 and 2019. Grey hi-lighted are for historical years representing a relatively normal 'cold' thermal phase of the Chukchi Sea, compared to the current 'warm' years (17 & 19).

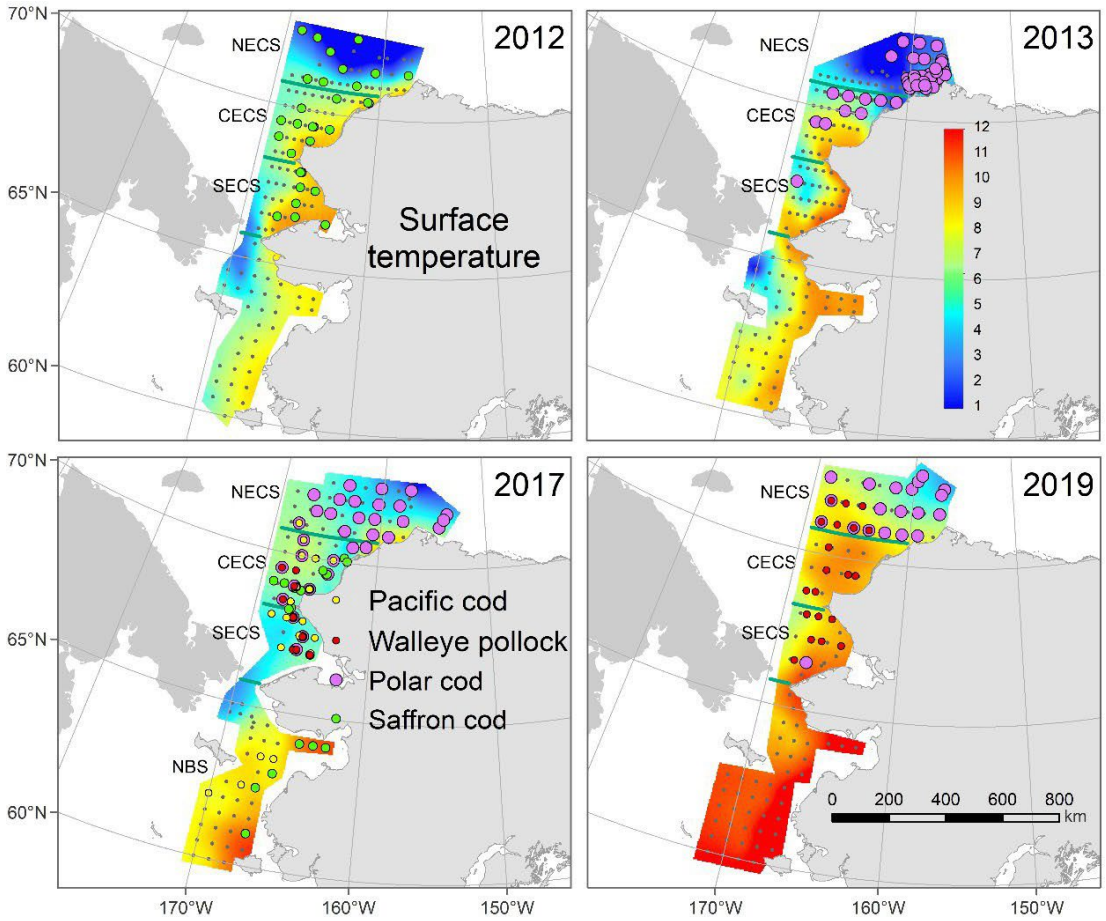

Fig. 1: Distribution of juvenile gadids collected on annual ecosystem surveys as detailed in Table 1. Species-specific stations are indicated for fish that were analyzed for detail condition and lipid biomarker analyses. Stations are plotted with surface temperature at the time of sampling to illustrate the dramatic warming in 2017 and 2019 compared with earlier sampling years.

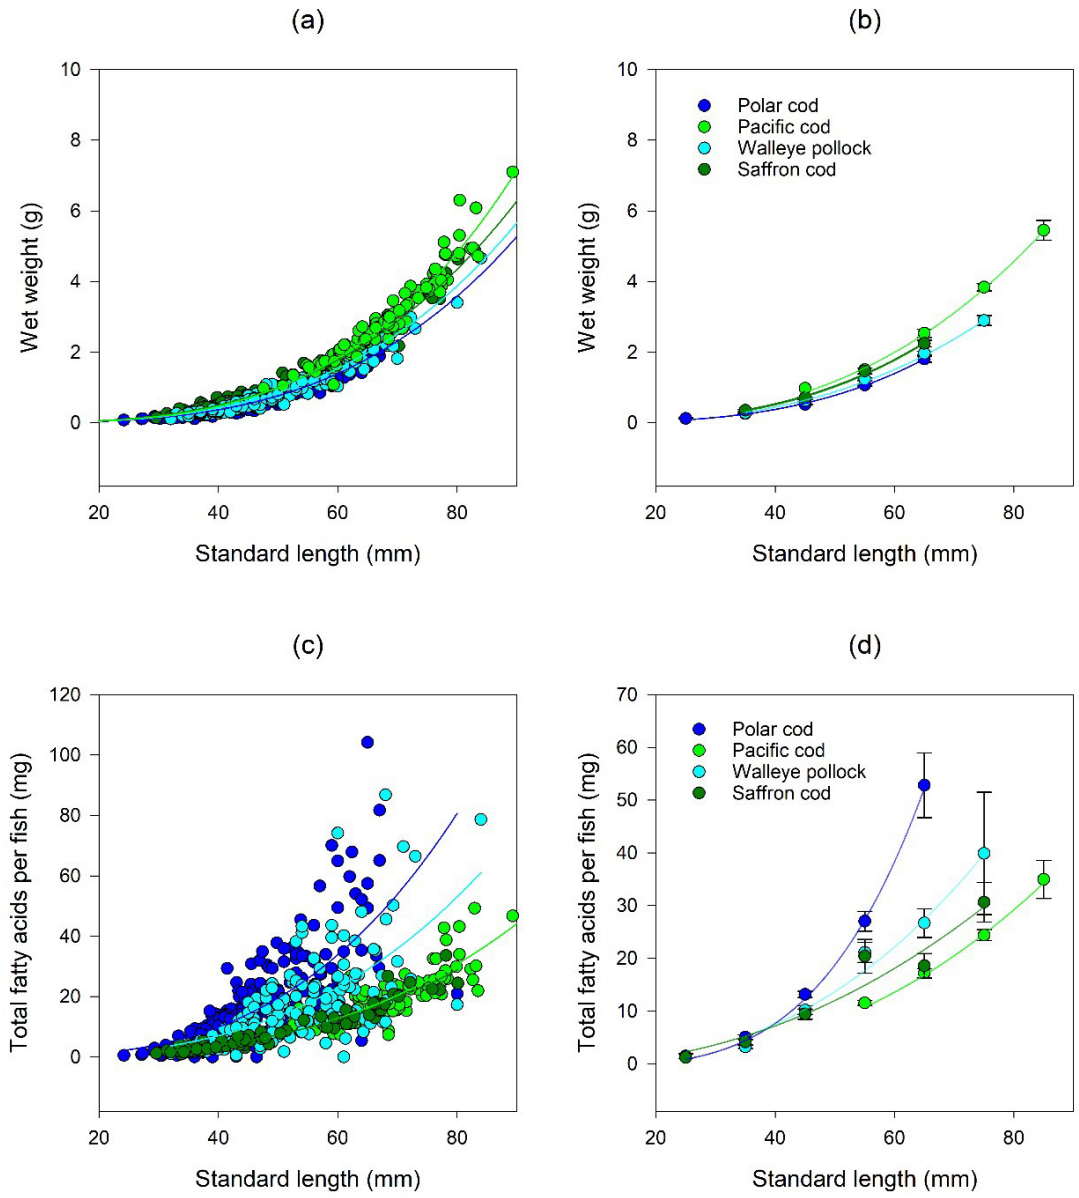

Fig. 2: Relationships between standard length (mm) and wet weight (WWT, g) as well as standard length (mm) and total fatty acids (mg per fish) for all age-0 juvenile Chukchi Sea gadids processed for lipid analyses (2012, 2013, 2017 and 2019). Data are shown for individual WWT (a), size binned WWT (b), individual total fatty acids (c) and size binned total fatty acids. Fish were binned into 10 mm increments to allow for visualization of the data.

Length-weight relationship on size binned data: Polar cod WWT (g) = 2.67E-006 SL(mm)$^{3.22}$, r^2 = 0.99, Pacific cod WWT (g) = 1.73E-005 SL (mm) $^{2.85}$, r^2=0.99, Walleye pollock lipids WWT (g) = 1.12E-005 SL (mm) $^{2.89}$, r^2 = 0.99, Saffron cod lipids WWT (g) = 9.7040E-006SL (mm)$^{2.96}$, r^2 = 0.91.

Length-total fatty acids relationship on size binned data: Polar cod lipid (mg) =5.41E-006 SL(mm)$^{3.85}$, r^2 = 0.99, Pacific cod (mg) = 0.0003 SL (mm) $^{2.61}$, r^2=0.99, Walleye pollock lipids (mg) = 0.0006 SL (mm) $^{2.58}$, r^2 = 0.99, Saffron cod lipids (mg) = 0.0024 SL (mm) $^{2.19}$, r^2 = 0.91

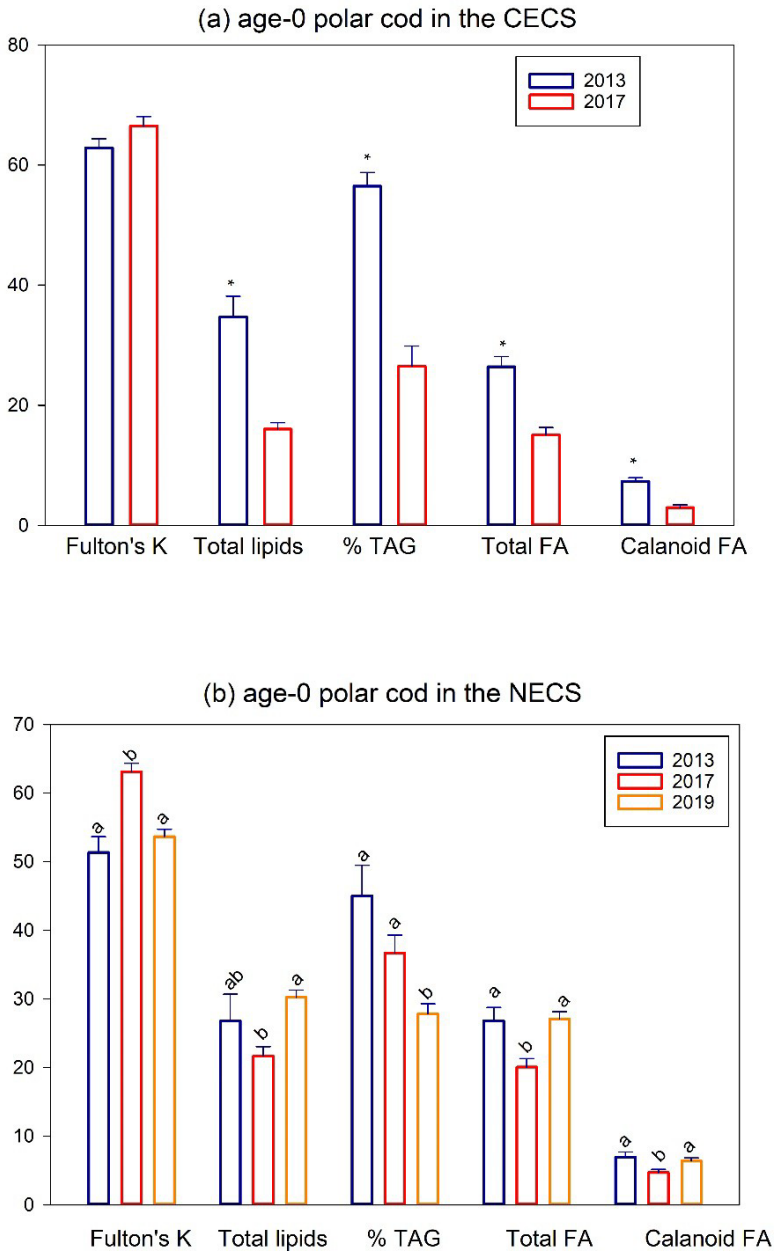

Fig. 3: Region-specific annual differences in condition metrics and lipid storage of age-0 polar cod in the Central Eastern Chukchi Sea (CECS) and the North Eastern Chukchi Sea (NECS). Fish were collected in one historical cold year (2013) and two current warm years (2017 and 2019). Polar cod were only captured in the NECS in 2019. Fulton's K (*100 percentage), total lipids (mg.g^{-1} WWT), triacylglycerols (% TAG), total fatty acids (mg.g^{-1} WWT), and total calanoid copepod fatty acid storage ($\sum C_{20}+C_{22}$ MUFA mg.g^{-1} WWT fish) are shown as mean ± SE by region-year. In the CECS * indicate significantly higher values in 2013 than 2017 while in 2019 different letters represent significant differences between years, ANOVA, $p<0.05$.

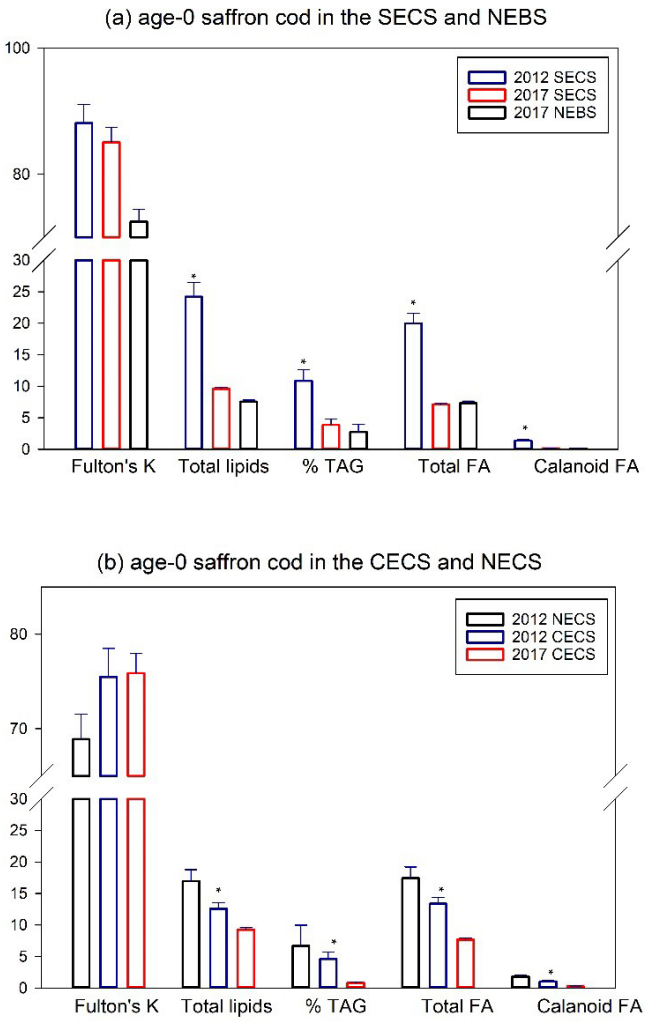

Fig. 4: Region-specific annual differences in condition metrics and lipid storage of age-0 saffron cod in the South Eastern Chukchi Sea (SECS) and the Central Eastern Chukchi Sea (CECS). Fish were collected in one historical cold year (2012) and one current warm year (2017). Saffron cod are shown for visual comparison only from the North Eastern Bering Sea (NEBS) in 2017 and the NECS in 2012. Fulton's K (*100 percentage), total lipids (mg.g^{-1} WWT), triacylglycerols (% TAG), total fatty acids (mg.g^{-1} WWT), and total calanoid copepod fatty acid storage ($\sum C_{20}$+C_{22} MUFA mg.g^{-1} WWT fish) are shown as mean ± SE by region-year. Statistical differences between 2012 and 2017 in the SECS and 2012 and 2017 in the CECS are indicated by an * with saffron cod having higher lipid indices in 2012 (cold) compared to 2017 (warm), ANOVA, $p<0.05$.

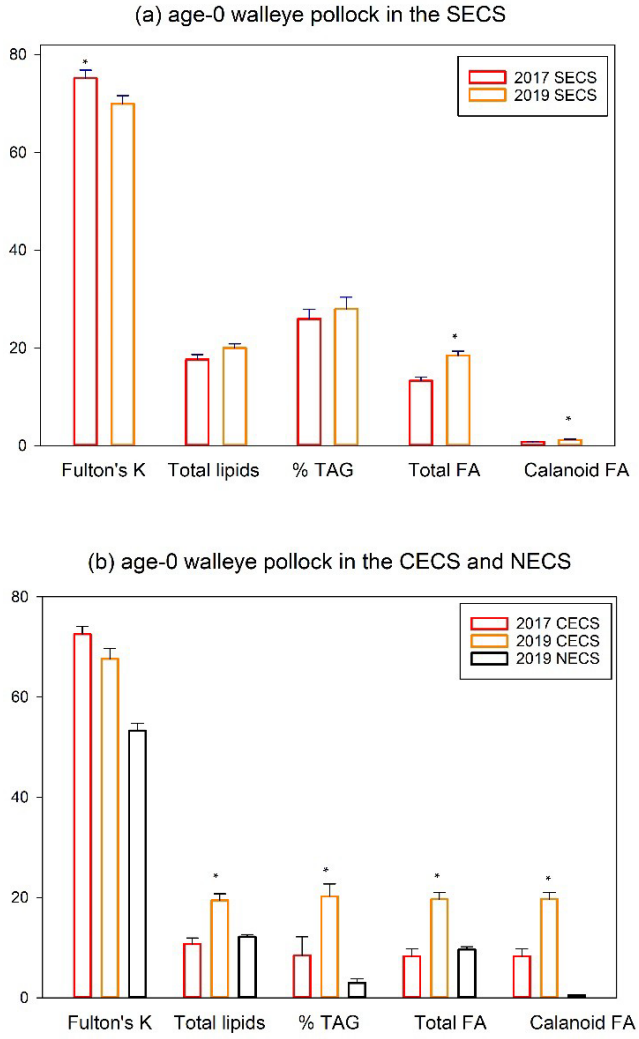

Fig. 5: Region-specific annual differences in condition metrics and lipid storage of age-0 walleye pollock cod in the South Eastern Chukchi Sea (SECS) and the Central Eastern Chukchi Sea (CECS). Fish were collected in two current warm year (2017 & 2019). Walleye pollock are also shown for visual comparison only from the NECS in 2019. Fulton's K (*100 percentage), total lipids (mg.g^{-1} WWT), triacylglycerols (% TAG), total fatty acids (mg.g^{-1} WWT), and total calanoid copepod fatty acid storage ($\sum C_{20}+C_{22}$ MUFA mg.g^{-1} WWT fish) are shown as mean ± SE by region-year. Statistical differences between 2017 and 2019 in the SECS and CECS are indicated by an * with walleye pollock having higher lipid indices in 2019 in the CECS than in 2017, ANOVA, $p<0.05$.

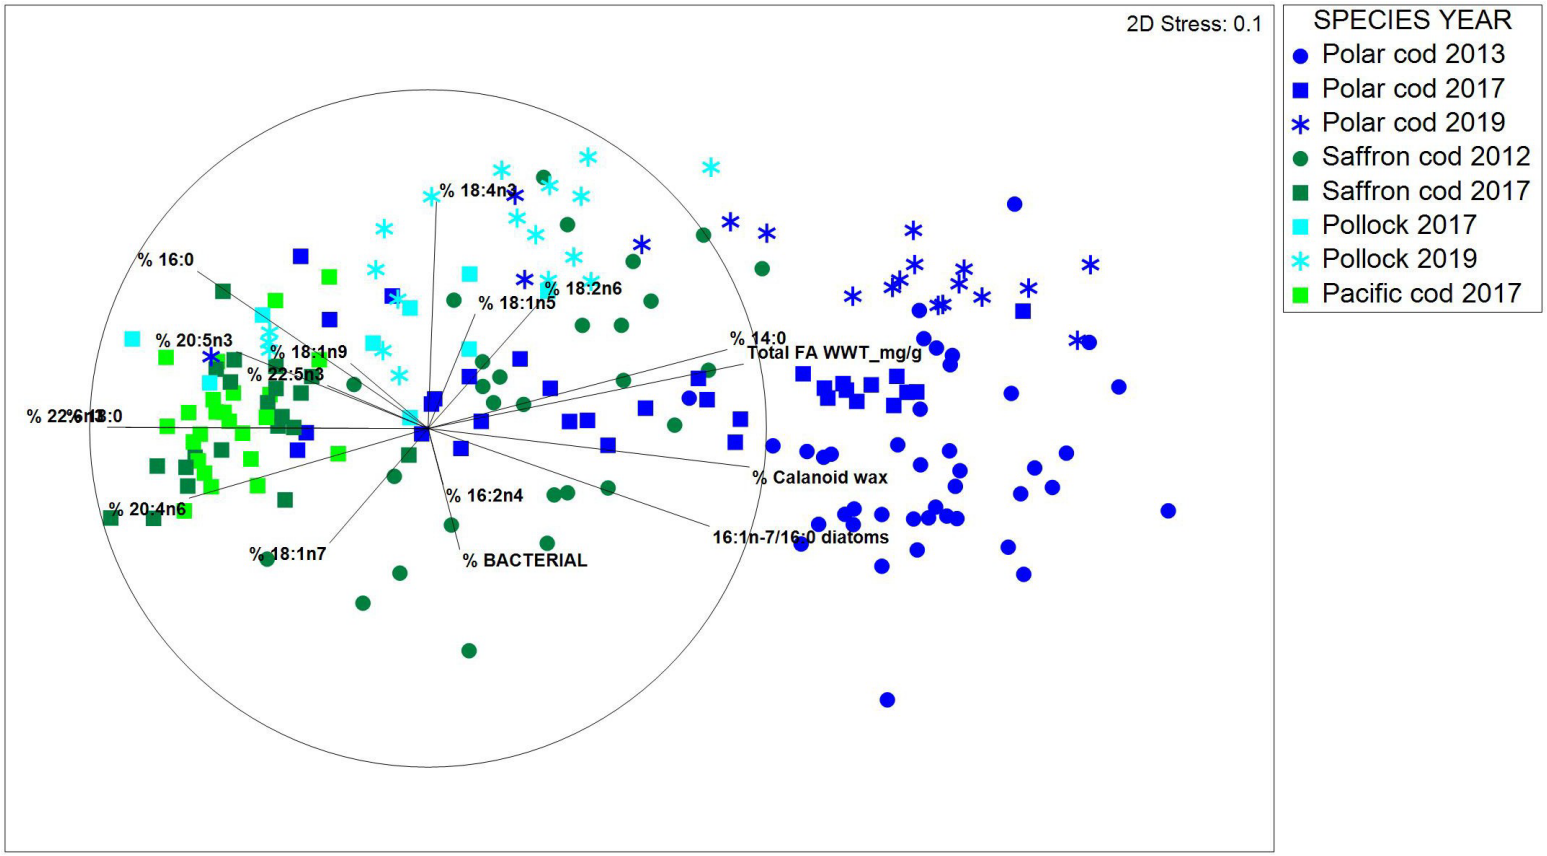

Fig 6: Nonmetric multidimensional scaling (*n*MDS) of the annual fatty acid composition of four species of juvenile gadids: saffron cod (*Eleginus gracilis*), polar cod (*Boreogadus saida*), Walleye pollock (*Gadus chalcogrammus*) and Pacific cod (*Gadus macrocephalus*) collected on ecosystem surveys during 2012, 2013, 2017 and 2019. Data points are annual station averages of ~ n=5 fish. Species and sampling as detailed in Table 1 & 2. Fatty acid vectors are shown for individual fatty acids >1% (Table 2) as well as total fatty acids per WWT (mg g−1), sum of calanoid-copepod fatty acids, bacterial fatty acids and a diatom indicator ratio. PERMANOVA for the effects of species and year showed a significant interactive effect Psuedo $F_{1,183}$=3.98, p=0.01 as illustrated by the larger annual change in polar cod lipids (2017 versus 2019) than measured for Walleye pollock over the same years.

	CECS 2013	NECS 2013	CECS 2017	NECS 2017
CECS 2013	*	*	*	*
NECS 2013	6.3	*	*	*
CECS 2017	**11.3**	10.8	*	*
NECS 2017	7.5	7.0	4.9	*
NECS 2019	7.8	8.2	9.1	6.8

Fig 7: Bootstrap averages (60 per grouping) with 95% confidence intervals, and centroids of lipid distribution for polar cod illustrated by region and year. Data are shown in metric multidimensional space and the distance between centroids is given in table format. Of note is the large region-specific distance in polar cod lipids in the CECS between 2013 and 2017. Following 2017, polar cod were only captured in the NECS.

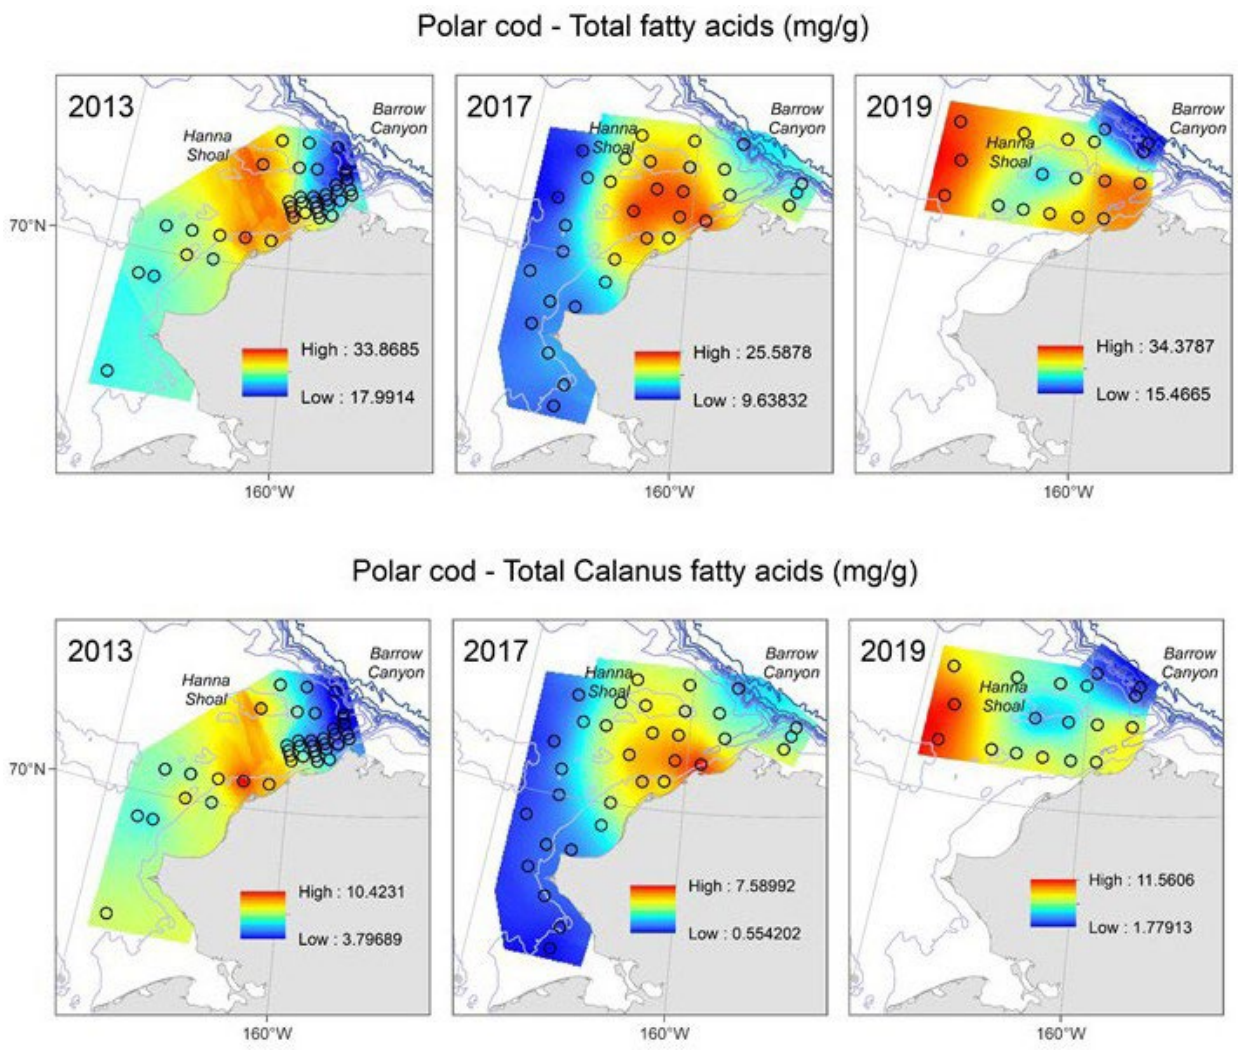

Fig 8: Annual spatial interpolation maps for 'hot spots' of a total fatty acids per WWT (mg.g^{-1}) and total *Calanus* fatty acid biomarkers $\sum C_{20}+C_{22}$ MUFA per WWT (mg. g^{-1}) in juvenile polar cod collected on Chukchi Sea Ecosystem surveys. Data sources and cruises details are as in table 1.

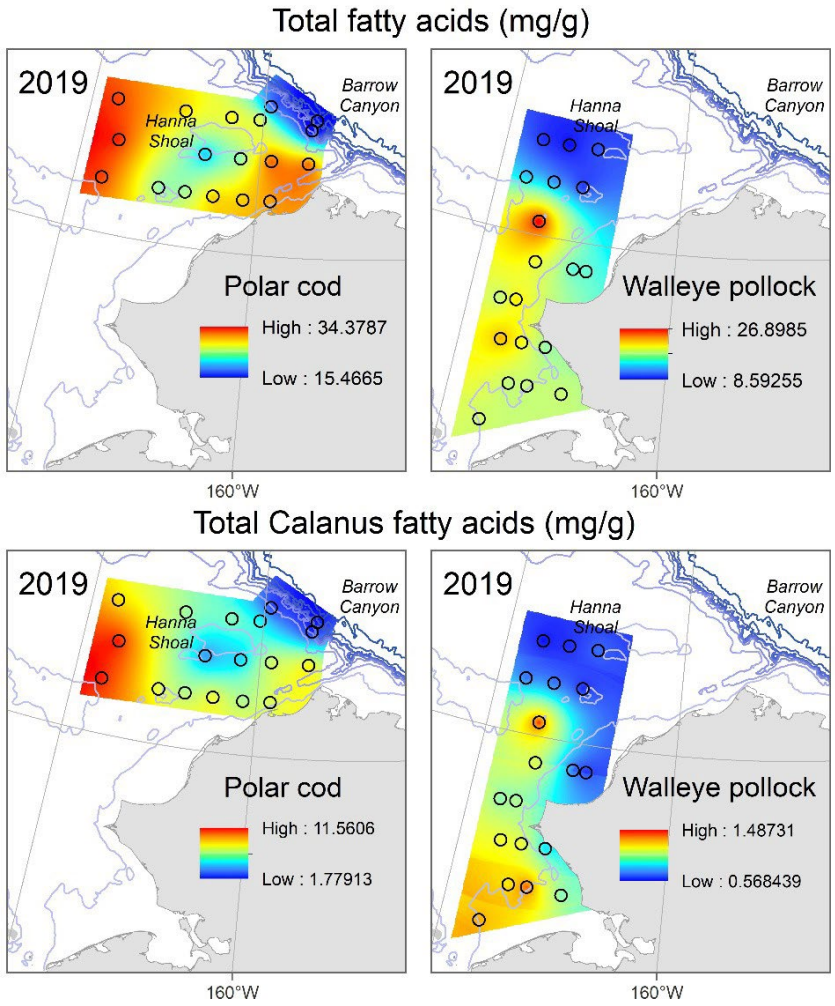

Fig 9: Species-specific spatial interpolation maps of 'hot spots' a total fatty acids per WWT ($mg.g^{-1}$) and total *Calanus* fatty acid biomarkers $\sum C_{20}+C_{22}$ MUFA per WWT ($mg.\ g^{-1}$) in juvenile polar cod and walleye pollock collected on Chukchi Sea Ecosystem surveys in 2019. Data sources and cruises details are as in table 1.

CHAPTER 12 - Corrigendum: Species and size selectivity of two midwater trawls used in an acoustic survey of the Alaska Arctic

Objective 3: Combine results from previous Arctic surveys (Arctic EIS, Phase 1, BASIS) and planned surveys (Arctic IES Phase 2) to assess variability in pelagic and demersal fish ecology over time relative to ocean conditions.

Alex De Robertis, Kevin C. Taylor, Kresimir Williams, Christopher D. Wilson. in review. Corrigendum: species and size selectivity of two midwater trawls used in an acoustic survey of the Alaska Arctic. AIERP Special Issue

Here we describe a correction to estimates of the size and species selectivity of two survey trawls in De Robertis et al. (2017a). In that study, trawl selectivity was investigated by equipping a modified Marinovich survey trawl with recapture nets to estimate the degree to which organisms entering the trawl mouth escape during the capture process. On a subset of hauls, paired hauls with both the Marinovich and a larger Cantrawl trawl were conducted. The size and species selectivity of the nets was estimated by combining the catch data from both trawls in a statistical model. Escapement (E) from each section of the Marinovich was characterized as $SS = \frac{cc_{mmmmmm}}{ff_{mmmmmm}}$ where c_{mar} is the catch in the Marinovich recapture net in a given section of the net and f_{mar} is the fraction of the trawl surface area covered by the recapture nets in that section.

In De Robertis et al. 2017a, f_{mar} of 0.022 was used in the forward portion of the trawl, and 0.055 was used in the aft portion of the trawl. We have discovered that these values were incorrectly computed. The correct value of f_{mar} in the experimental configuration is 0.065 in the forward portion of the trawl, and 0.132 in the aft portion of the trawl. Here we summarize the impacts of this inadvertent error on the selectivity estimates reported in De Robertis et al. (2017a). We also examine the effects of this error on the abundance estimates of acoustic-trawl surveys conducted in the Chukchi Sea in 2012 and 2013 as these surveys applied these selectivity relationships in an effort to correct for the selectivity of the survey trawl (De Robertis et al. 2017b).

The proportion of mesh area covered by the recapture net in De Robertis et al. (2017a) was incorrect for two reasons. First, the size of the recapture net was miscommunicated, and the number of meshes covered by the recapture net was under-estimated. Second, the codend was not included in the trawl diagram, and the area of the net covered by the fine-mesh (2 by 3 mm) codend liner was misinterpreted. We thus incorrectly assumed that the liner was placed in the aft section of the net during they survey rather than lining a separate, undocumented codend. These errors were discovered by comparing the trawl with the net diagram. These errors could have been avoided by better documentation of the trawl and recapture nets, and verifying that the recapture nets and trawl matched the net plans as part of the experiment. Corrected diagrams of the trawl and recapture nets as used in the experiment (Figs. S1.1-1.2), and a protocol to estimate recapture net coverage in this and future studies (S2) are given as supplementary material.

The primary consequence of under-estimating f_{mar} by a factor of 3 in the forward section and 2.4 in the aft section is that escapement from the Marinovich trawl was over-estimated. Escapement from the Cantrawl was also over-estimated as this depends on the estimated abundance of fish in the volume sampled which depends on the estimated selectivity of the Marinovich (De Robertis et al. 2017a, their equation 9). The reductions in estimated escapement can be visualized by comparing the revised calculations (Table 1 and Figs S1.3-S1.7) with those in the original publication (their Table 2, Figs. 4-5 and 7-9).
Although the qualitative pattern of escapement from different sectors of the net is similar to that described by De Robertis et al. (2017a), the proportion of fish escaping though the meshes is smaller (Fig. S1.4). In

general, the corrected probability of retention in both nets is higher, but the slope of the curves remains similar (Figs. S1.5-7). The length at 50% retention (L_{50}), which is directly affected by the absolute value of escapement, increases when f_{mar} is corrected (compare Table 1 and De Robertis et al. (2017a), their Table 2). However, the slope of the curve defined by *SR*, which describes the difference in length at 75% and 25% retention (i.e. L_{75} - L_{25}), is less affected. For example, for Arctic cod, the most abundant species, L_{50} for the Marinovich shifts from 6.2 to 5.2 cm after correction, while *SR* is unchanged at 2.2 cm. In the case of the Cantrawl, L_{50} shifts from 5.6 to 5.3 cm, and *SR* is unchanged at 0.8 cm. Stated another way, the primary impact is that the probability of retention increased in both nets (i.e. L_{50} decreased). For example, the probability of retaining a 4 cm Arctic cod increased from 0.11 to 0.23 for the Marinovich after correction, and 0.01 to 0.02 for the Cantrawl. However, *SR* was unaffected in this case. Thus, although the corrected results indicate that the trawls are more likely to retain these small fishes than initially estimated, the relative differences between different sizes, species and trawls are less affected. We regret the error, and the corrected selectivity values and figures presented here should supersede those in the original publication.

The primary application of these selectivity relationships was to estimate selectivity-corrected species and size distributions from trawl catches for use in acoustic-trawl abundance surveys (De Robertis et al. 2017b). These survey estimates are a complex function of acoustic backscatter measurements, trawl catches, selectivity estimates, and the acoustic properties of the organisms. We re-computed the abundance estimates with the corrected selectivity estimates and find that as expected from prior sensitivity analyses (De Robertis et al. 2017b, their table 3), the effect on abundance estimates is relatively modest.

Total estimates for Arctic cod were within 0.7% of the previous estimates and those of other, less abundant species differed by at most 9.9% (Table 1). In addition, the reduced selectivity shifted size distributions towards larger sizes: mean length increased by up to 1.1% for Arctic and saffron cod, and by up to 7.9% for capelin and herring (Table 1). These differences are small because the acoustic-trawl estimates are sensitive to the relative change in escapement between species and size classes (i.e. changes in size and species composition) rather than the absolute changes in escapement. Thus, the impact of the error described above on the acoustic-trawl abundance estimates reported by De Robertis et al. (2017b) is modest, and does not appreciably alter the conclusions of that study. A revised data set with abundances computed with the corrected f_{mar} parameter is available for use in future studies (De Robertis, 2021).

Table 1. Revised logistic selection curve parameters with bootstrapped confidence intervals. Methods are equivalent to those in De Robertis et al. (2017a) but with a correction for the degree of coverage of the recapture nets. L_{50} is the length in cm at 50% retention, and *SR* is the length in cm between 75 and 25% retention. Scientific names are follows: Arctic cod (*Boreogadus saida*), saffron cod (*Eleginus gracilis*), Arctic sand lance (*Ammodytes hexapterus*), Pacific capelin (*Mallotus villosus*). In the case of Arctic sand lance and capelin, some of the point estimates of L_{50} and SR fall outside of the 90% bootstrap confidence interval, which suggests that these values are affected by a small number of trawl hauls. Large values of SR imply little size selectivity across the observed size range. Note that *A. hexapterus* is referred to as Arctic sand lance (Orr et al., 2015), while this species was referred to as Pacific sand lance in De Robertis et al., 2017a,b.

Abstract

Many fish species have moved poleward with ocean warming, and species distribution shifts can occur because of adult fish movement, or juveniles can recruit to new areas. In the Bering Sea, recent studies document a dramatic northward shift in the distribution of *Gadus macrocephalus* (Pacific cod in English and tikhookeanskaya treska in Russian) during a period of ocean warming, but it is unknown whether the current northward distribution shift continues into the Chukchi Sea. Here, we use catch data from multiple gear types to present larval, age-0, and older Pacific cod distributions from before (2010 and 2012) and during (2017, 2018, and 2019) recent Chukchi Sea warming events. We also report on the habitat, diet and condition of age-0 Pacific cod, which were present in the eastern Chukchi Sea in recent warm years (2017 and 2019), but were absent in a cold year (2012). We hypothesize that age-0 recruitment to the eastern Chukchi Sea is associated with recent warm temperatures and increased northward transport through the Bering Strait in the spring. Age-0 fish were present in both benthic and pelagic habitats and diets reflected prey resources at these capture locations. Age-1 Pacific cod were observed in the western Chukchi Sea in 2018 and 2019, indicating possible overwinter survival of age-0 fish, although there was little evidence that they survive and/or remain in the Chukchi Sea to age-2. Observed low lipid accumulation in age-0 Pacific cod from the Chukchi Sea suggests juvenile overwinter mortality may be relatively high compared to more boreal regions (e.g., Gulf of Alaska). Adult Pacific cod were also observed in the Chukchi Sea during 2018 and 2019. Although densities in the western Chukchi Sea were very low compared to the Bering Sea, the adults are the first known (to us) records from the Chukchi Sea. The increased presence of multiple age-classes of Pacific cod in the Chukchi Sea suggests poleward shifts in both nursery areas and adult summer habitat beyond the Bering Sea, but the quantity and quality (e.g., summer productivity and overwintering potential) of these habitats will require continued surveys.

Introduction

The ranges of many marine fish species have moved poleward in response to recent warming temperatures (Mueter and Litzow, 2008; Nye et al., 2009; Kotwicki and Lauth, 2013), which is impacting fisheries and ecosystems (Mueter and Litzow, 2008; Figueira and Booth, 2010; Hollowed et al. 2013). Distribution shifts caused by temperature often vary by ontogenetic stage (Morley et al., 2017; Barbeaux and Hollowed, 2018), because species may expand their range by multiple mechanisms, including movement of subadults and adults (Nye et al., 2009; Hill et al., 2016), or juveniles recruiting to new areas and remaining there as they grow (Rindorf and Lewy, 2006; Nye et al., 2009; Figueira and Booth, 2010).

Summer temperatures in the Bering and Chukchi seas (Figure 1) have increased in recent years (Stabeno and Bell, 2019; Danielson et al., 2020; Woodgate and Peralta-Ferriz, 2021). In the Bering Sea, sea-ice coverage during winter and spring causes an area of cold (<2 °C) bottom water known as the cold pool, which persists through the summer (Wyllie-Echeverria and Wooster, 1998; Stabeno et al., 2001). The annual spatial extent of the cold pool varies with annual sea-ice extent and can extend far into the southeastern Bering Sea in cold years, or be limited to areas of the northern Bering Sea in warm years (Overland et al., 2012; Stabeno et al., 2012). In recent decades, the Bering Sea has alternated between multi-year periods of cold and warm summer ocean bottom temperatures (Overland et al., 2012; Stabeno et al., 2012), including a cold period from 2007 through 2013, and a warm period which began in 2014 (Stabeno and Bell, 2019). The summer distribution of *Gadus macrocephalus* (Pacific cod in English or tikhookeanskaya treska in Russian, hereafter referred to as "cod") shifted northward in the eastern Bering Sea (EBS) during the recent warm period (Thompson, 2018; Stevenson and Lauth, 2019; Baker, 2021), likely in response to the spatial reduction of the cold pool in the EBS, and warmer summer bottom temperatures in the northern Bering Sea (NBS) (Stevenson and Lauth, 2019). Sub-adult and adult cod abundance increased by more than 900% in the NBS between 2010 and 2017 (Stevenson and Lauth, 2019). The size range of cod inhabiting the NBS has also changed: in 2010, the surveyed population was comprised of juvenile fish from 10 to about 35 cm fork length (FL), and also larger adults > 60 cm FL, with few fish in the intermediate size range. However, in 2017, there was a continuous length distribution of cod from juveniles through adults (Stevenson and Lauth, 2019). Temperatures of the Bering Sea inflow entering the Chukchi Sea during the summer have increased in recent years (Woodgate and Peralta-Ferriz, 2021), and temperatures on the Chukchi Sea shelf were historically high from 2014 – 2018 (Danielson et al., 2020). In 2017, cod densities in the NBS were elevated near the Bering Strait (Stevenson and Lauth, 2019), which is at the southern border of the Chukchi Sea (Figure 1), indicating that the population distribution may have continued into the unsampled southern Chukchi Sea. However, cod distribution and abundance have not been examined in the Chukchi Sea during the recent warm period, and the life stages and size distributions of any cod recently present in the Chukchi Sea are also unknown.

Juvenile cod have been documented in the Chukchi Sea (Barber et al., 1997; Mecklenburg et al., 2011, 2018; Logerwell et al., 2015) and Beaufort Sea (Andriashev, 1937; Rand and Logerwell, 2010), however relatively few records exist (Mecklenburg et al., 2011). In the Chukchi Sea, the largest reported cod were 33 cm (Logerwell et al., 2015), 31 cm (Barber et al., 1997), and 17.6 and 8.7 cm total length (TL) (Mecklenburg et al., 2011), which are below the smallest known size of maturity for cod in the EBS or Gulf of Alaska (Stark, 2007). Habitat of juvenile cod in the Chukchi Sea has not been examined. In the EBS, age-0 cod inhabit nearshore benthic habitat, or pelagic habitat in offshore deeper areas (Hurst et al., 2015). Because size and energetic storage are important factors contributing to the overwintering survival of juvenile marine fishes (Sogard, 1997; Hurst, 2007), it is unclear whether small boreal gadids such as cod can survive long periods of cold in low productivity habitats typical of the Chukchi Sea.

The juvenile cod observed in the Chukchi Sea may be sourced from larvae advected northward from the Bering Sea. Cod spawn in the EBS from March to mid-April (Neidetcher et al., 2014) and eggs likely

remain at their spawned location because they are demersal (Thomson, 1963; Fadeev, 2005). Larvae become more buoyant at hatch (Laurel et al. 2010) and are typically in surface waters where they have been reported in the EBS from April through June (Matarese et al., 2003) and in the western Bering Sea (WBS) in June (Bulatov, 1986). Ocean currents during the larval period may carry larvae from the NBS to the Chukchi Sea through the Bering Strait. Currents are measured by a mooring (A3) located just north of the Bering Strait (Figure 1), which provides hourly time series of ocean temperatures and northward transport through the Bering Strait (Woodgate, 2018).

The objectives of this study were to 1) investigate thermal and ocean transport conditions which could affect cod larvae transported between the NBS and Chukchi Sea; 2) describe cod distribution in the Chukchi Sea by life stage before (2010 and 2012) and during (2017, 2018, 2019) the recent period of warm summer ocean temperatures in the Chukchi Sea; and 3) understand the potential survival trajectories of age-0 cod in the Chukchi sea by comparing their habitat, size, diet and condition to juveniles collected farther south, in the Gulf of Alaska (GOA).

Methods

Bering Strait temperature and transport

Monthly averaged near-bottom temperatures in April through June from 1998 through 2019 measured at a subsurface mooring were used to investigate the thermal exposure of any cod larvae possibly in the Bering Strait during the larval period (Mooring A3 in Woodgate et al., 2015; Woodgate, 2018; Woodgate and Peralta-Ferriz, 2021). This mooring is located ~35 km north of the Bering Strait proper, at a point where water temperatures are considered to be a meaningful average of the water temperatures in the eastern and western sides of the Bering Strait (Woodgate, 2018). These measurements are made near bottom and represent the bottom layer (~30-40 m) of the water column. In April – June, sea surface temperatures are ~ 1 to 2 °C warmer than the near-bottom temperatures in the annual mean (Woodgate and Peralta-Ferriz, 2021; Woodgate, 2018, Figure 14). Thus, depending where they reside in the water column, larvae in April – June may be exposed to warmer (~1 to 2 °C) temperatures than considered here.

Estimates of water volume transport from the NBS to the Chukchi Sea during the larval period were obtained to investigate possible inter-annual differences in northward larval transport through the Bering Strait. Monthly-averaged northward transport estimates during April – June from 2000 – 2019 were calculated from the A3 mooring data (see Woodgate, 2018 for method), and an average transport value for April – June was calculated for each year.

Larval distributions

Larval cod were collected in the Bering Sea and southeastern Chukchi Sea during research cruises funded by the Arctic Integrated Ecosystem Research Program (AIERP) of the North Pacific Research Board (NPRB) in the spring and early summer months (April – June) of 2017 and 2018 using a paired 60-cm diameter bongo net (505-µm mesh) that was towed obliquely from the surface to 10 m off the bottom. Flowmeters attached to each net were used to quantify the volume filtered, allowing estimation of larval catch per unit effort (CPUE). CPUE for these larvae is reported as the number of larvae per 10 m^2 surface area calculated based on the maximum depth of the tow and volume filtered (Matarese et al., 2003). Samples were preserved at sea in 5% formalin buffered with sodium borate and seawater and identified to the lowest taxonomic level at the Plankton Sorting and Identification Center in Szczecin, Poland. Taxonomic verifications took place at the National Oceanic and Atmospheric Administration, Alaska Fisheries Science Center in Seattle, WA, USA. Conductivity, temperature, and depth (CTD) casts (Sea-Bird SBE 911 plus) were conducted immediately prior to net deployments to examine temperature (°C) across the study region. CTD-derived temperature measurements were averaged over the entire water

column (deepest CTD cast was ~60 m in Bering Strait in both years) and, for data visualization, the means were interpolated onto a 1 km × 1 km grid using local polynomial interpolation across longitude and latitude with the "stats" package in R (version 3.6.1; R Core Team 2020). These interpolated temperature measurements were then plotted with larval cod distributions (log(x+1)-transformed CPUE per 10 m^2) in June of 2017 and 2018.

Juvenile and adult distributions

Cod juveniles and adults were caught in several trawl types used for multi-species surveys in the eastern Chukchi Sea (ECS) and western Chukchi Sea (WCS) in cold years (2010 and 2012) and recent warm years (2017 – 2019; Table 1 and Figure 2).

Surface Trawl

A Nordic 264 Rope Trawl (NETS Systems) was deployed at nearshore stations during AIERP surveys in the ECS in 2017 and 2019 (Table 1, Figure 2). The rope trawl was 184 m long with non-uniform hexagonal mesh in the wings and body (maximum mesh size = 162 cm) and a 1.2 cm mesh liner in the codend. Tows were made at or near the surface for 30 minutes at 0.77 – 1.54 ms^{-1} (1.5 – 3 nautical miles $hour^{-1}$), and had typical trawl mouth openings of 20 m horizontally and 19 m vertically. All sampling was performed during daylight hours. CPUE was calculated as the number of fish divided by the surface area swept by the trawl. Surface area swept by the trawl was calculated as the width of the trawl opening multiplied by the distance fished. Distance fished was measured by Global Positioning System (GPS).

Midwater trawl

A modified-Marinovich midwater trawl (~34.5 m long, 12 m headrope, 6.4 to 1.8 cm mesh) with a 0.3 cm mesh codend liner was deployed during AIERP surveys in 2017 and 2019 in the ECS to conduct targeted midwater hauls (Table 1, Figure 2). Trawling location and depth were determined based on identification of strong scattering layers in shipboard acoustic data. CPUE of the midwater trawl was calculated as number of fish per trawl tow divided by the volume filtered by the trawl. Volume filtered was calculated as the trawl mouth opening multiplied by the distance fished. Distance fished was measured by GPS position. Net opening was measured using observation from a net sonar (Simrad FS70) placed on the headrope. For all hauls, the vertical net opening averaged 7.85 m (5.1 - 10.6 m range) and horizontal opening averaged 7.49 m (5 - 9.1 m range). Average headrope depth of midwater trawls was 32.1 m, ranging from 11.4 to 227.9 m, with an average ship speed during the tow of 1 – 1.5 m s^{-1}. Bottom depths of trawl locations ranged from 23 to 1130 m.

Small-mesh benthic trawl

A small-mesh benthic trawl was deployed in the ECS during the arctic ecosystem integrated survey (EIS) in 2012, and during AIERP surveys in 2017, and 2019 (Table 1, Figure 2). The trawl was a 3.05-m plumb staff beam trawl with a 7 mm mesh and 4 mm mesh codend liner (Gunderson and Ellis, 1986). In 2012, a tickler chain preceded the footrope (Gunderson and Ellis, 1986; Kotwicki et al., 2017). In 2017 and 2019, the tickler chain was removed, and the trawl was modified with a footrope of 10.2 cm rubber discs over a steel chain as in Abookire and Rose (2005). Mean trawl durations and ranges (minutes) were 2.9 (range = 2.8 – 7.4), 5.4 (range = 4.0 – 9.1), and 6.0 (range = 2.8 – 8.9) in 2012, 2017, and 2019, respectively. Targeted towing speed was 0.77 ms^{-1} (1.5 nautical miles $hour^{-1}$). CPUE was calculated as the number of cod in the trawl tow divided by the area swept by the trawl. Area swept by the trawl was the effective width of the trawl multiplied by the distance fished by the trawl. Effective trawl width of the trawl was assumed to be 2.26 m in 2012 (Gunderson and Ellis, 1986; Kotwicki et al., 2017), and 2.1 m in 2017 and 2019 (Abookire and Rose, 2005). Distance fished was measured as the distance between the

locations that the trawl began and stopped contact with the bottom. Bottom contact was determined by HOBO G acceleration data logger (Onset Corp.) placed in a waterproof steel housing and hung from the footrope in a manner forcing the data logger to pivot when it contacted the bottom. Time stamps from the acceleration data logger were used to match the start and conclusion of trawl bottom contact with location from GPS data.

Large-mesh benthic trawls

A large-mesh benthic trawl (DT 27.1/24.4 bottom trawl; Zakharov et al., 2013) was deployed in the WCS in 2010, 2018, and 2019 (Table 1, Figure 2). Trawl mesh was 8.0 cm in the wings and body, 6.0 cm in the intermediate, 3.0 cm in the codend, and the codend was equipped with a 10 mm mesh liner. Target trawl speed was ~1.5 ms^{-1} (3 nautical miles per hour) for a target duration of 30 minutes. CPUE was calculated as the number or weight of cod in the tow divided by the area swept by the trawl. Area swept by the trawl was calculated as the horizontal opening of the trawl (16.2 m) multiplied by the distance fished by the trawl. Distance fished was the distance between the locations that the trawl began and stopped contact with the bottom.

The large-mesh benthic trawl deployed in the ECS in 2012 (Table 1, Figure 2) as part of the Arctic EIS survey was an 83-112 Eastern Trawl (Stauffer, 2004). Deployment of the trawl in 2012 is described by Kotwicki et al. (2017). The trawl horizontal opening was approximately 17 m. Stretched mesh size was 10.2 cm in the wings and body, 8.9 cm in the intermediate and codend, and the codend was equipped with a 3.2 cm mesh liner. Target trawl speed was ~ 1.5 ms^{-1} (3 nautical miles per hour) for a target duration of 15 minutes. CPUE was calculated as the number of cod divided by the area swept of the trawl. Area swept was calculated as the distance fished multiplied by the width of the trawl opening. Width of the trawl opening was measured with acoustic net mensuration sensors (Marport Deep Sea Technologies, Inc.). Distance fished was measured as the distance between the locations that the trawl began and stopped contact with the bottom.

Gulf of Alaska small-mesh demersal seine

Age-0 juvenile cod were collected in August of 2017 during the annual summer nearshore seine survey on Kodiak Island to compare condition to those collected in the ECS in 2017. The GOA survey uses a 36 m demersal bag seine with 1 m wide seine wings at the ends expanding to 2.25 m in the middle. The mesh size was 13 mm within the wings and 5 mm in the bag-end. The seine wings were attached to 25 m ropes for deployment using a small boat and was set parallel to shore at a distance of 25 m away and then retrieved by two people standing on the shore, effectively sampling ~900 m^2 of bottom habitat (see more details in Laurel et al., 2007).

Trawl survey temperatures

Bottom temperatures were recorded at each station for the small- and large-mesh benthic trawls in the ECS using an SBE-39 (Seabird Scientific, Inc.) temperature sensor attached to the trawl headrope. Bottom temperatures in the WCS were recorded with either an SBE-19 or SBE-25 temperature sensor from CTD cast conducted at the trawl location. Gear temperatures for the surface and midwater trawls were measured with CTD casts taken with an SBE 911 plus. Near surface temperatures were used for the surface trawl, and temperatures averaged over the depth range between the trawl headrope and footrope at the targeted trawl depth were used for the midwater trawl. CTD casts were co-located with surface trawl tows; however, midwater trawl tows were opportunistic and temperatures were obtained from the nearest CTD cast (the same sampling grid as for the small-mesh benthic trawl each year; Figure 2).

Fish length and length-based age classification

In the surface, midwater, and small-mesh benthic trawls, cod were measured to the nearest millimeter at

sea. In 2017, TL was measured, and in 2019, one large fish was measured to FL, and the smaller fish were measured to standard length (SL). For comparison with laboratory data and other studies of age-0 fish, lengths of juveniles were converted to SL. To compare sizes of the juvenile cod with larger cod caught with the large-mesh trawls, lengths of juvenile fish were converted to FL. Lengths of juvenile fish were converted between length types using length data provided by Oregon State University, the AFSC's Auke Bay Laboratories and RACE Division's Midwater Assessment and Conservation Engineering program for fish within the same size range as the observed fish. The conversion factors were SL = TL(0.902) + 1.284 (based on 120 samples up to 110 mm in length) and SL = FL(0.952) - 0.663 (based on 11 samples up to 78 mm in length). Cod caught in both large-mesh benthic trawls were measured at sea to the nearest cm FL.

The length mode (49 – 103 mm FL) of small juveniles caught in the ECS in the small-mesh benthic, midwater, and surface trawls was similar to reported lengths of age-0 fish in the EBS during the summer (Hurst et al., 2012a; Hurst et al., 2015) and these fish will be referred to as age-0 for this study. The larger length mode of juveniles (100 – 230 mm FL) caught in the large-mesh benthic trawls in the ECS and WCS were smaller than age-1 fish in the Gulf of Alaska during the summer (150 – 250 mm TL; Laurel et al., 2016a); however they are assumed to be age-1 based on length mode analysis (they were larger than the mode of age-0 fish), and will be referred to as age-1 fish for this study. There was an overlap in the size ranges of the age-0 and age-1 fish (100 – 103 mm FL); however, the size range contained only 3% of the fish in this study. The larger cod (550 – 780 mm FL) caught in this study are greater than the size of 50% maturity for cod from the EBS and GOA (Stark, 2007) and are referred to as adults for this study.

Age-0 Diets

Diets of the age-0 cod caught in the ECS in 2017 were analyzed by capture trawl type (small-mesh benthic, midwater, and surface trawls) to investigate whether the age-0 cod captured in different parts of the water column used different prey resources. Sample sizes were 40 fish from 10 stations in the small-mesh benthic trawl, 28 fish from 6 stations in the midwater trawl, and 40 fish from 5 stations in the surface trawl. Fish were frozen at sea. Stomachs were dissected in the laboratory and stored in 10% formalin to fix stomach contents. Stomach contents were sorted to lowest practical taxonomic resolution and developmental stage (as appropriate) and weighed to the nearest 0.01 µg, and counted.

To determine prey importance in the age-0 cod diets, we used the percentage of the prey-specific index of relative importance (%PSIRI) (Brown et al., 2012). %PSIRI was calculated for age-0 cod collected in each type of trawl. %PSIRI is calculated using frequency of occurrence (FO), prey-specific count ($\%PN_i$), and prey-specific weight ($\%PW_i$), which were calculated using the following equations:
Frequency of occurrence (FO):

$$FO_i = \frac{n_i}{n},$$

Prey-specific count (%PN):

$$\%PNi = \sum_{j=1}^{n} \%N_{ij}/n_i.$$

Prey-specific weight ($\%PW_i$):

$$\%PW_i = \sum_{j=1}^{n} \%W_{ij}/n_i,$$

where $\%N_{ij}$ is the count (PN_i) and $\%W_{ij}$ is the weight (PW_i)) of prey category i in stomach sample j; n_i is the number of stomachs containing prey i, and n is the total number of stomachs.
The %PSIRI is then calculated:

$\%PSIRI_i = \frac{\%FO_i*(\%PN_i+\%PW_i)}{2}$.

%PSIRI was calculated for prey items at the lowest practical taxonomic resolution, and also for prey items grouped by the following prey habitat types: endobenthic, epibenthic, hyperbenthic, planktonic, or various. Each prey item was assigned a prey habitat type based on a literature search.

The symmetric niche overlap coefficient (Pianka, 1973), was calculated to determine whether there was niche overlap among the diets of cod caught in the different trawl types using the following equation:

$$O_{kl} = \frac{\sum_i^n p_{il} p_{ik}}{\sqrt{\sum_i^n p_{il}^2 \sum_i^n p_{ik}^2}}$$

where O_{kl} is the resource overlap index between capture trawl type k and l, and p_{il} is the proportion of resource i that is used by capture trawl type l.

This resource overlap index produces values from 0 to 1, where 0 indicates that no resources are shared and 1 indicates complete shared resource utilization between the cod collected in different trawl types. The capture trawl type by prey matrix was randomized 2000 times. For each randomization, the Pianka coefficient was calculated to create the null distribution. All data analysis was conducted using R statistical analysis software (R Core Team, 2020). The EcoSimR package was used to calculate the Pianka coefficient and determine if there was niche overlap among trawl types using a null model.

Age-0 Condition

One-hundred and seventeen age-0 cod collected in the ECS in 2017 and 30 age-0 fish from the annual August GOA beach seine survey in 2017 were saved for condition analyses. Fish from the four different gear types described above, small-mesh benthic (n=45), midwater (n=31), surface trawls (n=41) and the GOA beach seines (n=30) were frozen immediately at -20 ℃ and were maintained at -80 ℃ at the land-based laboratory. Samples were frozen and shipped overnight from Alaska to the Marine Lipid Ecology Laboratory at Oregon State University's Center for Marine Ecosystem and Resources Studies facility at the Hatfield Marine Science Center in Newport, OR, USA. Samples were stored at -80 ℃ and dissected within 6 months of capture. At the laboratory, all fish were measured to SL, (± 0.1 mm) and wet weight (WWT; ± 0.0001 g). All of the fish from the Chukchi Sea and 18 of the 30 fish from the GOA were used in the biochemical analysis. For these fish, intestinal tracts were removed and fish were washed with filtered seawater, blotted dry, and heads were removed for later otolith analysis. Fish were bisected along a dorsal ventral plane and half of the tissues were frozen for other analyses while half of the body tissues were placed in chloroform under nitrogen until extraction, within 1 month of sampling.

Cod tissues were homogenized in 2:1 chloroform:methanol according to Parrish (1987) using a modified Folch procedure (Folch et al., 1956). Lipid extracts were derivatized through acid transesterification using a Hilditch Reagent, H_2SO4 in MeOH as described in Budge et al. (2006). Fatty acid methyl esters (FAMEs) formed in the reaction were analyzed on an HP 7890 GC FID equipped with an autosampler and a DB wax+ GC column (Agilent Technologies, Inc.). The column length was 30 m with an internal diameter of 0.25 mm and a film thickness of 0.25 μm. The column temperature profile was as follows: 65 °C for 0.5 min, hold at 195 °C for 15 min after ramping at 40 °C min^{-1}, and hold at 220 °C for 1 min after ramping at 2 °C min^{-1}. The carrier gas was hydrogen, flowing at a rate of 2 ml. min^{-1}. Injector temperature was set at 250 °C and the detector temperature was constant at 250 °C. Peaks were identified using retention times based upon standards purchased from Supelco (BAME, PUFA 1, 37 component FAME, PUFA 3). Nu-Check Prep GLC 487 quantitative FA mixed standard was used to develop correction factors for individual FAs. Chromatograms were integrated using Chem Station (version A.01.02, Agilent). Total fatty acids were expressed in relation to fish WWT (g) to give an index of total acyl lipid storage.

Regressions between $\log_{10}$ (SL) and $\log_{10}$ (WWT) as well as $\log_{10}$ (SL) and fatty acid concentrations (mg/g) were run as indices of morphometric- and lipid-based condition, respectively. Residuals from these relationships were compared between the GOA and ECS using a two-sample t-test.

Results

Bering Strait temperature and transport

Monthly-averaged near-bottom water temperatures in the Bering Strait in April were consistently cold throughout the time series, ranging from -1.58 to -1.89 °C (Figure 3). Both temperature and inter-annual variability increased in May, although May near-bottom temperatures remained below 0 ˚C for all years except 2017 (Figure 3). Inter-annual temperature variability increased in June, with monthly averaged temperatures ranging from -0.83 to 2.95 °C. Any larvae transported northward though the Bering Strait in June 2012 would have been exposed to temperatures of ~ 0.5 – 1.5 °C (near bottom temperature of -0.5 °C + 1 – 2 °C warmer in the water column). June near-bottom temperatures from 2015 to 2019 were among the highest in the time series. Larvae in June would have been exposed to temperatures of ~ 4 – 5 °C in 2017 and ~2.3 – 3.3 °C in 2019.

Net northward transport from the NBS to the Chukchi Sea averaged over the larval period (April-June) has increased over the past two decades from ~ 0.7 Sv ($1Sv=10^6 m^3/s$) in 2000 to ~ 1.5 Sv in 2017, the record maximum (Figure 3).

Larval distributions and temperatures

Larvae were present in the NBS near the Bering Strait in 2017 and 2018 at sites with water temperatures which ranged from 2.6 to 3.7 °C and 2.1 to 6.0 °C on average in 2017 and 2018, respectively (Figure 4).

Age-0 cod in the ECS

Distribution and temperature

Age-0 cod ranging in length from 45 to 94 mm SL (49 – 103 mm FL) were caught in the surface, midwater, and small-mesh benthic trawls in 2017 and 2019 in the ECS (Figure 5). Age-0 cod were absent from the ECS in 2012; however, the only trawl type deployed in 2012 capable of catching small juveniles was the small-mesh benthic trawl. Detailed results are reported by trawl type.

In 2017, age-0 cod were present in the surface trawl catch at one station near Point Lay, and at several stations from the vicinity of Cape Lisburne to the southern end of the survey area (Figure 6). In 2019, age-0 cod were caught only at the most northerly surface trawl station, between Point Lay and Cape Lisburne. Surface temperatures where age-0 cod were present i
n the surface trawl ranged from 5.0 – 6.2 °C in 2017, and surface temperature was 9.3 °C at the one station with age-0 presence in 2019. In both years, age-0 cod were present at stations near the median temperatures of all available surface trawl stations (Figure 7). Bottom temperatures at stations where age-0 cod were caught in the surface trawl were slightly colder than surface temperatures (range = 4.1 – 5.6 °C) in 2017; however, bottom temperature was slightly warmer at the one station with age-0 presence in 2019 (Figure 7).

In 2017, age-0 cod were present in the midwater trawl catch at stations from offshore of Point Lay south to the vicinity of Point Hope (Figure 6). In 2019, the observed distribution of age-0 cod shifted north, with absences near Point Hope and Cape Lisburne, and presences north of Point Lay. Age-0 cod were present in the midwater trawl catch at stations with gear temperatures ranging from 4.6 – 6.7 °C and 2.3 –

10.0 °C in 2017 and 2019, respectively. Age-0 cod were almost exclusively caught in the midwater trawl at locations warmer than the median temperature of all midwater trawls (Figure 7). At stations with age-0 presence, bottom temperatures were colder than the midwater gear temperatures, however, generally by less than 1 °C (Figure 7).

In 2012, age-0 cod were absent at all 40 stations sampled with the small-mesh benthic trawl (Figure 8). In 2017, age-0 cod were present at 11 of 59 sampled stations, from offshore of Point Lay south to the southern edge of the sampling grid, including at 7 stations which had been sampled in 2012 (Figure 8). CPUEs at stations with fish presence in 2017 ranged from about 1350 – 46,000 age-0s km^{-2}. In 2019, age-0 cod were present at 4 of 49 sampled stations, at CPUEs ranging from about 1700 – 7,100 age-0s km^{-2} (Figure 8). Age-0 cod were present in bottom temperatures ranging from 2.5 to 5.9 °C and 4.4 to 9.5 °C in 2017 and 2019, respectively. Station bottom temperatures during the 2017 and 2019 surveys ranged from below 0 °C in the northern part of the survey area to near or exceeding 10 °C in the inshore and southern part of the survey grids each year (Figures 7 and 8). In the mooring data, June temperatures in the Bering Strait were colder in 2012 than in 2017 and 2019 (Figure 3), and summer bottom temperatures were colder in the northern and offshore stations in 2012 than in 2017 and 2019 (Figure 8). However, bottom temperatures at the southern and nearshore stations with age-0 cod presence in 2017 were generally warmer in 2012 than in 2017 (Figure 8), and the range of available bottom temperatures surveyed by the bottom trawl in 2012 included the temperature range where age-0 cod were present in 2012 and 2019 (Figure 7).

Age-0 catch rates by depth

Catch rates of age-0 cod by bottom depth varied by gear type in a similar pattern each year (Figure 9). The highest catch rates in the small-mesh benthic trawl were between 20 and 29 m and 30 to 39 m bottom depth in 2017 and 2019, respectively, and in both years, catch rates were lower at depths greater than 40 m. In contrast, the highest catch rates in the midwater trawl were at greater bottom depths; between 40 and 59 m in 2017, and between 40 and 49 m in 2019. Catch rates in the surface trawl were highest in the 20 – 29 m bottom depth range, however the surface trawl was fished only at nearshore station, and most surface trawls occurred over relatively shallow bottom depths.

Age-0 diet by gear type

Age-0 cod collected in all the surface, midwater, and small-mesh benthic trawls in 2017 consumed a variety of prey taxa (Table 2, Figure 10). Copepods were the most important (importance measured by % PSIRI) prey taxa for fish collected in all three gears (Figure 10), with benthic-caught fish primarily consuming the epibenthic calanoid copepod species *Eurytemora herdmandi* (PSIRI = 13.55%), while the surface- and midwater-caught fish primarily consumed various pelagic calanoid copepods (PSIRI = 70.54% and 26.40% for the surface and midwater trawls, respectively). The benthic-caught age-0 cod also consumed near equal percentages of a taxonomically-broad suite of prey items; including benthic prey taxa such as polychaetes, benthic amphipods, benthic decapods, and benthic cnidarians (anemones). The most important prey taxa for the pelagic-caught fish, after calanoid copepods, were decapods for the surface trawl-caught fish, and fish (unidentified Gadidae) and decapods for the midwater trawl-caught fish. The niche overlap indices for diets of age-0 cod caught in the benthic and pelagic trawls were low (benthic and midwater = 0.01, benthic and surface = 0.08), indicating little overlap in diets and somewhat higher overlap for the diets of the two pelagic trawls (surface and midwater = 0.2). Grouped by general habitat classifications, prey of the pelagic-caught fish were almost entirely pelagic or unknown, while the benthic-caught fish also consumed endo-, epi-, and hyper-benthic prey (Figure 10).

Age-0 Condition: ECS versus GOA

Two measures of condition, length-weight residuals and total fatty acid concentration, were compared between age-0 cod from the ECS and the nearshore GOA (Fig. 11). Age-0 cod from the GOA were longer and heavier than age-0 cod from the ECS even though they were collected in August compared to fish collected in September in the ECS. Fish from the GOA in August averaged ~80 mm SL and weighed 5 grams while fish from the ECS were ~67 mm SL and 3 grams. The residuals from the log-length and log-weight relationship demonstrated that fish from the GOA were heavier at a given length than fish from the ECS. Total fatty acids per WWT did not increase with length (r^2=0.02). The residuals from the length to total fatty acids relationship showed that fish from the GOA had a higher concentration of fatty acids per WWT at a given length than fish from the ECS ($p<0.001$). Both morphometric condition and that based on length-lipid concentration showed that fish from the GOA were in better condition at the end of the summer/fall than fish from the ECS.

Age-1 and adults

WCS distributions and temperatures

Cod were absent from the trawl sampling in the WCS in 2010 (Figure 12). Both age-1 juveniles and adults were present in the WCS in 2018 and 2019 (Figure 12). In both years, there was a length mode of juveniles (assumed to be age-1), from 130 – 180 and 100 – 230 mm FL in 2018 and 2019, respectively, and larger adult-sized fish, from 660 – 780 and 550 – 750 mm FL in 2018 and 2019, respectively (Figure 5). Although there were two juveniles larger than 180 mm FL in 2019, there was little evidence of a new length mode of fish greater than 180 mm FL in 2019, and these two fish are also assumed to be age-1. CPUEs of age-1 cod at stations where they were present ranged from 23 – 133 and 9 – 95 fish km^{-2} in 2018 and 2019, respectively. A total of five adult cod were caught in 2018 and four in 2019. Estimated densities of adult-sized fish, where they were present, ranged from 12 – 24 and 10 – 22 fish km^{-2} in 2018 and 2019, respectively. CPUEs by weight for the age-1 and adults combined at stations where they were present, and in units for comparison with previous reports in the Bering Sea were 0.004 – 1.54 and 0.0018 – 1.073 kg ha^{-1} in 2018 and 2019, respectively.

Bottom temperatures where cod were present ranged from 1.9 – 4.7 °C and 3.3 – 4.7 °C for age-1s and adults, respectively in 2018 (Figure 7), and from 1.4 – 4.9 °C and 0.4 – 4.9 °C for age-1s and adults, respectively in 2019 (Figure 7). Although 2010 was a year with cold temperatures in the Bering Strait in June (Figure 3), much of the sampled area in the southwestern Chukchi Sea in 2010 was within the bottom temperature range that contained cod in 2018 and 2019 (Figures 7 and 12).

ECS distributions and temperatures

Age-1 cod were present at three stations in 2012 in the large-mesh benthic trawl in the ECS (Figure 12). These age-1s ranged in size from 100 – 130 mm FL (Fig. 5), and CPUE from 44 – 106 fish km^{-2}. Adults were absent at all stations in the ECS in 2012.

Bottom temperatures where age-1 cod were present in 2012 in the large-mesh benthic trawl sampling ranged from 1.3 – 9.9 °C (Figure 7). Similar to 2010 in the WCS, 2012 was a year with cold June water temperature in the Bering Strait, (Figure 3); however, much of the sampled area in the shallow southeastern Chukchi Sea in 2012 was as warm as or warmer than areas with age-1 and adult presence in the WCS in 2018 and 2019 (Figures 7 and 12).

In addition to the age-0 cod caught in the midwater trawl (section 3.3.1), one much larger (64.7 cm FL) adult was caught using the midwater trawl during a tow that fished near the benthos at the southern end of the survey area in 2019 (Figure 6).

Discussion

Age-0 and adult cod were absent from the Chukchi Sea in the cold years and present in recent warm years of this study. One question is whether the observed increases in age-0 and adult cod are related to temperature and recent Arctic warming. We hypothesize that changes in annual springtime conditions at the Bering Strait and in the NBS are a possible reason for the observed increase in age-0 cod in the Chukchi Sea. In 2012, a cold year, larvae near the Bering Strait in June would have been exposed to cold (estimated ~0.5 to 1.5 °C) water. The growth of cod larvae is highly temperature-dependent and survival in the laboratory is reduced at 2 °C (Hurst et al., 2010). Unfed yolksac larvae can survive lower temperatures (e.g., 0 °C), but growth and development rates are very slow (Laurel et al., 2008) and hatch success is poor (Laurel and Rogers, 2020). It is therefore unlikely that eggs and larvae have historically occupied these Arctic regions where juveniles have recently been observed. We note that larvae were observed near the Bering Strait in June in warm years, which would have likely contributed to better larval survival and increased presence of age-0 fish in the Chukchi Sea in 2017 and 2019. Warm June temperatures at the Bering Strait also occurred in a previous year (2007) when age-0-sized cod were observed in the Chukchi Sea (Mecklenburg et al., 2011), and two years when age-1 fish observed in this study would have been larvae (age-1 fish observed in 2012 and 2019 would have been larvae in June of 2011 and 2018).

Warm temperatures in the NBS and Bering Strait during the larval period may also cause successful larval delivery to the Chukchi Sea by other mechanisms (or a combination of mechanisms), such as by shifting spawning northward in the Bering Sea, improving egg survival (Laurel and Rogers, 2020), or improving larval prey fields (Laurel et al. 2021). Increased ocean transport during the larval period from the NBS to the Chukchi Sea may also be a cause or partial cause of the age-0 cod observed in the Chukchi Sea in recent years, which would be similar to pollock (*Gadus chalcogrammus*), a pelagic boreal species that has been observed in the Chukchi Sea in recent years of high transport (Orlov et al., 2019, 2020, 2021; Levine et al., this issue; Antonov et al., this issue; Emelyanova et al., this issue).
Recent adult cod presence in the Chukchi Sea may also be related to warmer temperatures in the NBS and Bering Strait in the spring. Adult cod avoid the cold pool in the EBS (Kotwicki and Lauth, 2013), and the movement of adult cod into the NBS between 2010 and 2017 coincides with a reduction in the cold pool in the NBS (Stevenson and Lauth, 2019; Baker, 2021). Preliminary tagging data suggests that adult cod move from the EBS into the NBS after sea ice has retreated northward in the spring and summer (J. Nielsen, Kingfisher Marine Research, and S. McDermott, AFSC, personal communication, February 23, 2021). Based on these tagging data, it is possible that the early ice retreat in both 2018 and 2019 (Stabeno and Bell, 2019; Siddon et al., 2020) allowed the fish to reach the Bering Strait early enough in the year to continue northward into the Chukchi Sea by August.

Increased temperatures on the Chukchi Sea shelf in the summer are less likely to be the cause of the increased cod presence in recent years than temperatures in the NBS and Bering Strait. Annual summer water temperatures on the ECS shelf have increased since 2014 (Danielson et al., 2020); however, even in the earlier and colder years of this study (2010 and 2012), when age-0 and adult cod were absent, some of the sampled habitat was warm enough (based on observed presence in 2017 and 2019) to support cod. The entire water column of the relatively shallow southeastern Chukchi Sea warms in the summer due to both advection and wind mixing (Grebmeier et al., 2015; Woodgate et al., 2015), and the nearshore areas are in the Alaska Coastal Current, which is typically warmer than the rest of the shelf from June to at least October (Woodgate et al., 2010; Woodgate, 2018). Even in the cold years of this study, the Chukchi Sea appeared warm enough during the summer for age-0 and adult cod to be present.

Age-0 cod in the Chukchi Sea use both pelagic and demersal habitats, which is similar to their habitat use in the EBS (Hurst et al., 2015). Diet differences between age-0 fish in pelagic and benthic habitats imply that age-0 cod remain at a habitat type for, at minimum, a daily feeding cycle. In the EBS, age-0 cod are

pelagic over deeper water and benthic in nearshore shallower areas, which is possibly related to temperature; the juveniles occupy demersal habitat in inshore areas with relatively warm bottom temperatures, and occupy warmer pelagic habitat when they are over deep water with cold benthic habitat (Hurst et al., 2015). Age-0 habitat use in the Chukchi Sea fits the same general pattern, with the addition that some fish use the pelagic nearshore habitat. This may mean that, in addition to temperature, fish in nearshore areas may select their depth in the water column based on some other factor, such as localized prey fields, or salinity.

The absence of a length mode of juveniles in the ECS in 2019 larger than that observed in 2018 suggests that the age-1 cod in 2018 may not have survived to age-2. All previous reports of cod from the ECS have been of juvenile-sized fish (Barber et al., 1997; Mecklenburg et al., 2011, 2018; Logerwell et al., 2015). It seems that cod juveniles in the Chukchi Sea either suffer high mortality rates, or migrate to other areas prior to adulthood.

The juveniles in the Chukchi Sea may not be able to successfully grow and provision themselves well enough to survive to become adults. Condition (lipid densities and weight at length) was lower in the 2017 age-0 cod from the Chukchi Sea than those from the GOA. Lipid densities were also lower in the age-0 cod in this study than in co-occurring gadids in the Chukchi Sea in 2017 (Copeman et al., this issue). The age-0 cod in the Chukchi Sea in this study inhabited colder waters (2017, 2 – 6 °C) than age-0 cod during the summer in the EBS (~6 – 12 °C; Hurst et al. 2015; Hurst et al., 2018) and the Gulf of Alaska (~8 – 11 °C; Abookire et al., 2007; Laurel et al., 2016a). Further, summer temperatures in the Chukchi Sea are lower than those modeled for maximum growth (~11.0 to 11.5 °C) and maximum lipid accumulation (10 °C) in controlled laboratory growth experiments (Laurel et al., 2016b; Hurst et al., 2010; Hurst et al., 2012b; Copeman et al., 2017). Thus, temperatures during the summer in the Chukchi Sea may be too low for juvenile cod to achieve sufficient size or energetic thresholds to survive long, low-productive Arctic winters. Future monitoring of age-0 cod in the Chukchi Sea should include both growth and condition metrics.

The abundance of age-0 cod in the ECS is potentially high enough to be ecologically meaningful if they could survive to adulthood. Only small numbers of juveniles were caught with our small-mesh benthic trawl, but catch rates in the nearshore areas of the ECS were similar to catch rates in EBS nursery areas using a similar trawl (Hurst et al., 2015; Table 3); however, they were one order of magnitude lower than catch rates in GOA nursery areas in high-abundance years (Table 3). An abundance estimate based on our limited number of stations in 2017 should be viewed with caution, but it provides a general sense of the potential number of cod juveniles in the ECS in 2017. Benthic trawl catch rates in the ECS were highest from 67 °N to 69 °N inshore of 40 m bottom depth, an area of approximately 14,500 km^2. Mean catch rates here were approximately 12,000 fish per km^2. Assuming the trawl caught all of the fish in the towpath, and our sampling was representative of the area, mean density multiplied by area would equal approximately 174 million fish present in 2017 within the area from 67°N to 69 °N inshore of 40 m bottom depth. Alternatively, estimating abundance from the mean catch rates and area of the entire survey area south of 70 °N provides an estimate of approximately 150 million fish. Even if these estimates are high, there were tens of millions of age-0 cod in the ECS in 2017. If these or future age-0 cod survive to adulthood, and either remain in the Chukchi Sea or successfully migrate to other spawning areas, it would mean a northward expansion of cod nursery area habitat, which is one type of poleward distribution shift that has been documented in marine fish due to ocean warming (Rindorf and Lewy, 2006; Nye et al., 2009; Figueira and Booth, 2010).

Densities of adult and age-1 cod estimated in this study are very low compared to reports from the Bering Sea. CPUE by weight for combined age-1 and adult fish at stations where fish were present ranged from 0.0018 to 1.5 kg/ha in this study. Even in 2010, when cod were considered “almost completely absent” from the NBS, cod CPUE values at some stations were greater than 10 kg/ha, and CPUE values in the

EBS may be greater than 50 kg/ha (Stevenson and Lauth, 2019). These catch rate comparisons are between the DT 27.1/24.4 bottom trawl used in the WCS in this study, and the 83-112 trawl used in the NBS and EBS, however catchability differences seem unlikely to cause the much lower CPUE values observed in the WCS in this study. In the western Bering Sea (WBS), cod densities have been reported from surveys using the same large-mesh trawl as used in the WCS in this study (Shuntov et al., 2014). Cod densities in the WBS were summarized by statistical regions and depth range over the time period from 2006 through 2012. In regions and depth ranges where cod are present in the WBS, reported mean densities ranged from 235 to 7,631 kg ha-1, however these densities assumed that only 40% of fish encountering the trawl were retained by the trawl (Shuntov et al., 2014). To make these numbers comparable to the CPUE units used in this study (100% of fish retained), the values reported by Shuntov et al. (2014) were multiplied by 0.4. These converted mean CPUE values are 94 to 3,052 kg ha-1 and are much higher than even the peak CPUE values observed in the Chukchi Sea in this study.

Although estimated densities were low, the adult cod observed in the WCS (and the one adult caught in the ECS) in this study are among the first known (to us) adult Pacific cod caught in the Chukchi Sea. The only other is an adult Pacific cod caught in a subsistence fishing net near Point Hope, AK, in August 2020, and reported as a novel occurrence to the Alaska Arctic Observatory and Knowledge Hub (AAOKH; Donna Hauser, International Arctic Research Center, University of Alaska Fairbanks, personal communication, January 29, 2021). The lack of observed intermediate size ranges of fish between age-1 and adults makes it likely that there is not a self-recruiting cod population in the Chukchi Sea, and that the adults likely moved northward from the Bering Sea, similar to how adults moved into the NBS from the EBS (Stevenson and Lauth, 2019). Only one adult was caught in the ECS during this study, but it was caught when the pelagic midwater trawl was incidentally fished on the bottom while targeting a deep acoustic layer. It is possible that adults and larger juveniles were also present at other sampling stations in the ECS in the recent warm years of this study, but avoided the pelagic and small-mesh benthic sampling gear. Adult cod are primarily benthic (Fadeev, 2005; Nichol et al., 2007) and would not be available to the pelagic trawls, and could also likely avoid the small-mesh benthic trawl due to the small mouth opening and slow fishing speeds (Lauth et al., In prep). Therefore, the presence of larger juvenile and adult cod in the ECS is unknown and will remain unknown until the area is surveyed across a range of habitats with gear suited to their capture.

The data presented here show that multiple life stages of Pacific cod were present in the Chukchi Sea in recent warm years, which suggests that the species is expanding into the Chukchi Sea by both recruitment and adult movement. However, the true extent of this range expansion, its potential to persist into the future, and the ultimate fate of individuals that move into the Chukchi Sea, are still unknown. Monitoring surveys designed to estimate abundances and condition of multiple life stages are required to better understand this poleward distribution shift, and to assess its impacts to the ecosystem.

Acknowledgments

We thank Aleksey Somov (TINRO, Vladivostok, Russia) for first noticing the difference between juvenile saffron cod (*Eleginus gracilis*) and Pacific cod in our trawl catches during the 2017 Arctic IERP cruise. We also thank the captains, crews, and scientists aboard the RV *TINRO*, FV *Alaska Knight*, RV *Ocean Starr*, and RV *Professor Levanidov* for deploying the trawls and processing the catches. We thank James Orr and Duane Stevenson of the AFSC for visually confirming the identities of some Pacific cod voucher specimens, as well as Sharon Wildes and others at the AFSC for genetic confirmation of vouchered fish identification. We thank Brian Voss, Director of the NOAA Western Center Regional Library for locating several historical publications. We thank the Plankton Sorting and Identification Center in Szczecin, Poland, and the Alaska Fisheries Science Center ichthyoplankton team for their larval fish taxonomic expertise. We thank Carlissa Salant and Michelle Stowell at the Marine Lipid Ecology Lab in Newport, OR, for help with juvenile fish dissection and fatty acid analyses. This work is

contribution EcoFOCI-1001 to NOAA's Ecosystems and Fisheries-Oceanography Coordinated Investigations (EcoFOCI), and was funded by the North Pacific Research Board Arctic Integrated Research Program, and NOAA Essential Fish Habitat research funds. Funding for the Bering Strait mooring work is currently through NSF-OPP, (awards: PLR-1304052, 1758565), and Bering Strait mooring data and products are available at psc.apl.washington.edu/BeringStrait.html. The 2012 Arctic ecosystem integrated survey (EIS) was funded by the Bureau of Ocean Energy Management (BOEM), and the Coastal Impact Assistance Program (CIAP). Ingrid Spies and Duane Stevenson of the AFSC provided thoughtful reviews of previous versions of the MS and greatly improved the final version.

Chapter 3: Seasonal and geographic variation of marine mammals in the northern Bering Sea

Stafford, K.M., Danielson, S.L. *in preparation for submission to Polar Biology*

The Pacific Arctic Region (PAR), which includes the Bering Strait region, and Chukchi and Beaufort Seas, is a bellwether for climate change in the Arctic with sea ice extent and thickness decreasing and freshwater and heat content increasing. In 2017-2018, the PAR experienced extreme warming evidenced by high water temperatures and greatly reduced seasonal sea ice in the northern Bering and Chukchi Seas. The biological responses to these extreme physical changes are complex but may result in ecosystem shifts from primary productivity to upper trophic predators. To observe the response of upper trophic level species via changes in occurrence and/or distribution over both temporal and spatial scales, passive acoustic recorders were deployed on three ecosystem moorings in PAR hotspots: the northern Bering Sea off western St Lawrence Island, in the Chukchi Sea at Hanna Shoal, and on the shelf break of the western Beaufort Sea from 2017-18 (Figure 5).

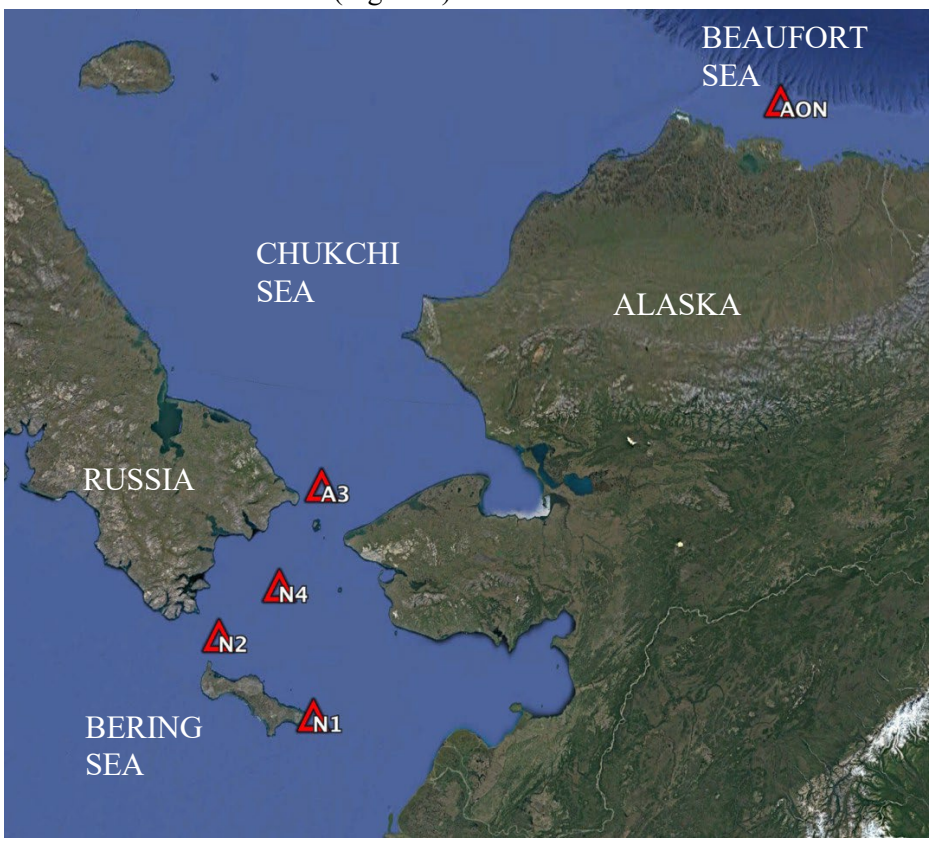

Figure 5. Map of the Pacific Arctic showing the locations of the five hydrophones used to examine the geographic variation in marine mammal occurrence.

To examine whether there were north-south or east-west changes in the presence of marine mammals, acoustic data from five biophysical moorings were used, including three from the ASGARD project (Table 1). Additional data were from a mooring just north of the Bering Strait (A3) and one from the

western Beaufort Sea (AON). Spectrograms of each acoustic data file were reviewed for the presence of marine mammals which resulted in time series of species presence by hour.

Mooring ID	Latitude	Longitude	Date range	Sample rate (Hz)	Duty cycle (min/hr)
N1	63 17.8	-168 25.7	8/1/17-6/28/18	16384	
N2	64 09.3	-171 31.6	6/8/17-7/7/18	16384	25/60
N4	65 55.7	-169 55.1	6/25/17-7/7/18	16384	25/60
A3	66 19.6	-168 57.6	7/14/17-7/7/18	16384	18/60
AON	71 24.0	-152 00	7/1/17-7/31/18	16384	5/60

The hydrophones in the Bering Sea (N1, N2, and N4) had the greatest seasonal occurrence of both subarctic and Arctic species. N2 and N4, in Anadyr Strait, showed that while subarctic and Arctic species had peak occurrences during different seasons, there was nevertheless extensive overlap in early winter of fin, humpback and bowhead whales. This overlap and overall community compositions decreased further north such that the only subarctic species detected in the Beaufort Sea was killer whales, which appear to have extended their distribution both northwards and eastwards into the Beaufort Sea (Willoughby et al. 2020; Stafford et al. 2022). The Arctic endemic species bowhead and beluga whales were each detected later in the fall and winter and earlier in the following spring along their migratory route in the Chukchi and Beaufort Seas.

Hypothesis 4 above seeks to understand whether there are north-south and east-west differences in marine mammal occurrence in the Bering Strait region. Although longer time series are required to understand how robust the patterns are, there is more acoustic diversity and longer acoustic seasonality of both subarctic and Arctic species to the west of St Lawrence Island than to the east and biodiversity decreases from south to north (Figure 6 and 7). Changes in sea ice extent and seasonality appear to be the most obvious drivers of the presence/absence of marine mammal species in the PAR (Figure 8). Understanding how these broad changes impact the smaller scale physical and lower trophic level biological environments that influence the phenology, residence time, and community composition of marine mammals, may shed light on whether an ecosystem transformation is underway in the Pacific Arctic and how robust the changes are. Given the recent proposal that 2017-2018 represented an ecosystem shift in the Pacific Arctic (Ballinger and Overland, 2022), the acoustic data presented here will be further explored in this context going forward.

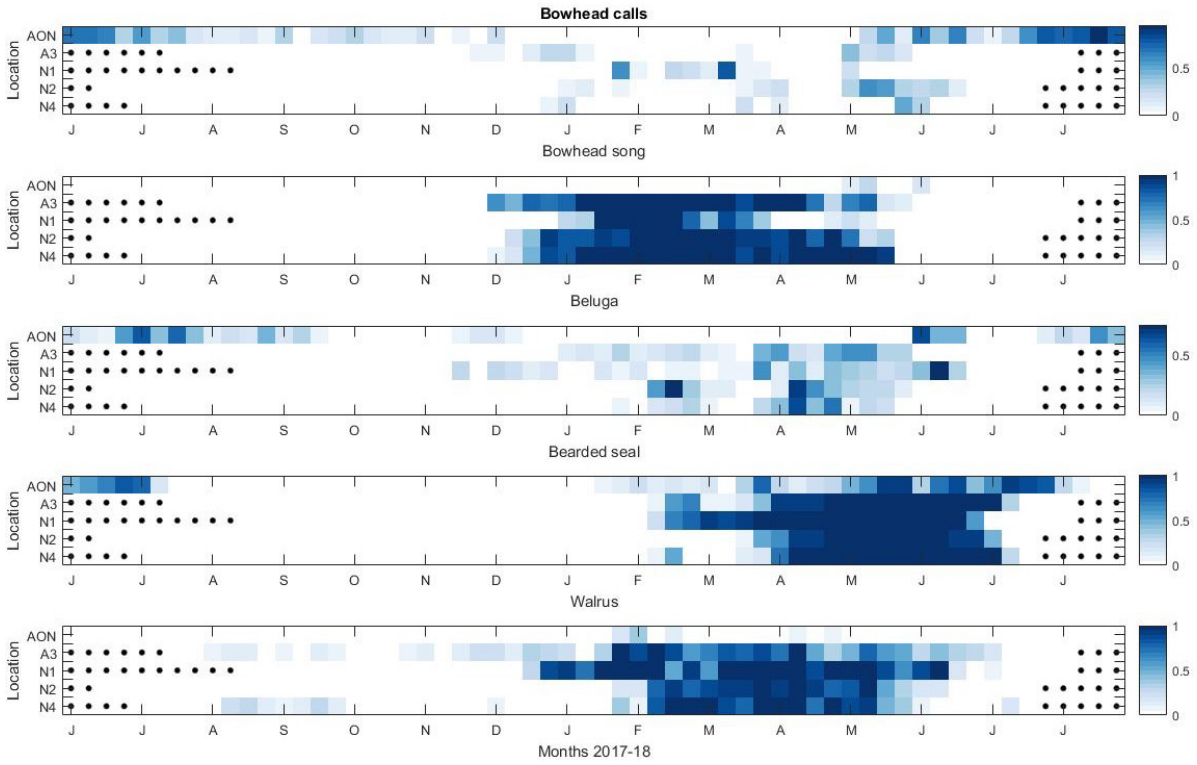

Figure 6. Seasonal occurrence of Arctic marine mammals from northern Bering Sea (N1, N2, N4) through the Bering Strait (A3) and into the Beaufort Sea (AON). Black dots indicate periods with no data.

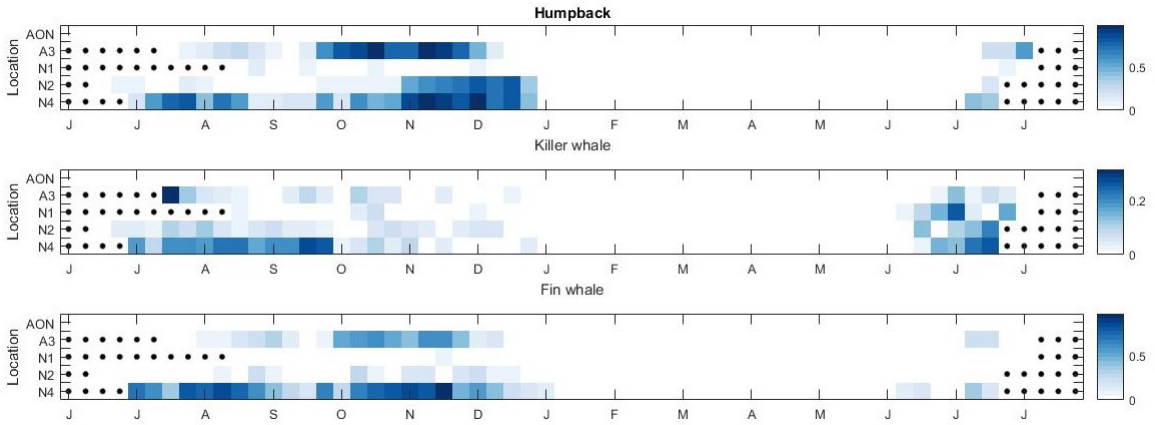

Figure 7. Seasonal occurrence of subarctic marine mammals from northern Bering Sea (N1, N2, N4) through the Bering Strait (A3) and into the Beaufort Sea (AON). Black dots indicate periods with no data.

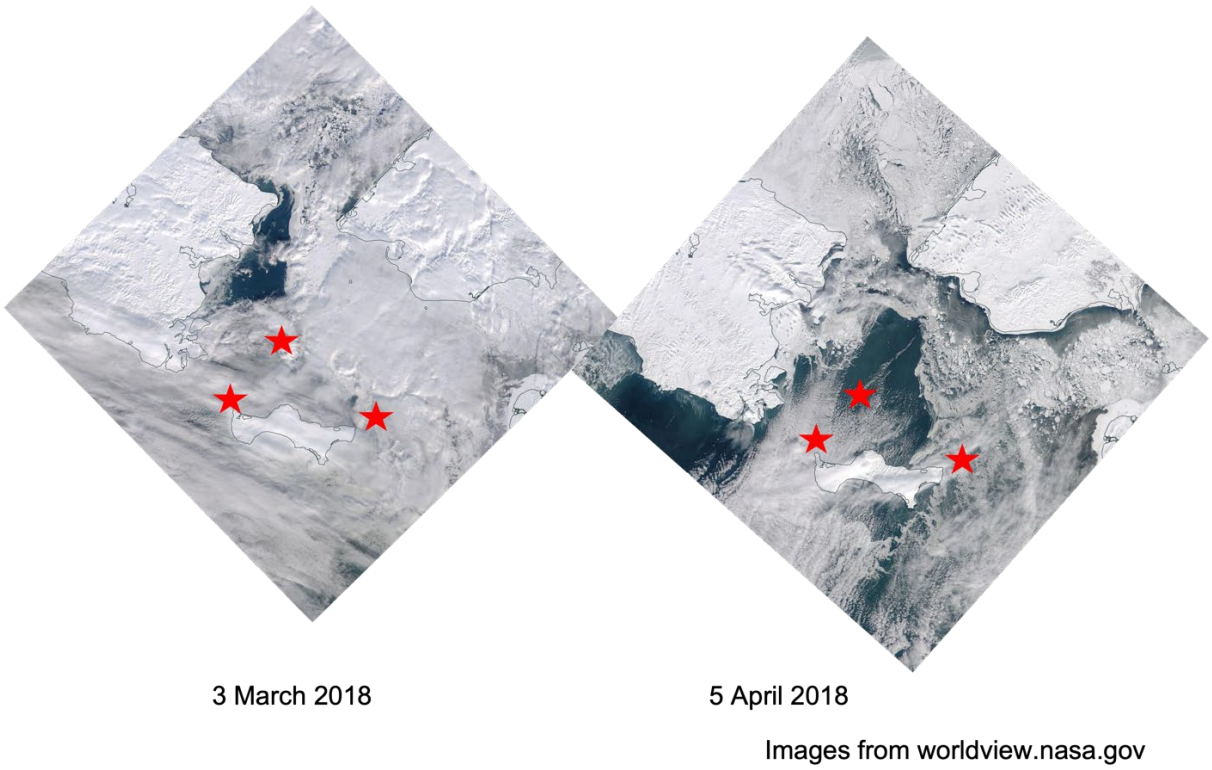

Figure 8. Sea ice coverage in the northern Bering Sea in March and April 2018 illustrating the greater extent of ice in the eastern region as compared to the west. Mooring locations from east to west are N1, N4, N2.

Chapter 4: Long-term marine mammal occurrence at the Chukchi Ecosystem Observatory

Stafford, K.M., Danielson, S.L., Escajeda, E. *in prep* Walrus and Bearded Seal Detections at the Chukchi Ecosystem Observatory 2016-2020

The Arctic as we know it is experiencing changes that range from invasions from subarctic species, changes in phenology of arctic species, and changes in Arctic food webs. The added pressure of increased economic ventures highlights the urgent need for long-term observations in the Arctic Ocean, including changes in biodiversity. Chukchi Ecosystem Observatory (CEO) was established in 2014 to provide year-round observations of core physical, chemical and biological processes in the Arctic. The CEO mooring is located in the biological "hotspot" located on the NE Chukchi Sea shelf near Hanna Shoal at 71°36N, 161°31.6W, where a thriving benthic community supports a major walrus foraging ground during summer and fall months. Beginning in 2015, a passive acoustic recorder was added to monitor the presence of vocal marine mammals and the overall Essential Ocean Variable of 'sound.'

The hydrophone package was programmed to record acoustic data from 10 Hz to 8 kHz on a 25% duty cycle (the first 15 min of every hour) for the duration of each year's deployment at the Chukchi Ecosystem Observatory (Figure 4 above). Upon recovery, the data were visually and aurally examined to determine the presence/absence of walrus and bearded seal vocalizations (Figure 9).

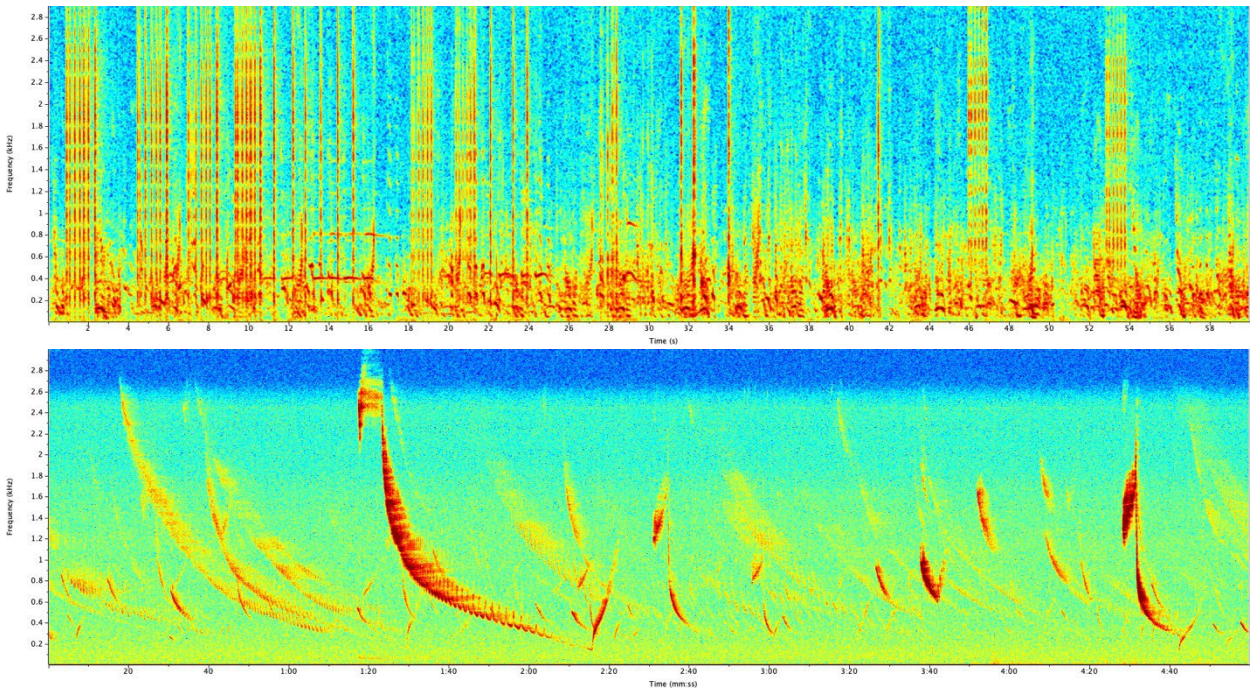

Figure 9. Spectrograms of characteristic signals produced by walrus (top panel) and bearded seals (bottom panel) used to detect the presence of each species. Note the different time axes.

Each of these species contribute significantly to the overall underwater soundscape at the CEO but at different times of the year (Figure 10). Walrus sounds started in late May, when sea ice concentration began to abruptly decrease and were heard continuously until early November annually. Walrus vocalizations ceased 1-3 weeks before sea ice began to form in autumn. In contrast, bearded seals were only seldom heard during the open water period, but their vocalizations were recorded 24h/day as soon as sea ice concentrations increased to over ~75% in early December. Bearded seal trills were heard through late June/early July and declined with sea ice concentration, except for 2019, when there was little or no ice at the CEO from late May to mid-June, when bearded seals were nevertheless recorded at very high levels. Although both walrus and bearded seals are Arctic endemic species that rely on sea ice for critical life history stages, and fill similar ecological niches, they clearly have different timing in their occupation of the CEO/Hanna Shoal region. This suggests that these Arctic pinnipeds may be partitioning this region of the Arctic based on the presence or absence of sea ice.

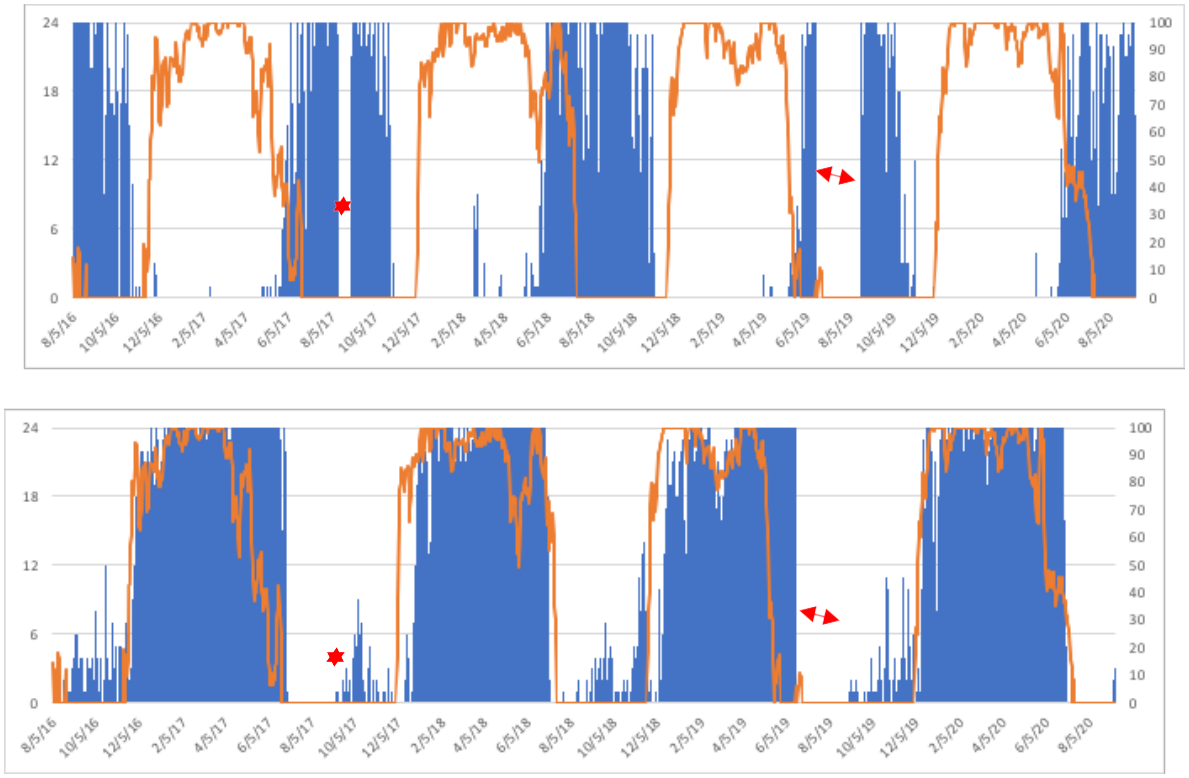

Figure 10. Acoustic detections of walrus (top panel) and bearded seals (bottom panel) with sea ice concentration (orange line) at the Chukchi Ecosystem Observatory from 2015-2020. Red star and arrows indicate missing data.

The presence of walrus at the CEO site was consistent from year to year; this species was heard from May until late October annually and likely reflects the migratory phenology of Pacific walrus. The modeled distribution of radio-tagged walrus which consistently showed walrus at the Hanna Shoal region from 2009-2011 (Jay et al. 2012). However, the high number of hours with detections in October is somewhat inconsistent with these earlier data and with the acoustic detections reported by Hannay et al. (2013). Clearly, walrus have changed their haulout behavior in the Chukchi Sea as the decline of sea ice has resulted in thousands of animals on shore of northwestern Alaska (Jay et al. 2012, 2017; Udevitz et al.,

2018; Fischbach et al. 2022). Jay et al. (2017) examined walrus haulout behavior on ice and found that walrus were less likely to be hauled out in windy conditions with cool air temperatures. Future work will include comparing the acoustic detections with wind speed and air temperature to determine if there are more acoustic detections due to animals being in the water.

Bearded seals appear to be year-round residents of the Chukchi Sea (Macintyre et al. 2013) however, they are only vocally active seasonally. Males produce elaborate trills (see Figure 9 above) to attract females and for male-male interactions. Bearded seal trill production is closely linked to their breeding season and the presence of sea ice on which they haul out, give birth and nurse young (Macintyre et al. 2015). During the open water season, bearded seals are present in the Chukchi Sea but produce many fewer sounds. Bearded seal trill seasonality closely matched the mean sea ice concentration at the CEO with the exception of spring 2019 when sea ice disappeared in early June but bearded seals continued to be heard until the hydrophone stopped recording in mid-June that year. The seasonality seen at the CEO from 2016-2020 is similar to that seen a decade prior (Hannay et al. 2013) when sea was more extensive in the region.

Chapter 5: Shipping noise in the Bering Strait region

Escajeda, E., Stafford, K.M., R. Woodgate, K.L. Laidre. *Under revision.* Quantifying the effect of ship noise on the acoustic environment of the Bering Strait. *Submitted to the Journal of the Acoustical Society of America.*

These data and analysis will form part of the PhD dissertation of Erica Escajeda at the University of Washington. This manuscript is currently under revision.

Abstract

The Bering Strait is the only conduit between the Pacific and the Arctic Oceans, making it an important location to study ship noise. We used *in situ* measurements to examine how ship noise impacts the Bering Strait soundscape during the open-water season (June–November) for 2013–2015, including quantifying ship source levels and modeling the extent of elevated sounds levels due to the presence of a ship. We also examined the relationship between ship source levels and vessel speed under varying wind conditions. Ships elevated ambient sound levels during the open-water season by ~6 dB on average, and moving vessels produce potentially harmful sound levels for marine mammals (≥120 dB re 1 μPa) out to ~0.9 km away, depending on the vessel type. We did not find significant relationships between vessel speed and source levels for the two major vessel types observed in the strait, cargo (n = 10) and tugboats (n = 19), indicating that other untested factors may influence vessel source levels in the area. Both wind and water speeds were significantly correlated to sound levels measured during the open-water season, indicating that environmental conditions need to be accounted for when examining ship noise in a shallow-water environment.

I. INTRODUCTION

Declining sea ice is opening the Arctic to increased ship activity, potentially impacting the acoustic habitat of marine mammals that inhibit Arctic waters (Moore *et al*., 2012; Halliday *et al*., 2017, 2021; Hauser *et al*., 2018). Known impacts of shipping on marine mammals include masking of important biological signals (Clark *et al*., 2009; Pine *et al*., 2018), increasing stress hormone levels (Rolland *et al*., 2012), and provoking avoidance behavior (Nowacek *et al*., 2007; Southall *et al*., 2007). Shipping in the Arctic is increasing (Eguíluz *et al.*, 2016), and the two major shipping routes—the Northwest Passage through the Canadian Arctic Archipelago, and the Northern Sea Route along the northern coast of the Russian Federation—are expected to see a sharp increase in trans-Arctic ship passages by 2050 (Stephenson *et al*., 2011, 2013; Smith and Stephenson, 2013). Both sea routes pass through the Bering Strait, making it an important region for studying the effects of ship noise on the underwater environment. In the present study, we set out to quantify the impact of ship noise on the soundscape of the Bering Strait region and evaluate the potential of vessel speed limits as a mitigation tool for managing ship noise.

The Bering Strait connects the Bering Sea to the south with the Chukchi Sea to the north (Fig. 1). The region is shallow (30-60 m), and relatively narrow, spanning only ~80 km at its narrowest point. The marine ecosystem of the Chukchi Sea is one of the richest in the world, home to dense aggregations of benthic invertebrates and swarms of lipid-rich zooplankton that attract marine mammals to the region (Grebmeier *et al*., 2006; Eisner *et al*., 2013; Ershova *et al*., 2015). Marine mammals endemic to the Arctic and commonly observed in the Chukchi Sea include bowhead whales *(Balaena mysticetus)*, belugas *(Delphinapterus leucas)*, walrus *(Odobenus rosmarus)*, bearded seals *(Erignathus barbatus)*, and ringed seals *(Pusa hispida)*, all of which are important subsistence species for the Chukchi, Iñupiaq, St. Lawrence Island Yupik, Siberian Yupik, and Yup'ik Peoples of the coastal Pacific Arctic (Huntington *et al*., 2015).

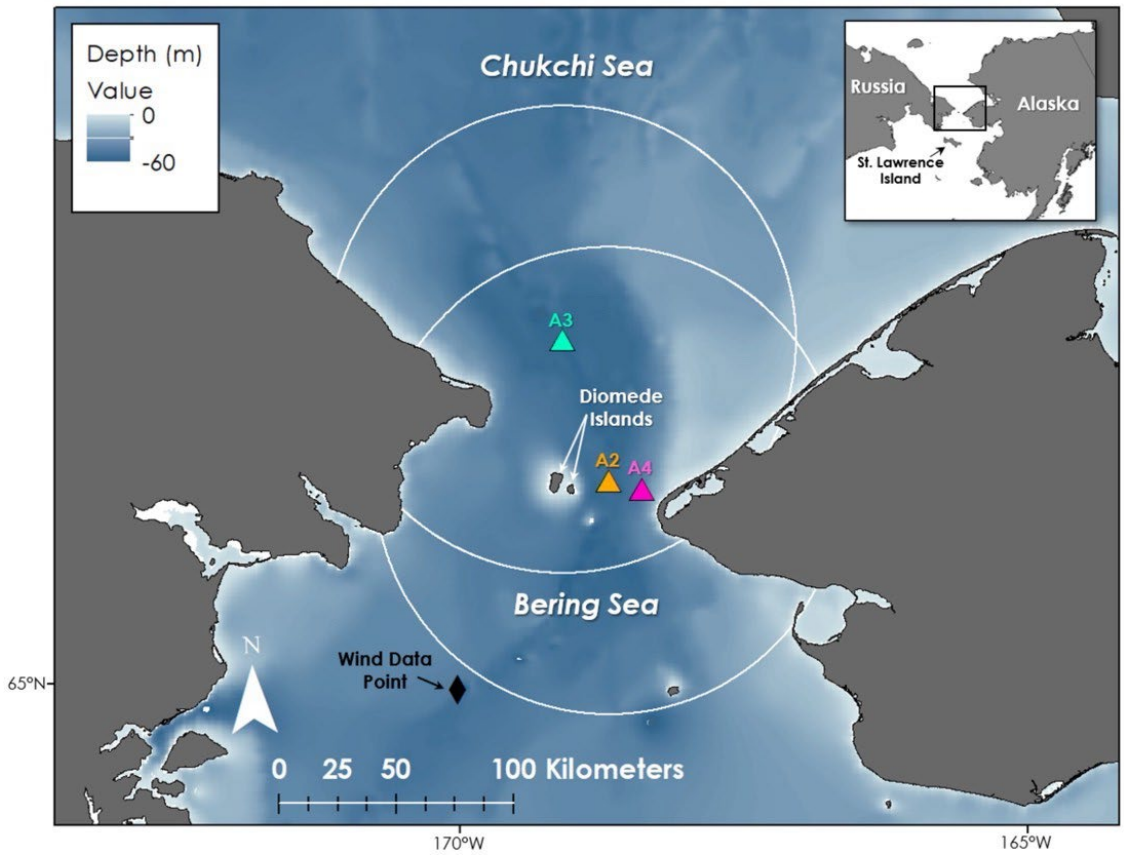

FIG. 1. Map of the Bering Strait study area with the three mooring locations—Sites A2 and A4 in the eastern channel of the strait, and Site A3 north of the strait. The nearest NCEP-NARR wind data point is located southwest of the strait (65°N, 170°W; Mesinger *et al*., 2006). The two white circles represent 100-km buffers around Sites A2 and A3, respectively, and were used for identifying ships within the Bering Strait region. Depth data are taken from the International Bathymetric Chart of the Arctic Ocean version 3.0 (500-m resolution; Jakobsson *et al*., 2012).

The seasonal ebb and flow of species into the Bering Strait region is driven by the melting of sea ice in the spring (~May), and formation of sea ice in the late fall and early winter (November–December; Frey *et al*., 2015; Serreze *et al*., 2016). When the sea ice disappears in the summer, subarctic baleen whales—namely gray whales *(Eschrichtius robustus)*, humpback whales *(Megaptera novaeangliae)*, fin whales *(Balaenoptera physalus)*, and minke whales *(B. acutorostrata)*—migrate northward into the Chukchi Sea to feed on seasonally abundant prey (Clarke *et al*., 2013; Woodgate *et al*., 2015; Brower *et al*., 2018; Escajeda *et al*., 2020). Marine mammals rely on sound as their primary sense (Richardson *et al*., 1995); consequently, the intrusion of ships into the Pacific Arctic presents a potential threat to the acoustic habitat of these animals.

Despite the looming threat of increased ship noise, there has been little work quantifying the impact of ship noise on ambient sound levels in the Bering Strait region. McKenna *et al*., (2021) examined the impact of ship noise on annual median sound pressure levels for third-octave frequency bands measured at a site west of St. Lawrence Island and found that noise measured from ships within 10 km of their hydrophone had little impact on year-round ambient levels (<1 dB difference between median sound levels with ships present and annual median sound levels for third-octave frequency bands between 100 and 1000 Hz). Instead, wind and sea ice were the most significant contributors to annual ambient sound levels (except for the 1000-Hz third octave band; McKenna *et al*., 2021). Most vessels are only able to transit the Arctic when its waters are ice-free (June-November), necessitating an examination of how ships affect ambient sound levels specifically during the open-water season.

In this study, we characterize the acoustic effects of shipping activity in the Bering Strait during the open-water season (June through November) for 2013–2015 using three moored hydrophones within the Bering Strain region. We expand upon previous work in the Pacific Arctic by Halliday *et al*. (2017, 2021) by examining the spatial impact of ship noise by modeling the "acoustic footprint" of ships, in addition to quantifying the impact of ship noise on ambient sound levels with a focus on frequency bands used by baleen whales (<1000 Hz; Southall *et al*., 2007; Moore *et al*., 2012). Lastly, we examine the relationship between ship source levels and vessel speed to evaluate speed limits as a means of reducing underwater ship noise. We take a similar approach to examining the relationship between vessel type and size. The results of our study could provide important information to managers and policymakers on the effectiveness of vessel speed limits in mitigating ship noise in the shallow-water environment of the Bering Strait.

II. METHODS

Acoustic Data Collection

We collected acoustic recordings from AURAL-M2 hydrophones (Autonomous Underwater Recorder for Acoustic Listening-Model 2; Multi-Électronique, Inc.) attached to three moorings positioned within the Bering Strait. Mooring site A2 was positioned in the center of the eastern channel and Site A4 on the east side of the eastern channel. Site A3 was positioned ~35 km north of the strait in the southern Chukchi Sea (Fig. 1). The mooring sites were originally established for measuring the physical properties of oceanic throughflow through the strait and have been collecting data for decades (Woodgate *et al*., 2015; Woodgate, 2018). The acoustic dataset we use here spans from July 2013 to December 2015. Hydrophone sensitivity was -155 dB re 1 V/µPa with a gain of 16 dB and a 16-bit recording resolution. Each hydrophone was positioned 4–8 m above the seafloor and sampled at 8192 Hz, with a 20-min (2013 and 2014) or 22-min (2015) duty cycle and varying deployment periods (Table I). All recordings were timed to start at the top of the hour.

We focused our analyses on recordings from June through November of each year since the Bering Strait is typically ice-free during this period (Serreze *et al*., 2016). Recordings were visualized in the *Ishmael* software program (2014 version; Mellinger, 2002) using a fast Fourier transform (FFT) size of 4096 samples with a Hamming window and spectrogram equalization enabled (time constant of 30 s). Hours with ship noise, as well as biotic sounds (e.g., whale calls) and instrument strumming (created by water rushing past the mooring) were identified by manually analyzing spectrograms of each recording. Marine mammals are sensitive to changes in frequency between third-octave bands, therefore summarizing sound amplitude using third-octave bands is useful for approximating sound level for a range of frequencies (Richardson *et al*., 1995). For reference, an octave is a range of frequencies where the highest frequency is twice the lower frequency, and for third-octaves, the upper limits is equal to the lower band frequency multiplied by the cube root of two. We calculated the root-mean-square (RMS) sound pressure levels integrated over third-octave frequency bands between 25–1000 Hz for each recording using *PAMGuide* software in *MATLAB* (FFT with a 1-s long Hann window and 50% overlap; Merchant *et al*., 2015). For the ship source level analysis, we took the RMS average for each minute, and for the ambient sound level analysis we took the RMS average of each individual recording (duty cycles; 2013 and 2014 = 1199 s; 2015 = 1399 s). We assumed that ambient sound levels recorded during the duty cycles were representative of the entire hour.

Effects of Wind and Water Speed on Ambient Sound Levels

To understand how ambient sound levels naturally vary during the study period, we examined the impact of wind and water speed on third-octave sound levels (25–1000 Hz) recorded by our hydrophones. Wind is an important contributor to ambient sound levels during the open-water season (Wenz, 1962; Hildebrand, 2009; Roth *et al*., 2012; Insley *et al*., 2017; McKenna *et al*., 2021), and thus, should be taken into consideration when quantifying the impact of ship noise since high winds can elevate background sound levels. The Bering Strait is also known to have high water speeds (Woodgate, 2018), which can lead to flow nosie and/or instrument strumming (McKenna *et al*., 2021) Consequently, it was important to consider how water speeds contribute to sound levels recorded by the hydrophone in each third-octave frequency band. Note that both flow noise and instrument strumming result from water flowing past the mooring, therefore they are not considered features of the broader acoustic environment.

To isolate the effect of wind and water speeds, we analyzed recordings with no ship noise, instrument strumming, or biotic sounds present. Data on wind speed and direction were taken from the National Centers for Environmental Predication (NCEP) North American Regional Reanalysis 2 (NARR) wind data product (grid size of ~32 km; Mesinger *et al*., 2006) calculated for the nearest grid point to the moorings (65°N, 170°W; Fig. 1). We calculated daily mean water speeds using hourly data measured at 30 m depth by Acoustic Doppler Current Profilers (ADCP) attached to each mooring. We examined the influence of daily mean wind and water speeds on daily median sound levels for third-octave bands between 25–1000 Hz using Spearman correlation tests in addition to linear regressions for each site all years combined

(e.g., 2013–2015 at Site A2). We used a significance threshold of 0.05 for all statistical tests, assuming that daily means for wind and water speeds were independent. All quantitative analyses were computed using the software package *R* (v. 4.1.0; R Core Team, 2021).

C. Characterizing Ship Activity & Estimating Ship Source Levels

We used Automatic Identification System (AIS) vessel tracking data to characterize the presence of ships throughout the open-water season (June–November) in the Bering Strait region, which we defined as within 100 km of the A2 and A3 moorings (see Fig. 1 for boundaries). We also noted whether any ships were present in May or December, however we did not examine the sound recordings for either month due to the abundance of vocalizing bearded seals and sea ice, which make isolating ship noise difficult. AIS data were obtained from the Nationwide Automatic Identification System (NAIS) dataset managed by the United States Coast Guard (https://marinecadastre.gov/ais/). The NAIS dataset is collected by land-based receivers every minute and includes vessel name (2015 only), status (2015 only), length, width, a unique Maritime Mobile Service Identity (MMSI) number, vessel type, latitude and longitude, speed over ground (knots), course over ground, and heading. The International Maritime Organization (IMO) only requires large vessels (>300 gross tonnage), passenger vessels, and large fishing vessels to carry AIS transmitters (IMO International Convention for the Safety of Life at Sea, 1974). Consequently, AIS is not a reliable tool for tracking the presence of small vessels (Hermannsen *et al*., 2019).

For quantifying ship noise and estimating ship source levels, we matched recordings with ship noise to concurrent AIS transmissions from ships that were within 100 km of the mooring. We refer to a recording that matched with the closest pass of a single, unique vessel by the mooring as a "ship event" (unique vessels were identified using their MMSI number). AIS transmissions for each ship event were visualized in *ArcMap* (v. 10.8; Environmental Systems Research Institute, ESRI, 2019) to ensure that the vessel was in a reasonable position to be heard by the hydrophone (i.e., not behind a landmass), and that the vessel was moving during the recording. We also eliminated any ship events with fewer than two AIS transmissions during the ~20/22-minute recording window, as well as ship events that had other sound sources present (e.g., whale calls, instrument strumming). We then eliminated duplicate ship events where the same vessel was detected at two mooring sites by selecting the recording from the closest hydrophone to the ship's track.

We calculated source levels (SL) for each ship event using the sonar equation (Urick, 1983), where SLs are estimated from received sound levels recorded by the receiver (i.e., the hydrophone) plus some transmission loss due to propagation. For the received levels, we used the RMS sound pressure level for the 250-Hz third-octave band for each minute of the ship event recording. The 250-Hz band likely captures peak sound levels for smaller vessels (Merchant *et al*., 2014), making it a good choice for quantifying ship sound levels. Additionally, sound levels at lower frequency bands (e.g., 63 and 125 Hz) tend to attenuate in shallow water, whereas sound

levels in the 250-Hz band do not (Merchant *et al*., 2014). We then estimated transmission loss using an empirical model that parameterizes transmission loss as geometric spreading plus some loss due to absorption. The model assumes that sound energy spreads spherically until it reaches an obstruction, assumed to be the seafloor or surface, after which it spreads cylindrically, resulting in the following equation (adapted from Richardson *et al*., 1995, p. 71):

$$SL = RL + 20\log_{10}(r_o) + 15\log_{10}\left(\frac{r}{r_o}\right) + \alpha r$$

where r is the slant distance from the ship to the hydrophone, r_o is the range at which spreading switches from the spherical to a form of cylindrical spreading, and α is an absorption coefficient. We estimated r_o as the difference between the sound source depth, assumed here as the draft of the ship, and water depth at the mooring site where the ship was recorded. We initially used a published value of 0.004 dB/km for the absorption coefficient (Francois and Garrison, 1982), however the published value underestimated propagation loss and resulted in a poor fit to our measured received levels (RL). Instead, we fitted an empirical absorption coefficient for all ship events combined using linear least squares regression. We then used the empirical absorption coefficient (α) along with normalized received levels from each ship event (i.e., $(RL_i – RL_{mean})/RL\sigma$) to calculate SL for each ship using a linear least squares regression (the resulting α is discussed in Section 3B).

D. Relationship Between Vessel Speed and Source Level

Previous research has shown that ship source levels increase with increasing vessel speed (Ross, 1976; McKenna *et al*., 2013; Cion *et al*., 2019; ZoBell *et al*., 2021) as well as vessel size (McKenna *et al*., 2013). The AIS data provided speed over ground, but a more relevant metric for quantifying vessel noise is speed through water (McKenna *et al*., 2012), which we calculated by subtracting the hourly mean water velocity from the reported speed over ground for each ship. Hourly mean water velocities (m/s) at ~12 m depth were taken from the ADCP data from the closes mooring to the ship. Northward water velocities during the 2013–2015 open-water seasons ranged from ~22–62 cm/s (~0.6–1.2 knots) and changed on the same timescale of the winds (hours to days; Woodgate, 2018). Prior work shows the flow field of the strait to be largely homogenous except for a coastal current on the Alaskan side (Woodgate *et al*., 2015). For vessel size, we used the vessel lengths (m) reported in the AIS data since we did not have gross tonnage data for 2013 and 2014.

We hypothesized that environmental factors, such as sea state, could affect engine power output at a given speed, and thus, vessel source levels. Therefore, we used wind speed as a proxy for sea state and divided the ships into categories based on daily wind speeds on the day of the ship event, arbitrarily defining “low-wind” ship events as transits that occurred on days with mean wind speeds <10 m/s, and “high-wind” events on days with mean wind speeds ≥10 m/s. Note that 10 m/s is the threshold between Beaufort sea states of 5 and 6 where large waves begin

to form, and that the prevailing northward current through the Bering Strait may be reversed to flow southwards by southward winds exceeding 10 m/s (Woodgate *et al*., 2005). We also included whether the ship was moving against the wind or with the wind as a predictor, using the mean course over ground (COG) during the ~20/22-minute recording window and daily mean wind velocities from the NCEP-NARR dataset. We classified a ship as moving "against" the wind if the ship's mean COG was within $\pm$45° of the wind's direction, and "with" the wind if its mean COG was within 180 $\pm$ 45° of the wind's direction (e.g., if a ship's COG = 23° and the wind direction as 175°, the ship would be classified as moving with the wind).

Following the suggestion of Mckenna *et al*., (2012), we examined the relationship between vessel speed and source levels for each vessel type separately. We used a separate general linear model with Gaussian errors for each vessel type to test for significant relationships between ship source levels and speed through water, vessel length, wind speed, wind speed category (i.e., "high wind" vs. "low wind"), and direction relative to the wind as a categorical variable ("against the wind" vs. "with the wind"). We confirmed normality of the ship source levels using a Shapiro-Wilks test and used the Akaike's information criterion with a correction for small sample size (AICc) to evaluate the model (Akaike, 1973). We then evaluated each variable separately using its significance term.

Comparison Between Vessel Noise and Ambient Sound Levels

We compared received sound levels when a single ship was present to ambient sound levels for the entire open-water season across all sites and years. We quantified both ambient and ship noise as third-octave sound pressure levels (SPL) averaged over the full duration of each recording (2013 and 2014 = averaged over 1199 s; 2015 = averaged over 1399 s), and then compared median ambient third-octave SPLs for all sites and years to median third-octave SPLs (McDonald *et al*., 2006; Insley *et al*., 2017), therefore we also examined median ambient and ship SPLs for days with wind speeds <10 knots (~5 m/s). Finally, we compared median sound levels for ambient vs. ship by vessel type.

Mapping the Acoustic Footprint of Ships

To estimate the acoustic footprint of a passing ship, we back-calculated received levels extending from the ship track using the estimated source level for the 250-Hz third-octave band and propagation loss as a function of range from the ship, *r* (see Section 2C for source level and propagation loss methods). We selected a ship from the six major vessel categories, including a cargo ship, military ship, research vessel, tanker, tugboat, and a ship in the "other" category, and mapped the areas where received levels were expected to exceed certain thresholds. The thresholds included: received levels $\geq$120 dB re 1 μPa, the behavioral disturbance threshold for marine mammals defined by the U.S. National Oceanic and Atmospheric Administration (NOAA, 2016); 110 dB re 1 μPa, which is the average ambient sound level on high-wind days in the Canadian Arctic found by Halliday *et al*., (2017); 105 dB re 1 μPa; and 100 dB re 1 μPa, the

level where some disturbance behavior has been observed in marine mammals (Southall *et al*., 2007). Transmission loss was estimated without consideration of interactions with the seafloor or elevated sound levels are likely overestimates (Farcas *et al*., 2016). We assumed that the vessels maintained a steady speed (and this we assume a steady sound source) over the length of the trackline segment.

III. RESULTS

We analyzed 36,274 recordings combined across the three sites and years. There were 2,998 recordings with ship noise, with 1,030 recordings at Site A2, 1029 at Site A3, and 939 recordings at Site A4. In total, there were 93 days with ship noise present in 2013, 103 days in 2014, and 131 days in 2015 (we refer to a day as a 24-hr period starting at 00:00 GMT). Most of the ships detected at Site A3 were also detected at Sites A2 and A4, and the AIS transmissions were closer to A2 and A4. Consequently, we focused our analyses only on Sites A2 and A4 (Fig. 1).

Effects of Wind and Water Speed on Ambient Sound Levels

The Spearman correlation test revealed significant correlations between daily mean water speeds and third-octave sound levels for all bands between 25–1000 Hz except the 250-Hz band (Spearman ρ range: ~0.2–0.9; Fig. 2A). Other bands had a non-significant correlation with water speed, and the sign, magnitude, and significance of the correlations differed by site (Fig. 2A). Correlations between water speed and low-frequency sound levels (third-octave bands <250 Hz) were positive, indicating that low-frequency sound levels increase with increasing water speed. In contrast, higher-frequency sound levels (>315 Hz) were negatively correlated with water speed (Fig. 2A), although those correlation values were small in magnitude (0 to -0.2). Conversely, sound levels for all bands were positively correlated with wind speed at both sites, with significant correlations for bands >80 Hz (Fig. 2B). Sound levels for bands ≥50 Hz increased with increasing daily mean wind speed at both mooring sites, indicating that background sound levels were higher on days with higher wind speeds. For example, there was a significant, positive relationship between daily mean wind speed and median sound pressure levels for the 250-Hz band for all three years at Site A2 pooled together (Fig. 3).

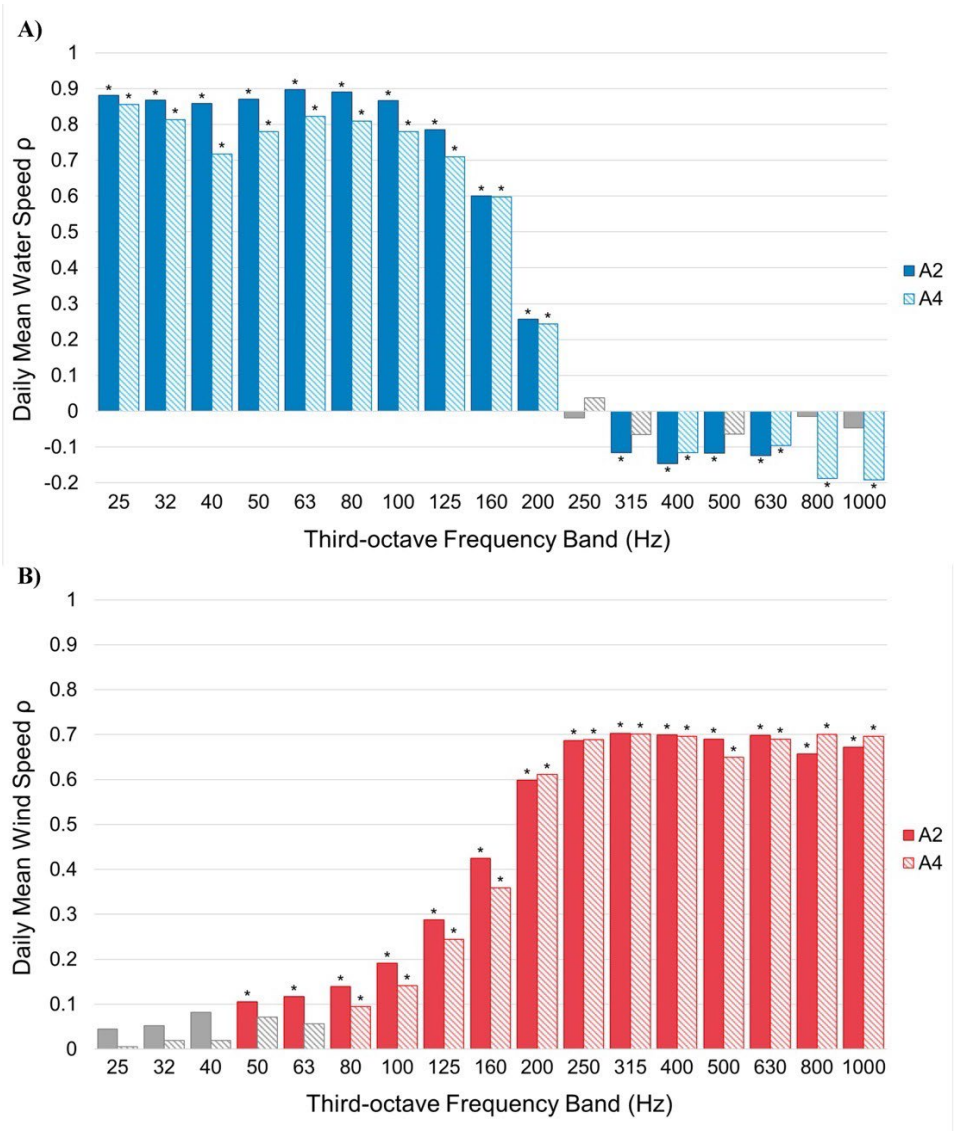

FIG. 2. Spearman ranked correlation coefficients (ρ) for correlation tests between (A) sound levels and water speeds and (B) sound levels and wind speeds. Daily median ambient third-octave sound levels (x-axis) were measured between June–November 2013–2015 at Sites A2 (darker colors) and A4 (lighter colors). Daily mean water speeds (ADCP data) were collected at 30 m depth, and daily mean wind speeds were taken from the NCEP-NARR dataset (Mesinger *et al*., 2006). Bars with an asterisk (*) indicate significant correlations ($p < 0.05$) and gray bars indicate non-significant correlations.

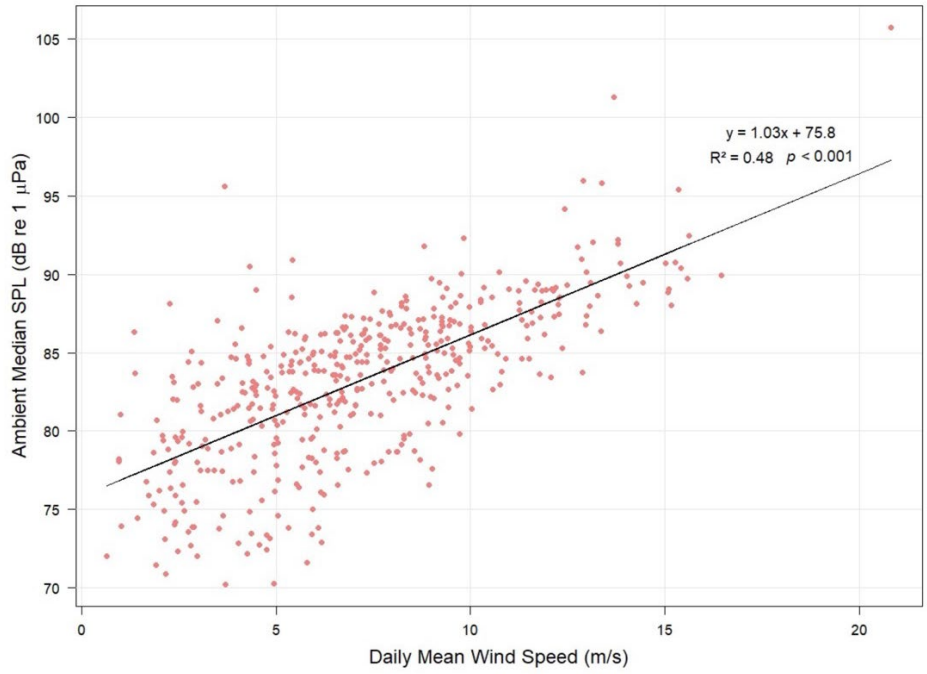

FIG. 3 . Median ambient sound pressure levels (SPL, dB re 1 μPa) measured for the 250-Hz third-octave band at Site A2 during the open-water season (June–November) 2013–2015 plotted as a function of daily mean wind speeds (NCEP-NARR data; Mesinger *et al*., 2006). Fitted values from the linear regression are plotted as a straight line (R^2 = 0.48) and show a significant positive relationship between the two variables ($p < 0.001$).

B. Ship Activity in the Bering Strait and Ship Source Levels

A total of 410 unique AIS-transmitting vessels entered the Bering Strait region from May to November 2013–2015. The highest number of unique passages occurred in 2013 with 154 vessels, compared to 122 vessels in 2014, and 134 vessels in 2015. Peak ship activity occurred in the months of July through September (Fig. 4), with the earliest ship transmission occurring in early May and the latest in mid-December. Two cargo ships and a military vessel traveled north of Site A3 on 4–6 May 2015, and the latest passage was made by a Russian icebreaker which transited northward through the western channel on 17 December 2015. A summary of the vessel types observed in the Bering Strait region can be found in Table II. Cargo ships were most common (n = 138 unique vessels, 33.7%), followed by tugboats (n = 85 vessels, 20.7%), and those in the "other" category (n = 75 vessels, 18.3%), which included research vessels, offshore supply vessels, and military/public vessels.

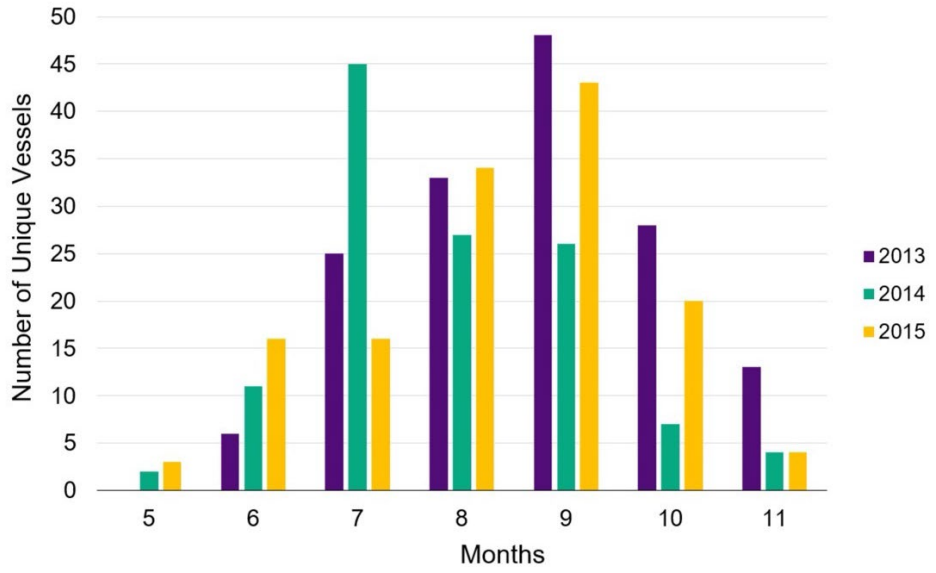

FIG. 4. Total counts of unique vessels that transited within 100 km of the Bering Strait region. Ships that had AIS transmissions within the merged 100-km buffers around Sites A2 and A3 counted as being within the Bering Strait (see Fig. 1). Note that the totals presented are likely underestimated since not all vessels are required to carry AIS transmitters.

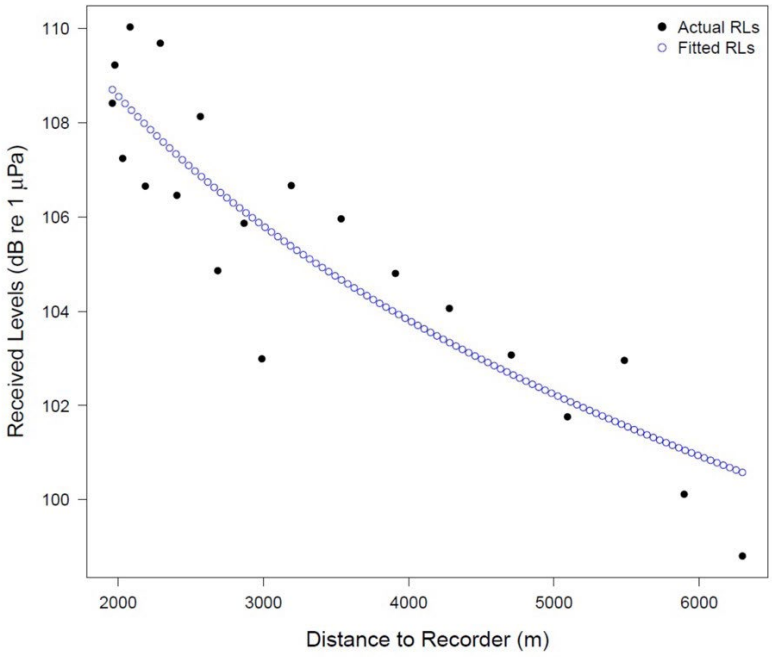
A total of 63 recordings were matched with a single, unique vessel within 14 km of a mooring, and had no other sound sources present. The closest points of approach (CPA) for the ship events ranged from ~0.5 km to 13.9 km with an average of 4.4 km (standard deviation (SD): $\pm$ 2.8 km). Third-octave level received levels (dB re 1 μPa) at CPA for the 63 ship passages ranged from 61 to 123 dB re 1 μPa depending on the frequency band. We examined plots of received levels for the 250-Hz band as a function of range to the receiver when calculating the source levels for all 63 ship events and eliminated three ship events that had irregular patterns in their received level vs range plots (e.g., the received levels increased as the distance from the receiver increased). Estimation of source levels for vessels with CPAs > 10 km is likely unreliable, thus we also eliminated ships with CPA ranges > 10 km from the dataset. Source levels for the remaining ships (n = 57) were estimated using an absorption coefficient (α) of 1.46×10^{-7} dB/km (95% confidence interval: 8.56×10^{-8}, 2.07×10^{-7} dB/km) in a linear least squares regression model (R^2 = 0.62). See supplementary material at [URL will be inserted by AIP] for an example of the source level model fit. Source levels for remaining ship events ranged from 141 to 173 dB re 1 µPa at 1 m (source level ranges by vessel type are reported in Table III).



Supplemental FIG. S1. Example of the source level model fit for cargo ship #215000028. The hollow circles represent the fitted received levels (RLs) that were calculated using the estimated source level for the ship.

C. Vessel Speed and Source Levels

Speed through water for all vessel types combined (n = 63) ranged from 2.3 knots (tugboat) to 15.7 knots ("other" ship), with an average of 9.7 knots (SD: ± 3 knots). Cargo ships had the highest speeds on average with a mean of 12.4 knots (SD: ± 2.6 knots), while tugboats had the lowest speeds with a mean of 7.3 knots (SD: ± 2.2 knots; Table III).

We modeled the relationship between source level (SL) and various factors for cargo ships (n = 12) and tugboats (n = 19) since the two vessel types constituted the majority of ships that transited through the strait during the study period (Table II). We removed two cargo ships that had atypical lengths (≤70 m compared to > 120 m for the other vessels), reducing our cargo ship sample size to 10 vessels. All selected cargo ship events occurred on days with low wind speeds, thus we removed the wind speed category from the cargo ship model. The best cargo ship model according to the Akaike's information criterion score (AICc) was SL ~ WindSpeed, though the correlation of WindSpeed and SL was not significant (p = 0.08, R^2 = 0.33; Table IV). The best fit tugboat model according to the AICc score was SL ~ speed through water, however again the correlation between SL and speed through water was not significant (p = 0.42, R^2 = 0.04; Table IV).

Next, we separated the cargo ships and tugboats into length categories and wind speed categories (tugboats only). We defined "large" cargo ships as ships >200 m long (n = 8) and "small" cargo ships as <200 m long (n = 2). "Large" tugboats were tugs ≥30 m in length (n = 14), while "small" tugboats were <30 m long (n = 5). Insufficient sample sizes for small cargo ships (n = 2) and small tugboats (n = 5) precluded an examination of the relationship between ship source levels and speed through water for either category. We did not find a significant relationship between source levels and speed through water for large tugboats that transited on "low-wind" days (n = 10, R^2= 0.08, p = 0.44; Fig. 5), and whether the ship was traveling against or with the wind had a non-significant effect on source levels (p = 0.21, R^2 = 0.19). The model for large cargo ships that transited on "low-wind" days (n = 8) similarly produced non-significant results (p = 0.47), with a negative relationship between source levels and speed through water (R^2 = 0.09).

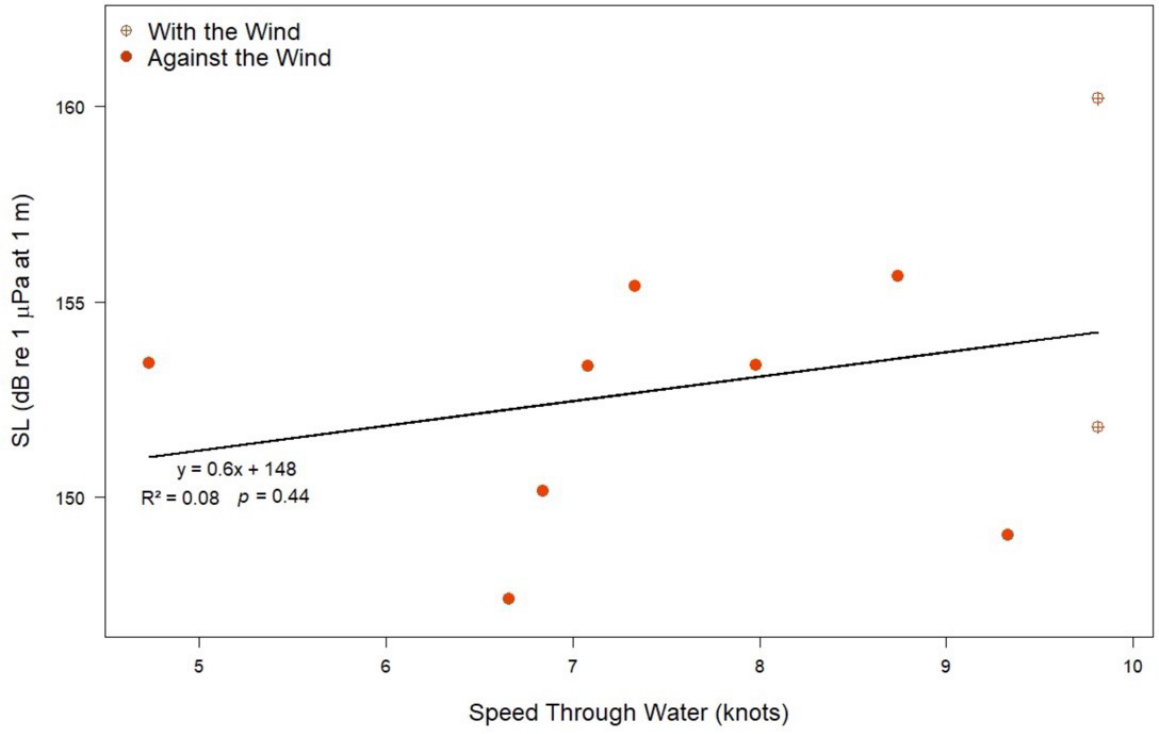


FIG. 5. Source levels (SL, dB re 1 µPa at 1 m) for large tugboats (>30 m long; n = 10) that transited on "low-wind" days (daily mean wind speed <10 m/s) plotted against speed through water (knots). Data points are symbolized by whether the vessel was traveling in the same direction as the wind ("With the Wind," hatched circles) or in the opposite direction ("Against the Wind," filled circles).

D. Comparison Between Vessel Noise and Ambient Sound Levels

Median sound levels when a ship was present were higher than ambient sound levels for third-octave frequency bands between 80–1000 Hz, with ships elevating sound levels by 3–9 dB above ambient (Fig. 6). The highest median received levels for both ambient and ship events were observed in the lower third-octave frequency bands (25–50 Hz; Fig. 6), potentially reflecting the influence of high water speeds (Section 3A; Fig. 2A). Median ambient sound levels on days with low wind speeds (<10 knots) were lower than those of the entire open-water season for third-octave frequency bands between 63–1000 Hz, though they were very similar to seasonal ambient levels for bands ≤50 Hz (Fig. 6A). To ensure that winds were not contributing to the difference between ship and ambient levels, we compared median sound levels when ships were present on low-wind days to ambient sound levels on low-wind days and found that ship levels were on average ~7 dB above ambient for frequency bands between 80–1000 Hz (Fig. 6A).

Since we found that lower frequency sound levels were correlated with water speeds, we examined ambient sound levels on days with low water speeds in comparison to ambient sound levels for the open-water season. We defined low water speeds as the first quartile of the daily mean water speeds measured at Sites A2 and A4 combined (27.6 cm/s), and pulled out ship events that occurred on days with mean water speeds below 27.5 cm/s (Fig. 6B). Median sound levels on days with ships present and low water speeds were still higher than ambient except for the 25-Hz band (mean difference = ~7 dB; Fig. 6B).

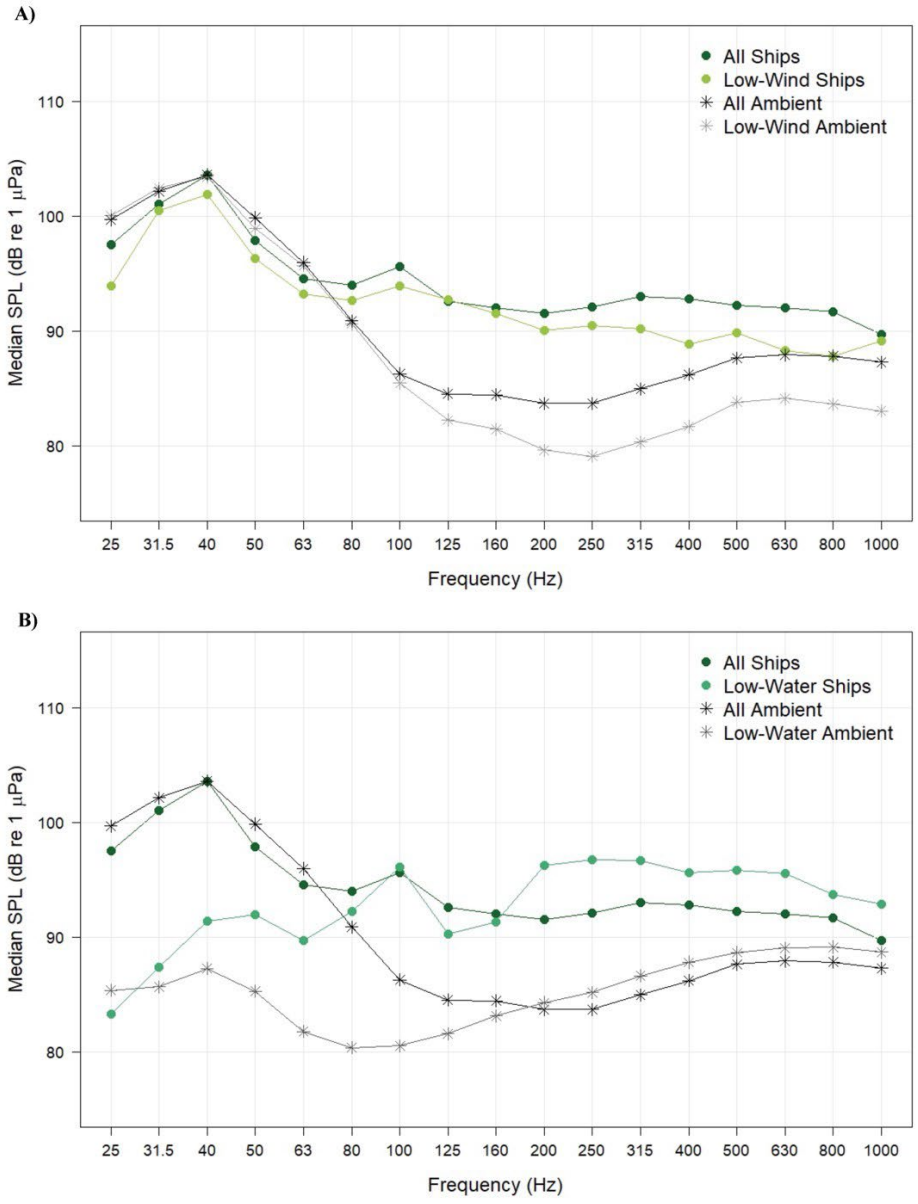

FIG. 6. Median sound pressure levels (SPL) measured across third-octave frequency bands (Hz) for ship events ("All Ships") plotted against ambient SPLs for the open-water season 2013–2015

("All Ambient"). Ambient SPLs for 2013–2015 at the two mooring sites were pooled and the median calculated for all ambient files ("All Ambient," n = 15,346 recordings; dark stars), and A) for days that had wind speeds <10 knots (~5 m/s; "Low-Wind Ambient," n = 3,925 recordings; light stars) and B) for days that had low water speeds (<27.6 cm/s; "Low-Water Ambient," n = 4,095 recordings). Median SPLs are plotted for all ships (n = 63 recordings; dark circles) and ship events on days with A) low wind speeds ("Low-wind Ships," n = 21 recordings; light circles), and B) low water speeds ("Low-Water Ships," n = 10 recordings). Note that the x-axes are not linear.

All vessel types had higher median sound levels than ambient for third-octave frequency bands ≥125 Hz (Fig. 7A). Only offshore supply vessels had higher median sound levels than ambient for bands ≥50 Hz and ≥63 Hz, respectively (Fig. 7A). The two military vessels had lower median sound levels than ambient for the lower frequency bands, likely because the ships transited on days with low wind and water speeds. Since lower frequency bands tend to be strongly correlated to water speeds (Section 3A; Fig. 2A), we plotted the median SPLs for ships vs. ambient for frequency bands 100–1000 Hz (Fig. 7B) and found that median sound levels with ships present were consistently higher than ambient, often by ≥10 dB. Except for low frequencies, ship noise exceeded ambient for the open-water season by >1 dB re 1μPa.

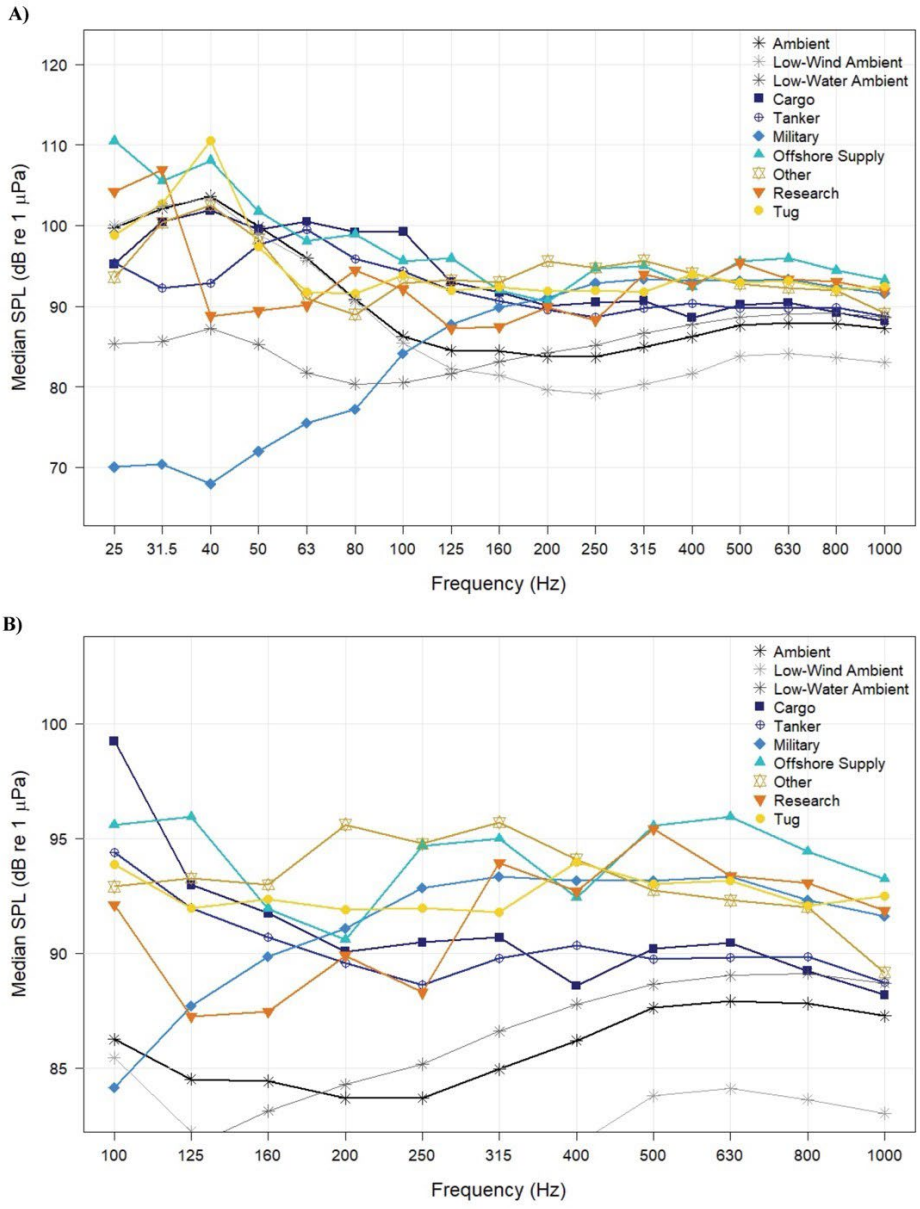

FIG. 7. Median ship sound pressure levels (SPL) measured at each third-octave frequency band (dB re 1 µPa) visualized by vessel type and plotted against median ambient SPLs for the open-water season (2013–2015) for (A) all third-octave frequency bands between 25–1000 Hz, and (B) bands between 100–1000 Hz. Note the difference in y-axis scale between the two plots. The plots include seven general vessel categories: cargo (n = 15), tanker (n = 4), military (n = 2), offshore supply (n = 3), other (n = 14), research (n = 3), and tug (n = 20). Ambient SPLs for days with low wind speeds <10 knots (~5 m/s; "Low-Wind Ambient") and low water speeds (<27.6 cm/s; "Low-Water Ambient") are included in the plot.

E. Acoustic Footprint of Ships

The modeled acoustic footprints varied in size across the six selected vessel types (Table V; Fig. 8). The loudest vessel, a military vessel (source level = 172 dB re 1 µPa at 1 m, 95% confidence interval: 171.5–173.4 dB re 1 µPa at 1 m), had the largest footprint with received levels exceeding 120 dB re 1 µPa out to ~0.9 km away from the vessel (Table V). Received levels around the quietest vessel, a ship in the "other" vessel class (source level = 141 dB re 1 µPa at 1 m, 95% confidence interval: 140.4–141.9 dB re 1 µPa at 1 m), only exceeded the 120-dB disturbance threshold (NOAA, 2016) out to 7 m. All six vessels produced modeled received levels that exceeded the 100-dB disturbance threshold (Southall *et al*., 2007), with radii ranging from ~0.2 km to 11 km around the vessel (Table V). We calculated the distance across the eastern channel of the Bering Strait as ~37 km from the eastern edge of Little Diomede Island to the Alaskan mainland (Fig. 1) and compared the widths of the acoustic footprint for each selected ship to this distance to estimate the spatial extent of elevated received levels. The loudest vessel (#367205050) was estimated to elevate received levels above the 120-dB disturbance threshold in ~5% of the eastern channel of the strait, while the remaining vessels elevated received levels above the 120-dB threshold in ≤2% of the eastern channel. In comparison, modeled received levels around the loudest vessel exceeded the 100-dB disturbance threshold in >50% of the eastern channel (Fig. 8).

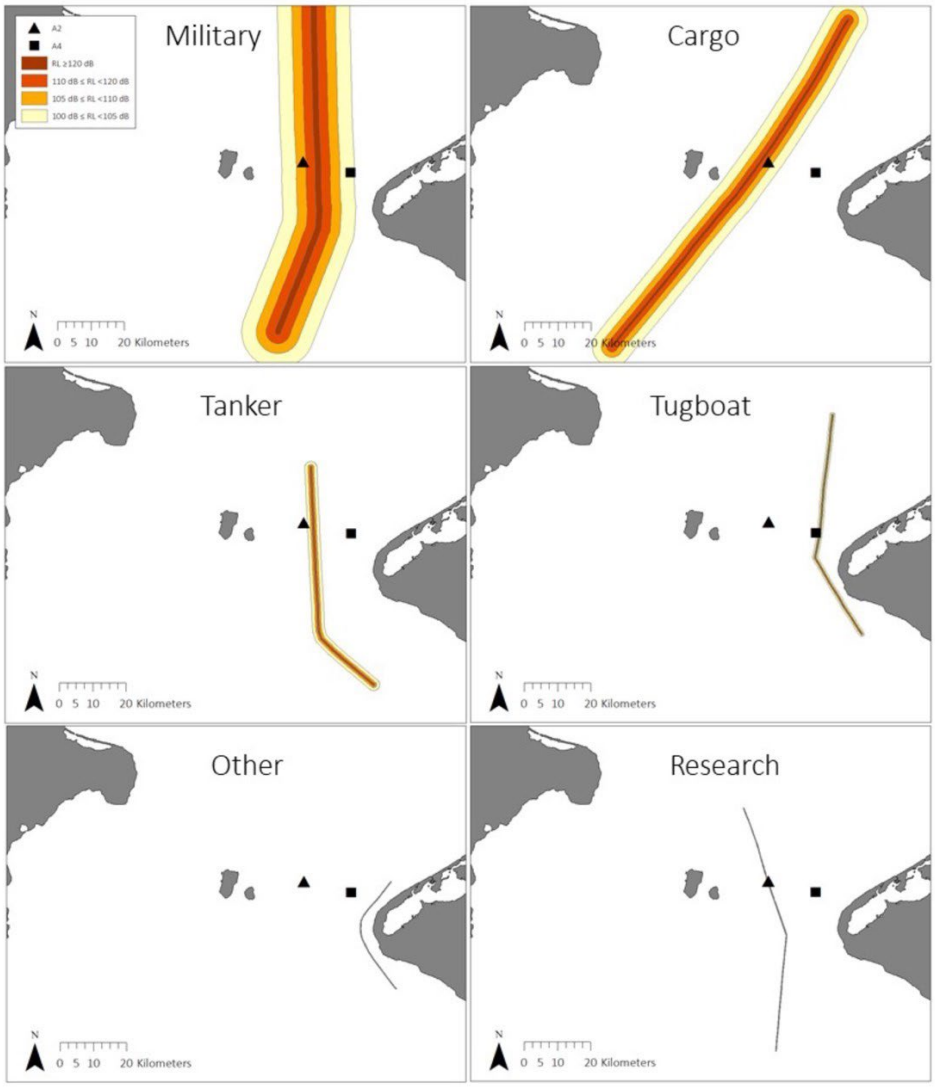

FIG. 8. Modeled acoustic footprint of ships selected from the major vessel types observed in the Bering Strait 2013–2015 (see Table II). The different colors represent the area where received sound levels are estimated to be within a certain radius around the ship's track.

IV. DISCUSSION

We set out to quantify how shop noise affects the soundscape of the Bering Strait region during the open-water season and found that ships elevate sound levels by ~6 dB on average for third-octave frequency bands >80 Hz, and an average of ~8 dB to ambient sound levels on days with low-wind speeds (Fig. 6). Moreover, how much sound a single ship contributed to ambient sound levels depended on vessel type. Offshore supply vessels had the highest sound levels above ambient while tankers and research vessels had the lowest (Figs. 7A and 7B). Similar to Halliday *et al*., (2017), we found that louder vessels affected larger areas than quieter vessels and the zones where received levels exceeded potentially harmful levels ranged from 7m to 10 km away from a ship's path (Table V; Fig. 8). Lastly, we did not find a significant relationship between vessel speed and source levels for cargo ships and tugboats, suggesting that vessel speed alone is not a good predictor of source levels for these two vessel types in our shallow study region. A larger sample size is needed to verify that reducing the speed of vessels will lead to lower noise levels in the Bering Strait.

Most of the ships detected in the Bering Strait during our study period were cargo ships and tugboats, reflecting an increasing trend in commercial shipping in the Arctic. The Bering Strait has served as a conduit for large vessels transiting to the Arctic from the Pacific since the late 1800s when commercial whaling vessels prowled its waters (Bockstoce, 1986). In the 20th century, most of the vessels in this region were small cargo ships, tugboats, tankers, and barges en route to support coastal Arctic communities in the Chukchi and Beaufort seas (AMSA, 2009). With increased industrial activity and resource extraction in the western Arctic, the number of cargo ships and tankers observed in the region increased steadily between the years of 2008 and 2013 (AMSA, 2009; Huntington *et al*., 2015). Along with cargo, ship activity related to tourism is expected to increase in the 21st century (AMSA, 2009). Only 6% of the AIS-transmitting vessels we observed in the Bering Strait region from 2013–2015 identified as pleasure crafts/passenger ships (Table II), however we anticipate that future studies of ship activity in the Bering Strait will observe more vessels of this type. (Note that more smaller ships may have been present during our study period but did not have AIS.)

Most of the ship transits through the strait occurred in the summer and early fall months (July–September; Fig. 4), similar to Eguíluz *et al*., (2016) and Halliday *et al*., (2021) who noted the highest numbers of Arctic transits in July–October. The peak in ship activity overlaps with the migrations of subarctic baleen whales through the strait (Clarke *et al*., 2013; Woodgate *et al*., 2015; Escajeda *et al*., 2020), increasing the probability of interactions between ships and whales. Though it was not the focus of the present study, we noted that October had the highest number of recording hours with both whales and ships present, followed by September and July. Ships transiting through the Bering Strait during the month of October should be aware of migrating whales in the region and slow down when whales are observed.

The source levels for various ship types calculated here are lower than previous studies. Veirs *et al*., (2016) estimated an average broadband source level of 175 ± 5 dB re 1 µPa at 1 m (20–40,000 Hz) for 206 unique cargo ships. For tugboats, they calculated a broadband source level of 175 ± 5 dB re 1 µPa at 1 m averaged over 85 unique vessels (20–40,000 Hz; Veirs *et al*., 2016). Both vessel types had a higher average speed over ground (14 knots) than the ships we examined (10 knots), and the authors did not calculated speed through water, which along with measuring broadband received sound levels over a wide frequency band (20–40,000 Hz) could have contributed to the difference in source level calculations. We found that sound levels in lower frequency bands were correlated to water speeds (Fig. 2A), indicating that flow noise impacts lower sound levels and could potentially bias broadband sound measurements. Additionally, Veirs *et al*., (2016) conducted their study in Haro Strait, a 200–300 m deep channel in British Columbia with likely different propagation conditions than the shallow Bering Strait.

Perhaps a more comparable study is that of Halliday *et al*., (2017) who calculated the source level for the Canadian icebreaker *CCGS Amundsen* using a shallow-water deployment near Sachs Harbor in the Canadian Arctic. The *CCGS Amundsen* is 98 m long and had an estimated broadband source level of 176 dB re 1 µPa at 1 m (63–20,000 Hz; Halliday *et al*., 2017). A similarly sized vessel in our dataset, a ship in the "other" vessel type class measuring 102 m long, had a source level of 169 dB re 1 µPa at 1 m (95% confidence interval: 168.4–170.2 dB re 1 µPa at 1 m). A review study by Chion *et al*., (2019) found that reported broadband source levels for various ship types differed as much as 30 dB, therefore it is not surprising to see a difference between source levels reported here and those from previous studies. A likely explanation for the difference in calculated source levels is in how each study calculated propagation loss. Most of the studies reviewed by Chion *et al*., (2019) were conducted in deep water, and thus, used spherical spreading for estimating transmission loss. Spherical spreading tends to overestimate transmission loss (Thilges *et al*., 2019), which may explain why previous calculations of source levels were much higher than those presented here.

It is likely that propagation loss in the Bering Strait is more complex than geometric spreading plus absorption loss, as we assumed. Sound propagation in shallow-water environments, such as the Bering Strait, can be complicated by interactions between sound waves, and the surface and seafloor. Absorption of sound by the seafloor and shifts in sound speeds due to varying water and sediment density can also contribute to propagation loss (Richardson *et al*., 1995; Farcas *et al.*, 2016). Such as interactions would result in a greater propagation loss than we estimated, and consequently, higher source levels. Future studies should employ the use of more complex propagation models, such as normal mode models (Richardson *et al*., 1995; Jensen *et al*., 2011; Wang *et al*., 2014) or parabolic equations (Halliday *et al*., 2021), for estimating transmission loss, pending the availability of accurate water column and sediment sound speed data for the Bering Strait.

Another key finding was that high water speed affected sound levels at lower frequencies, which has important implications for the frequency band used for quantifying ship noise. The

European Union currently recommends using the 63-Hz and 125-Hz third-octave band for measuring ship noise (Dekeling *et al*., 2014). However, both bands exhibited positive correlations to water speed (Fig. 2B), suggesting that sound levels for the 63-Hz and 125-Hz bands recorded by the hydrophone on days with strong currents may be artificially high. Our results corroborate the suggestion by Merchant *et al*., (2014) to use the 250-Hz band for quantifying ship noise when flow noise is a concern.

The acoustic footprints presented here likely represent a first approximation of ships' "zones of impact" for the Bering Strait region and show that ship noise potentially reduces the acoustic habitat available for communication among baleen whales. For instance, the area where sound levels exceeded 100 dB, a threshold where some disturbance to marine mammal behavior was observed by Southall *et al*., (2007), extended to ~6 km for the cargo ship and to ~11 km for the military ship we examined (Table V). Both distances exceed the communication for space of humpback whales, which is estimated to extend ~4 km (Dunlop, 2018). It is likely then that cargo and military ships could interrupt intraspecies communication for humpback whales, especially since they have been observed to cease calling when ships were present (Fournet *et al*., 2018). The impact of ship noise on the acoustic habitat of the Bering Strait is likely exacerbated by the presence of multiple ships. Here we estimated the impact of single ships on ambient sound levels, so quantifying the effects of multiple ships should be the focus of future inquiry.

Our result that ships raise sound levels 2–9 dB (mean: 6 dB) above ambient for third-octave frequency bands between 100 and 1000 Hz in the Bering Strait (Fig. 7B) is strikingly different from those of McKenna *et al*., (2021). McKenna *et al*., (2021) conducted a similar study using a single hydrophone west of St. Lawrence Island and found that median third-octave sound levels (100–1000 Hz) produced by ships traveling at >5 knots within 10 km of their recorder were <1 dB higher than annual median ambient sound levels. McKenna *et al*., (2021) also examined ship transits at a location in the Bering Strait during a 13-day period in October 2015, and found that ships elevated sound levels by 3–5 dB for third-octave frequency bands between 100–1000 Hz on days when wind speeds were less than ~5 m/s. For comparison, we conducted a similar analysis for three ships that transited on days with wind speeds ≤5 m/s in October 2013 and found that the ships contributed ~2–12 dB of sound to ambient third-octave sound levels for bands 100–500 Hz and were similar to ambient (within <1 dB) for bands 630–1000 Hz. A possible explanation for the disparity in results is that we compared ship sound levels to median ambient sound levels measured over the open-water season as opposed to median levels measured for the entire year. Additionally, the ships analyzed here were within a closer range of our hydrophones (<14 km) than the ships in the Bering Strait analyzed by McKenna *et al*., (2021) (15–40 km), which could have affected the amplitude of measured received levels.

Unlike previous studies (McKenna *et al*., 2013; Simard *et al*., 2016; Veirs *et al*., 2016; Chion *et al*, 2019; MacGillivray *et al*., 2019; ZoBell *et al*., 2021), we did not find a significant relationship between source level and speed through water. Note however the wide range of regression slopes found in previous studies: 0.4 to 6.6 dB per knot (Veirs *et al*., 2016; ZoBell *et al*.,

2021), which suggests that the relationship between source level and vessel speed likely differs depending on vessel type and environmental conditions. It may also depend on water depth since most of the previous efforts to quantify the relationship between vessel noise and speed were conducted in deep water (e.g., Haro Strait which ranges from 200–300 m depth; Veirs *et al*., 2016). Our results were unable to show that the positive relationship between vessel noise and speed holds for a shallow, coastal area, although our sample size was very small (n = 10). A greater sample size is necessary to test whether source level increases with speed for all vessel classes in the Bering Strait.

As the presence of ships continues to increase in the Bering Strait region, ship noise will become an ever-present threat to marine animals that rely on sound for critical life functions (Erbe and Farmer, 2000; Halliday *et al*., 2019, 2020). Previous management recommendations include limiting commercial ships to a specific route through the strait as well as encouraging vessel speed limits (Halliday *et al*., 2017, 2020). In late 2018, the IMO approved a joint proposal from the U.S. Coast Guard and Russian Federation for a two-way route for large ships in the western and eastern channel of the Bering Strait (IMO, 2017). The routing measures also include multiple "Areas to be Avoided," including the coastal region surrounding St. Lawrence Island, south of the Bering Strait. The routes are voluntary for vessels 400 gross tons and above, however a 2019 study by the Nuka Research and Planning Group found that compliance was high among large commercial vessels, including bulk carriers, tankers, and cargo ships (Fletcher *et al*., 2020).

Shipping routes through the Bering Strait region are a good first step to managing vessel traffic in this sensitive area, however they do not address the issue of ship noise. Though we did not find a significant relationship between vessel speed and source levels, results of previous studies (e.g., ZoBell *et al*., 2021) suggest that the reducing speed of ships could reduce noise levels. We also found that large vessels transiting the Bering Strait are already traveling at speeds around or below the 13-knot speed limit currently enforced in Glacier Bay National Park, Alaska (mean speed over ground = 10 ± 3 knots SD; Code of Federal Registrations [CFR] 36 CFR 13.65, 2001; Frankel and Gabriele 2017). Installing a voluntary speed limit through the strait is likely to have high compliance among ship operators given the fact that ships are already transiting at relatively slow speeds, and the fact that there is currently high compliance with Bering Strait routing measures (Fletcher *et al*., 2020). Decreasing the speed of vessels traveling the strait could have additional benefits such as of reducing the risk and lethality of vessel strikes for whales (Vanderlaan and Taggart, 2006) and lowering carbon emissions (Leaper, 2019). Therefore, voluntary speed limits should be pursued for the Bering Strait region.

Coordinated efforts among multiple governments and agencies are required to reduce the potential harm to marine organisms from the expansion of economic activity in the Arctic. It is also important to realize that noise pollution is just one impact of increased shipping in the Arctic. Ship strikes, oil spills (leaks or major accidents), introduction of invasive species, and disruption of marine mammal behavior such as feeding and migration (AMSA, 2009) will negatively affect sensitive species that are already facing challenges created by shifting habitat conditions brought on

by climate change (Laidre *et al*., 2008; Hauser *et al*., 2018; Halliday *et al*., 2020). The results presented here can serve as a baseline for measuring future impacts of shipping on the acoustic environment of the Bering Strait, however they are just a start. More research is needed to understand, anticipate, and mitigate the impacts of ships on the marine environment of the Pacific Arctic.

ACKNOWLEDGEMENTS

We are grateful for the guidance of Alexander Hornof, Dr. Peter Dahl, and Hanah Choice in developing the methods for this study. This study is based upon work supported by the National Science Foundation (NSF) Graduate Research Fellowship Program under grant number DGE-1256082. Any opinions, findings, and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of NSF. We also wish to thank the University of Washington School of Aquatic and Fishery Sciences for providing funding for the primary author. Additional funding for this study was provided to K. Stafford from the North Pacific Research Board Arctic IERP (A94-00), the Office of Naval Research Marine Mammals and Biology Program N000141712274, and the National Science Foundation Polar Programs ARC-1107106; and to R. Woodgate from the NSF Arctic Observing Network PLR-1304052 and 1758565. The Bering Strait mooring data can be found in the permanent archives of the U.S. National Centers for Environmental Information/National Oceanographic Data Center, (www.ncei.noaa.gov), and at: psc.apl.washington.edu/BeringStrait.html.

Chapter 6: Northward Range Expansion of Subarctic Upper Trophic Level Animals into the Pacific Arctic Region

Stafford, K.M.[1,2], E. Farley[3], M. Ferguson[4], K.J. Kuletz[5], R. Levine[6]. 2022. Northward Range Expansion of Subarctic Upper Trophic Level Animals into the Pacific Arctic Region. Oceanography 35(2). DOI: https://doi.org/10.5670/oceanog.2022.101

Abstract

In the Arctic, studies of the impacts of climate change in marine ecosystems have largely centered on endemic species, ecosystems, and the people who rely on them. Fewer studies have focused on the northward expansion of upper trophic level (UTL) subarctic species. We provide an overview of changes in the temporal and spatial distributions of subarctic fish, birds, and cetaceans, with a focus on the Pacific Arctic Region. Increasing water temperatures throughout the Arctic have increased 'thermal habitat' for subarctic fish species, resulting in northward shifts of species including walleye pollock and pink salmon. Ecosystem changes are altering the community composition and species richness of seabirds in the Arctic, as water temperatures change the available prey field which dictates the presence of planktivorous versus piscivorous seabird species. Finally, subarctic whales, among them killer and humpback whales, are arriving earlier, staying later, and moving consistently farther north, as evidenced by aerial survey and acoustic detections. Increasing ice-free habitat and changes in water mass distributions in the Arctic are changing the underlying prey structure, drawing UTL species northwards, by increasing spatial and temporal habitat for them. A large-scale shuffling of subarctic and Arctic communities is reorganizing high-latitude marine ecosystems.

INTRODUCTION

Poleward range expansion of plant and animal species is one clear indication of climate change. Such distribution shifts in the ocean may be driven by changes in temperature, nutrients or, as in the Arctic and Antarctic, sea ice extent. These atmospherically driven alterations are inextricably linked to changes in wind-driven mixing or circulation, which affects nutrient supply; greenhouse gases, which trap heat; and subsurface and deep ocean heat, which drives sea ice declines (Tamarin-Brodsky and Kaspi, 2017; Woodgate and Peralta-Ferriz, 2021). Under new climate regimes, species whose life history strategies allow them to rapidly adapt or expand into novel habitat, such as large, migratory generalist feeders, can become climate change "winners" (Kortsch et al., 2015; Moore and Reeves, 2018). Subsequent impacts on endemic ecosystems will depend on resource availability and competition among species. As the climate continues to warm, temperate regions are becoming "tropicalized" and Arctic regions are becoming "borealized," with subarctic species increasing in abundance and expanding their ranges northward (Fossheim et al., 2015; Alabia et al., 2018; Polyakov et al., 2020).

While climate change is altering the entire Arctic, not every region in the highly heterogeneous Arctic is equally affected (e.g., Moore et al., 2019; Polyakov et al., 2020; Mueter et al., 2021a). In the Atlantic, there are two wide, deep, high-latitude gateways to the Arctic: Davis Strait (300–900 km wide) and Fram Strait/Barents Sea (~450 km wide). The sole gateway to the Pacific Arctic is through the narrow Bering Strait (80 km), south of the broad, shallow Chukchi Sea shelf (**Figure 1**). Observed differences between the Atlantic and Pacific Arctic regions include a much greater increase in the open water season in the Barents Sea than in the Chukchi Sea, and differ- ences in water mass composition and advection of heat and nutrients, all of which shape ecosystem structure (Hunt et al., 2013; Oziel et al., 2017).

Numerous recent studies illustrate how changes in sea ice are potentially altering biological components of subarctic and Arctic marine ecosystems. Many of these studies focus on the impacts of climate change on Arctic endemic species (Laidre et al., 2008; Divoky et al., 2021), ecosystems (Post et al., 2013; Grebmeier and Maslowski, 2014; Pecuchet et al., 2020), and the people who rely on them (Huntington et al., 2016, 2020, 2021). In particular, the inclusion of upper trophic level (UTL) taxa in the suite of measurements collected by the Distributed Biological Observatory provides novel information on ecosystem dynamics at key locations across decadal time scales (Moore and Kuletz, 2019; Stafford et al., 2021). Several recent studies also highlight the role that UTL consumers such as marine fish, birds, and mammals can play as bellwethers of climate change, and how understanding their abundances, distributions, and diets can aid in tracking ecosystem-level biological responses to rapid change (e.g., Moore et al., 2014, 2019; Sydeman et al., 2021).

Here, we review recent information on northward range expansions of subarctic marine fish, seabirds, and mammals whose life histories have in some instances included limited seasonal occupation of the Arctic, with a focus on exemplar case studies from the Pacific Arctic Region. Our overarching goal here is to provide an updated overview of observed recent changes in the spatial and temporal distributions of subarctic marine fishes, seabirds, and marine mammals, and to explain related linkages among changes in biology, the atmosphere, the ocean, and the cryosphere.

MARINE FISHES

Marine fish species can rapidly track environmental change (Sorte et al., 2010; Pinsky et al., 2013). This is evident in the borealization of the Barents Sea in particular, where subarctic species including mackerel and Atlantic cod are expanding their ranges from the North Atlantic (Johannesen et al., 2012) while the distribution of Arctic species is retract- ing northward (Fossheim et al., 2015; Frainer et al., 2017). As the region continues to warm, the thermal habitat for boreal species has shifted farther into the Arctic (Eriksen et al., 2020), and

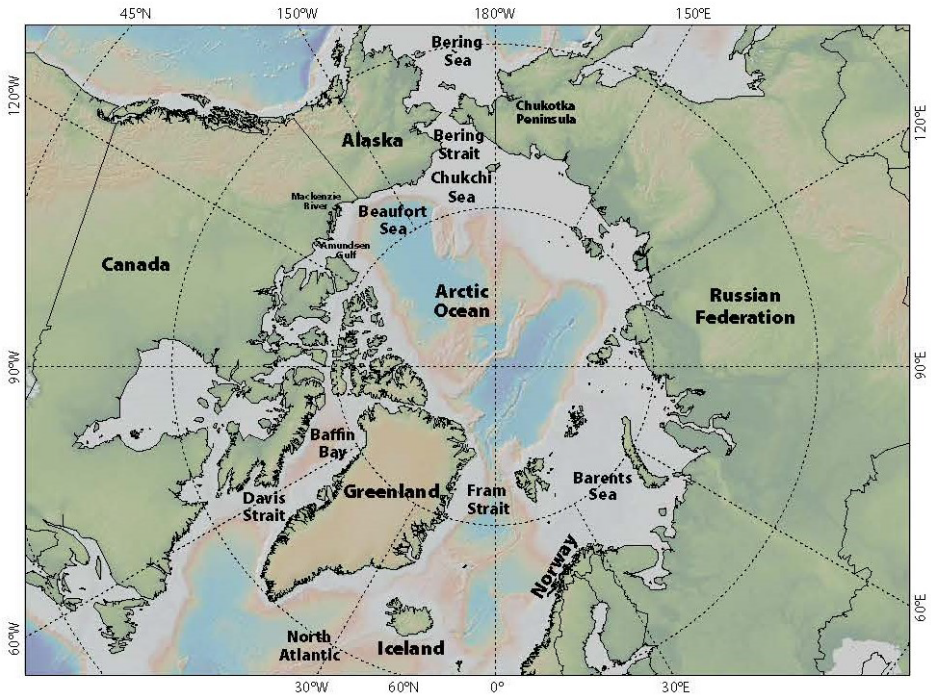

FIGURE 1. Map of the Arctic showing major gateways and waterways. Map made with GeoMapApp (http://www.geomapapp.org/; Ryan et al., 2009).

generalist boreal fishes are likely to outcompete the specialist diets of Arctic species (Kortsch et al., 2015).

Sigler et al. (2011) examined fish distribution records for the Pacific Arctic Region from the first decade of this century and found clear divisions in the distributions of planktivorous versus piscivorous species between the Bering Sea and the Chukchi and Beaufort Seas, as well as regional differences in taxa among bottom and surface fishes. Despite some evidence of northward migrations of subarctic species from the Bering Sea, these authors concluded that the persistence of the Bering Sea cold pool (Stabeno et al., 2001) would restrict range extensions of bottom fish such as walleye pollock, while pelagic species, such as pink salmon, might not be restricted by this thermal barrier (Sigler et al., 2011). However, given the retraction and possible collapse of the cold pool in recent years (Stabeno and Bell, 2019), more recent data suggest that these range extensions are long term (Grüss et al., 2021).

Walleye Pollock

Walleye pollock are widely distributed throughout the North Pacific, with known spawning grounds across the continental shelves from Japan to western Canada (Bailey et al., 1999). Cold bottom water in winter typically restricts the northward extent of the population. Adult pollock seasonally migrate northward and inshore in summer and then return to the outer shelf to avoid the cold pool (Kotwicki et al., 2005). A reduction in the size of the cold pool lessens the barrier for adult pollock to remain on the inner and northern shelf throughout the year, resulting in a northward shift during recent warm conditions (Stevenson and Lauth, 2019; Eisner et al., 2020; Grüss et al., 2021).

FIGURE 2. Historic and recent observations of walleye pollock distributions in the Bering and Chukchi Seas. Recent warming has led to a northward shift of the population in the Bering Sea (approximate distributions from Eisner et al., 2020), and surveys have reported large pollock populations in the east- ern (juvenile only; recent work of author Levine) and western (adult and juve- nile; Orlov et al., 2020) Chukchi Sea.

North of the Bering Strait, the summer forage fish community is dominated by small juvenile Arctic cod (De Robertis et al., 2017). Other common forage fishes in the region include capelin and Pacific herring, both of which are observed nearshore and largely in the southern Chukchi Sea. Juvenile pollock had previously been found in very low densities with few adults present (Wyllie-Echeverria, 1995; Mecklenburg et al., 2007; Rand and Logerwell, 2011; Goddard et al., 2014). Surveys during the recent period of extreme warming (2017–2020) indicate that while the distributions of the other pelagic forage fishes have not significantly changed, pollock abundance in the Pacific Arctic has substantially increased (**Figure 2**). In the eastern Chukchi Sea, juvenile pollock were widespread and highly abundant in 2017 and 2019 and found in comparable densities to Arctic species (Levine et al., 2021; recent work of author Levine). In the Russian sector, surveys in 2018 and 2019 found a significant increase in both juvenile and adult pollock north of the Chukotka Peninsula (Orlov et al., 2020). It is hypothesized that the recent increase in adult pollock in the northern Bering Sea serves as a source population for the larval and juvenile population observed in the Chukchi and Beaufort Seas (Levine et al., 2021) due to increased transport of Pacific water (Woodgate and Peralta-Ferriz, 2021) that advects juvenile fish northward.

Juvenile pollock growth rates exceed those of other gadid species under the warm conditions of the Arctic summer (Laurel et al., 2016), potentially allowing them to outcompete Arctic species; however, their hatch and survival rates are reduced under the seasonal freezing conditions (Laurel et al., 2018).

Thus, while the substantial increase in juvenile pollock in the Pacific Arctic suggests that environmental conditions now allow pollock to extend into the Chukchi Sea on a seasonal basis, their ability to establish permanent populations in the Arctic remains unknown.

Pink Salmon

Among salmonids, pink salmon are the most abundant species in the North Pacific Ocean (Ruggerone and Irvine, 2018) and have the broadest distribution in the Pacific Arctic Region. They occur from the large Yukon River to smaller coastal streams as far north as Point Barrow (Craig and Haldorson, 1986). Vagrants have also been found upstream in the Mackenzie River, extending east- ward across the Beaufort Sea toward Amundsen Gulf, and along the east coast of Greenland (Dunmall et al., 2013, 2018). Spawning pink salmon have also been documented along the Chukotka Peninsula coastline from the northern Bering Sea into the Chukchi Sea and as far west as the Kolyma River (Radchenko et al., 2018). While pink salmon abundance in northern regions of their range is still quite low in rela- tion to stocks farther south, there is evi- dence that the abundance of some north- ern stocks is increasing. For example, adult pink salmon have become more prevalent in subsistence catches in the high Arctic, particularly during even-numbered years (Dumnall et al., 2013, 2018). Furthermore, a survey during late summer 2007 found large numbers of juvenile pink salmon in the southern Chukchi Sea; these juveniles were larger and had higher energy content than juvenile pink salmon captured farther south (Moss et al., 2009). Consequently, adult pink salmon returns to the Beaufort Sea coast during 2008 were higher than in 2007 (Dunmall et al., 2013, 2018). It is still not clear whether the large catch of juvenile pink salmon in the Chukchi Sea in 2007 contributed to the higher returns in 2008. Conditions in both freshwater and marine environments are import- ant to the survival of pink salmon (Farley et al., 2020). In the northern extent of pink salmon distribution, cold river and stream temperatures in the fresh- water environment are believed to limit salmon production (Dunmall et al., 2016); however, continued warming of air and stream temperatures, and longer periods of ice-free conditions, may benefit salmon survival in this environment (Nielsen et al., 2013).

SEABIRDS

Seabirds link Arctic and subarctic marine and terrestrial ecosystems because they require land to nest and raise young, but forage in the ocean. Globally, pelagic seabird occurrences and distributions reflect the presence of the surface and subsurface zooplankton and forage fish upon which they feed (e.g., Sydeman et al., 2010). In the Pacific Arctic region, seabirds have been associated with underwater features and water mass characteristics that aggregate their prey (Gall et al., 2013; Kuletz et al., 2015). During chick rearing, seabirds must find sufficient high-quality prey within foraging distance of their nests, a distance that can vary from a dozen to hundreds of kilometers, depending on species and reproductive phase. When not breeding, many species are capable of long-distance migrations covering thousands of kilometers.

Sea ice cover in the Arctic affects seabird foraging, and extensive ice can restrict their access to prey. However, the marginal ice zone can provide a rich foraging opportunity (Hunt et al., 1996), as zooplankton and fish species often aggregate at ice edge habitats (Daase et al., 2021). Changes in sea ice extent and water temperature have resulted in changes in the available prey field for seabirds throughout the Arctic (Mallory et al., 2010; Frederiksen et al., 2013; Gall et al., 2017; Mueter et al., 2021a). For instance, in the North Atlantic, little auk wintering distribution expands and contracts with the distribution of their subarctic copepod prey, which is shifting northward (Amélineau et al., 2018). In the Pacific Arctic, low amounts of sea ice and warmer sea temperatures have been associated with low reproductive success and seabird die-offs, apparently due to low prey availability (Duffy-Anderson et al., 2019; Romano et al., 2020).

The timing of spring ice retreat in the Pacific Arctic has been shown to affect seabird distribution on the Bering Sea shelf, with contrasting patterns between birds that forage at the water's surface and species that are subsurface foragers (Hunt et al., 2018). Early spring sea ice retreat thus affects the spatial distributions of seabird species evident in summer and alters seabird communities. Ecosystem changes are clearly altering the community composition and species richness of seabirds in the Arctic (Descamps and Strøm, 2021; Mueter et al., 2021b).

Four decades of at-sea surveys (avail- able in the North Pacific Pelagic Seabird Database; Drew and Piatt, 2015) generally show that decreased sea ice cover and higher ocean temperatures during the first decade of this century favored planktivorous seabirds over piscivorous seabirds in the Chukchi Sea (Gall et al., 2017). With further warming, some species have shifted their overall distributions northward, likely in search of food (Kuletz et al., 2020).Will et al. (2020) concluded that conditions during the relatively warm years of 2016–2019 were detrimental to planktivorous auklets nesting in the northern Bering Sea. Because warmer ocean temperatures have been linked to the replacement of larger, lipid-rich zooplankton species with smaller, lipid-poor species (Eisner et al., 2013), ongoing changes in the Pacific Arctic may no longer favor planktivorous seabirds.

In the Bering Sea, subarctic sea- birds that appear to be expanding their post-breeding dispersal ranges north- ward include three species of Pacific albatrosses (Kuletz et al., 2014), northern fulmars (Renner et al., 2013), and ancient murrelets (Day et al., 2013). For all seabirds combined, there was a shift in distribution farther into the Pacific Arctic during the warm years of 2017–2019 compared to the previous decade (**Figure 3**). This northward shift included birds that breed in the Bering and Chukchi Seas (e.g., thick-billed murre), migrants that breed in the Southern Hemisphere but move to Alaska during their non-breeding season (e.g., short-tailed shearwater; Kuletz et al., 2020),

and Atlantic species that might have crossed the Canadian Arctic Archipelago (e.g., northern gannet; Day et al., 2013). Based on data from the eastern Chukchi Sea, seabirds that had been spatially correlated with prey communities during a relatively cool year (2015) were decoupled from the same communities in a warm year (2017), suggesting that these seabird communities did not adapt, at least in the short term, to a rapid change in conditions (Mueter et al., 2021b).

CETACEANS

Marine mammals have exhibited phenological and distributional changes throughout the Arctic. Endemic Arctic marine mammals spend their lives in the Arctic, often closely associated with sea ice. A number of subarctic species, particularly cetaceans, have become regular summer and autumn visitors to the Arctic, migrating into the region as sea ice melts in the spring or early summer and out of the region as the sea surface freezes in late autumn or early winter (Hamilton et al., 2021). As sea ice has declined in age, thickness, and extent throughout the Arctic, prey distributions have shifted and new migratory corridors have opened for subarctic marine mammal species (Buchholz et al., 2012; Berge et al., 2015; Storrie et al., 2018). These changes have expanded the temporal and spatial boundaries of habitat for cetaceans: they are now arriving in the Arctic earlier, staying later, and migrating farther north (Nieukirk et al., 2020; Ahonen et al., 2021).

Killer Whales

Killer whales are a globally distributed top predator with ecotypes that are distinguished by their phenotypes and preferred prey (de Bruyn et al., 2013). Killer whales are not a new species in the Arctic, as they have been documented there sporadically in summer months, feeding on a variety of marine mammal species (Stafford, 2019; LeFort et al., 2020). In the Arctic, killer whales avoid dense ice, and heavy multi-year sea ice once excluded them from most high Arctic regions during many months of the year. Though these whales still avoid heavy sea ice (Matthews et al., 2011), their increasing occurrence in the Arctic as sea ice declines in thickness and extent represents seasonal and geographic expansion. Recent (2010 to present) sighting and passive acoustic monitoring data provide evidence that this species is arriving in the Arctic earlier, departing later, and moving farther north in the eastern Canadian Arctic, and north and east in the Pacific Arctic (Higdon and Ferguson, 2009; S.H. Ferguson et al., 2010; Stafford, 2019; **Figure 4**). In the Pacific Arctic, passive acoustic monitoring has recently documented killer whales throughout the Chukchi Sea as far north as 75°N (recent work of author Stafford). This species has been heard in the Pacific Arctic as early as May and as late as October (Stafford, 2019). In both the Canadian and Pacific Arctic, the number of bowhead whales with killer whale scars has increased over time (Reinhart et al., 2013; George et al., 2017) as has evidence of depredation in bowhead whale carcasses (Willoughby et al., 2020). Matthews et al. (2019) posit that periodic ice entrapments of killer whales, which are usually fatal (Westdal et al., 2016), may slow their expansion into the Arctic, particularly as naive whales explore regions that can be ice choke points.

The northward range expansion, lon- ger seasonal presence, and higher num- bers of a top predator in the Arctic has the potential for top-down ecosystem reorganization and may represent the most immediate threat to Arctic endemic species (S.H. Ferguson et al., 2010). In the eastern Canadian Arctic, endemic narwhals, belugas, and bowhead whales

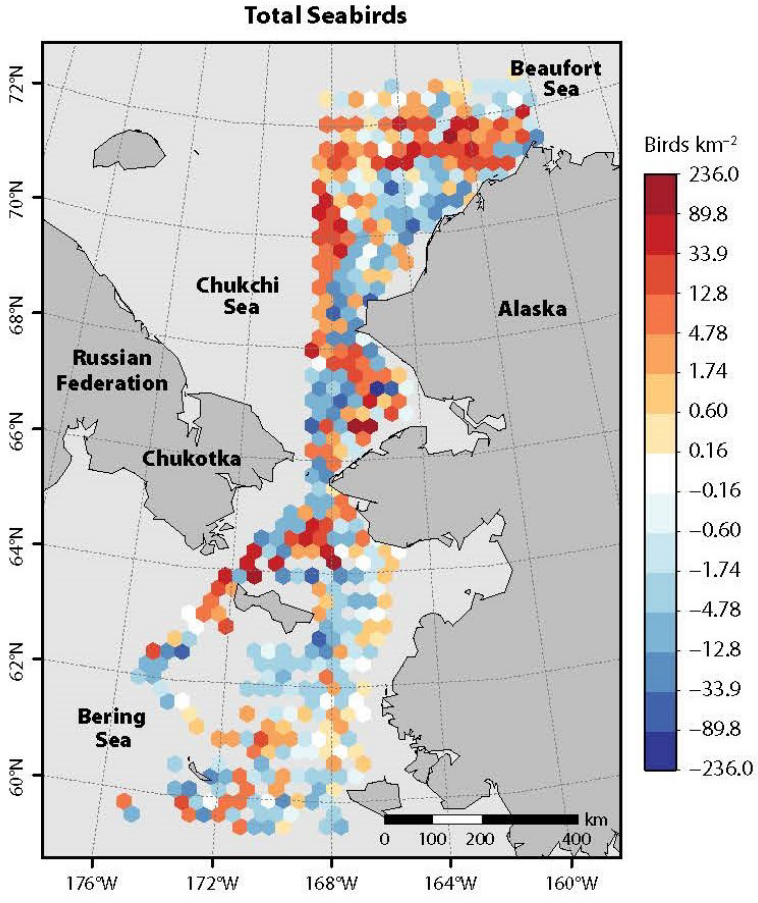

FIGURE 3. Distribution changes in the Pacific Arctic region for total seabird densities (birds km^{-2}) during 2017–2019 compared to the previous decade. Cells with increasing (orange) and decreasing (blue) densities during 2017– 2019 were based on mean densities of all observations within each 50 km grid cell. *Adapted from Kuletz et al. (2020)*

change their behavior in the presence of killer whales (reviewed in Matthews et al., 2020). Lefort et al. (2020) suggest that this species could have a significant negative impact on narwhal populations in the Canadian Arctic Archipelago.

Subarctic Baleen Whales

The historical occurrence of humpback, fin, and minke whales north of Bering Strait was documented by Soviet scientists, particularly near the Chukotka Peninsula, from June to October (summarized in Clarke et al., 2013). These species are regularly found in the Bering Sea during summer (M.C. Ferguson et al., 2015), and fin whales are present there year-round (Stafford et al., 2010). Evidence from visual (shipboard and aerial) and acoustic monitoring suggest that their use of the Pacific Arctic may be increasing (Clarke et al., 2013, 2020; Brower et al., 2018).

Four decades of aerial surveys (Clarke et al., 2020) provide the most extensive information on subarctic whales in the US Pacific Arctic. Fin whales first appear north of Bering Strait in the aerial survey database in 2008, humpback whales in 2009, and minke whales in 2011. All three subarctic baleen whales were sighted in every month from July through October, although most of the sightings through 2019 occurred from July through September (Clarke et al., 2020). Furthermore, fin and humpback whale calves have been observed in the region (Clarke et al., 2020). Aerial survey observers have commonly recorded all three species in close proximity to one another and to gray whales, particularly in Hope Basin, a benthic hotspot in the south central Chukchi Sea (Clarke et al., 2020). In 2019, the number of subarctic baleen whales detected per kilometer surveyed over Herald Shoal, which is ~145 km northwest of Point Lay, was 12.5 times greater than in any previous survey year. All three species have been documented feeding in the Pacific Arctic Region, and it is likely that the northward expansion of prey (krill and forage fish/or small schooling fish) distributions provided the whales' motivation to migrate to the Pacific Arctic (Clarke et al., 2020).

CONCLUDING THOUGHTS

What does the future hold for upper trophic level species and communities in the Arctic? It is clear across taxa that the effects of climate change are variable and dependent on the different ecological requirements of communities, feeding guilds, species, and age classes. There is no indication that climate change in the Arctic is going to decelerate any time soon. The habitat changes that have been seen in the past two decades will become the "new normal" (Thoman et al., 2020). There is clear evidence of temporal-spatial range expansion for many subarctic UTL species. Increasing ice-free habitat and changes in water mass distributions are altering the underlying prey structure and therefore attracting new UTL species, increasing habitat extent, and/or increasing the duration of residency in Arctic habitats. But for many subarctic species, annual sea ice cover, freezing temperatures, and months of darkness may still prevent them from becoming true Arctic residents. Pollock eggs and larvae are highly sensitive to cold temperatures, central place foraging seabirds need adequate nesting habitat within foraging distance of high prey abundance, and subarctic cetaceans can still be excluded from heavy ice as they risk injury to their dorsal fins and ice entrapment. To permanently expand northward, UTL species require the flexibility in physiology and behavior to adapt to ongoing habitat perturbations. If new species can adapt to year-round life in the Arctic, understanding the risks to Arctic endemic species from

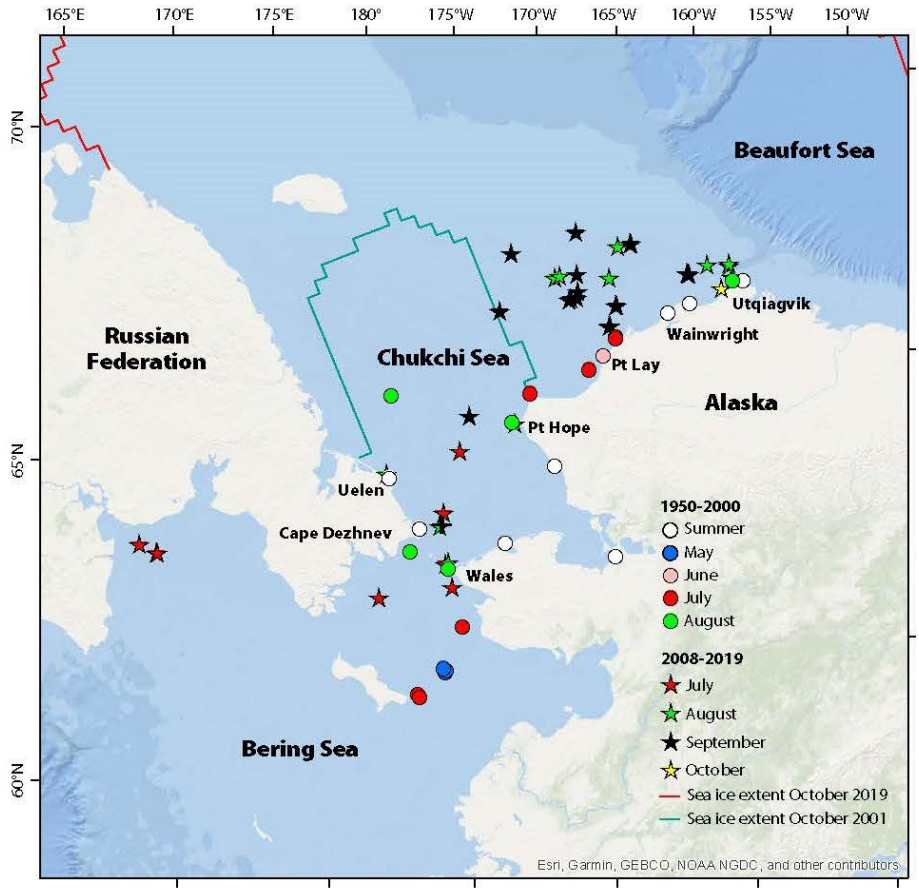

FIGURE 4. Killer whale sightings in the Pacific Arctic by month from 1950 to 2000 (circles) and 2008 to 2019 (stars). Sea ice extent is shown for October 2001 (blue line) and 2020 (red line). *Adapted from Stafford (2019)*

competition for prey, novel predators, and exposure to novel pathogens will be critical (e.g., Post et al., 2013; Kortsch et al., 2015; VanWormer et al., 2019). The evidence we summarize here indicates large-scale shuffling of subarctic and Arctic marine animal communities as high-latitude marine ecosystems undergo rapid reorganization.

Evidence suggests potential transformation of the Pacific Arctic ecosystem is underway. *Nature Climate Change*, 10(4), pp.342-348

Abstract

The highly productive northern Bering and Chukchi marine shelf ecosystem has long been dominated by strong seasonality in sea ice and water temperatures. Extremely warm conditions from 2017 into 2019 – including loss of ice cover across portions of the region in all three winters – were a marked change even from other recent warm years. Biological indicators suggest this state change could alter ecosystem structure and function. Here we report observations of key physical drivers, biological responses, and consequences for humans, including subsistence hunting, commercial fishing, and industrial shipping.

We consider whether observed state changes are indicative of future norms, whether an ecosystem transformation is already underway, and if so, whether shifts are synchronously functional and system-wide, or reveal a slower cascade of changes from the physical environment through the food web to human society. Understanding of this observed process of ecosystem reorganization may shed light on transformations occurring elsewhere.

The highly productive northern Bering and Chukchi marine shelf ecosystem has long been dominated by strong seasonality in sea-ice and water temperatures. Extremely warm conditions from 2017 into 2019—including loss of ice cover across portions of the region in all three winters—were a marked change even from other recent warm years. Biological indicators suggest that this change of state could alter ecosystem structure and function. Here, we report observations of key physical drivers, biological responses and consequences for humans, including subsistence hunting, commercial fishing and industrial shipping. We consider whether observed state changes are indicative of future norms, whether an ecosystem transformation is already underway and, if so, whether shifts are synchronously functional and system wide or reveal a slower cascade of changes from the physical environment through the food web to human society. Understanding of this observed process of ecosystem reorganization may shed light on transformations occurring elsewhere.

The Pacific Arctic, which comprises the Chukchi and northern Bering seas (Fig. 1), is one of the world's most productive ocean ecosystems[1] and is characterized by high benthic biomass resulting from persistent, nutrient-rich flow through the Bering Strait[2], which fuels high primary production[3]. The region is home to millions of nesting and migratory seabirds in summer and autumn, with hotspots of foraging activity shared with marine mammals[4], supporting coastal Indigenous communities. The delivery of nutrients together with the extent and timing of the sea ice[5] are dominant environmental factors that structure this ecosystem. A freeze-up in autumn and winter eliminates large expanses of open water, causing whales, Pacific walruses (*Odobenus rosmarus divergens*), many seals and seabirds to migrate southwards into the Bering Sea and beyond[6]. The return of sunlight in spring heralds snow melt, growth of sea- ice algae, and a phytoplankton bloom that typically exceeds the consumption capabilities of pelagic consumers, resulting in carbon falling to the seabed and fuelling rich benthic communities[7,8]. Solar radiation and melting sea ice help stratify the upper water column, impeding the ability of winds to mix surface and subsurface waters. In summer, low-salinity surface waters near the pack ice remain cool relative to the shelf waters that are warmed by insolation. The Bering Sea cold pool (near-bottom shelf waters cooler than 2 °C, located south of the Bering Strait) has long served as a thermal barrier that prevents northwards migration of subarctic groundfish[9], which are major stocks for the southeastern Bering Sea's US $2 billion dollar fishery and account for about half of the seafood landings in the United States[10,11].

Recent changes in the Pacific Arctic marine ecosystem

Declining sea ice in this century has reduced surface albedo in spring and summer, accelerating oceanic heat uptake and causing earlier and more rapid sea-ice melt[12]. The pack ice and marginal ice zone has retreated north beyond the Chukchi shelf in recent summers, whereas warmer shelf waters delay sea-ice formation in autumn. Simultaneously, the flow of water northwards through the Bering Strait has increased, as has its temperature[2], so that it now delivers more heat, freshwater, nutrients and biota northwards into the Arctic[13]. Near-bottom water temperatures now exceed 0 °C for a larger portion of the year (Fig. 2).

The ramifications of these physical changes include more salmon in the Chukchi and Beaufort seas[14,15], walruses hauling-out on shore instead of sea ice in northwestern Alaska in late summer[16], an increase in the frequency and seasonal duration of killer whale (*Orcinus orca*) presence in the Chukchi Sea[17], an increase in planktivorous seabirds in the Chukchi Sea[18] and a northwards shift in the distribution of other seabird species[19,20]. For the Indigenous peoples of the region, spring marine mammal hunting opportunities that are dependent on the presence of sea ice have decreased and shifted in time[21], although the lack of sea ice has allowed additional whaling to occur in autumn and early winter in the northern Bering Sea[22].

And then came 2017

In 2017, physical conditions in the Pacific Arctic marine shelf ecosystem of the Chukchi and northern Bering seas described above showed signs of a sudden and dramatic shift relative to historical means and even to other recent unusually warm years. These physical changes seemingly precipitated several important ecological shifts, with consequences for the region's residents. On the basis of published material and unpublished data from the authors, many changes persisted in 2018 and even into 2019, suggesting that 2017

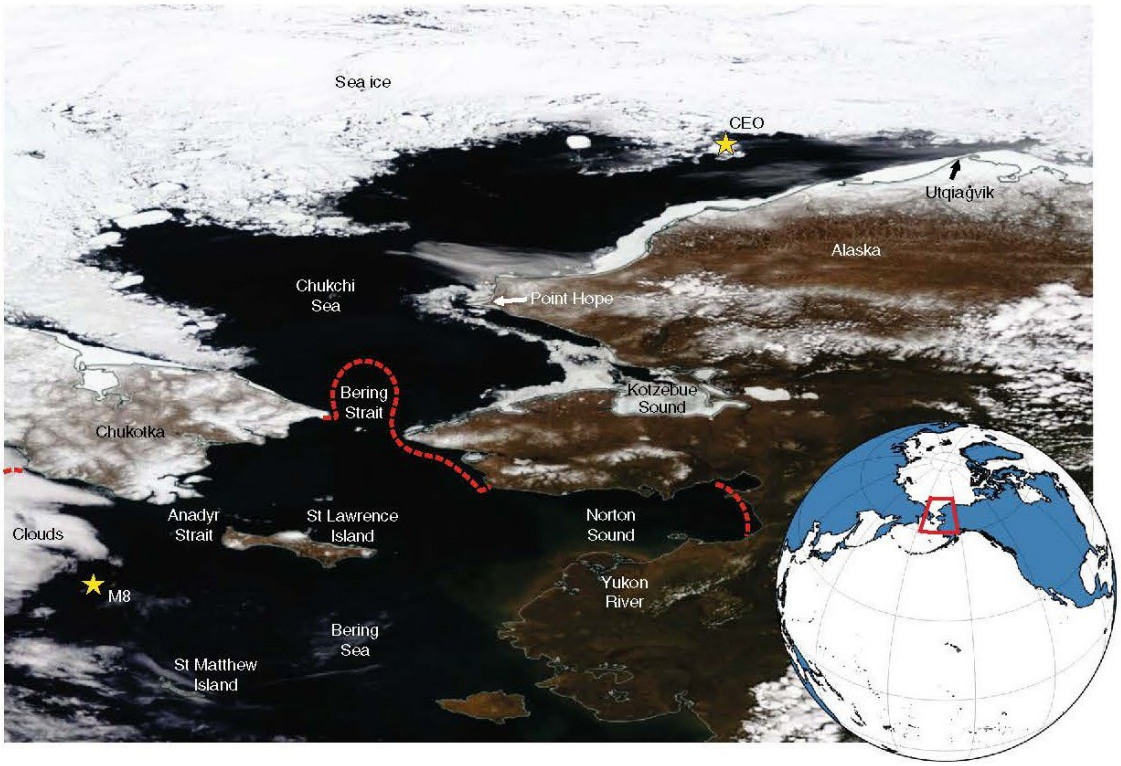

Fig. 1 | Sea-ice changes in recent years. A true-colour MODiS satellite image showing northern Bering and Chukchi sea-ice conditions on 2 June 2017. The red dotted lines denote the 1980–2010 ice-edge climatology for 2 June. Yellow stars denote locations of oceanographic moorings M8 and CEO. The inset locates the study region. Credit: NASA Worldview.

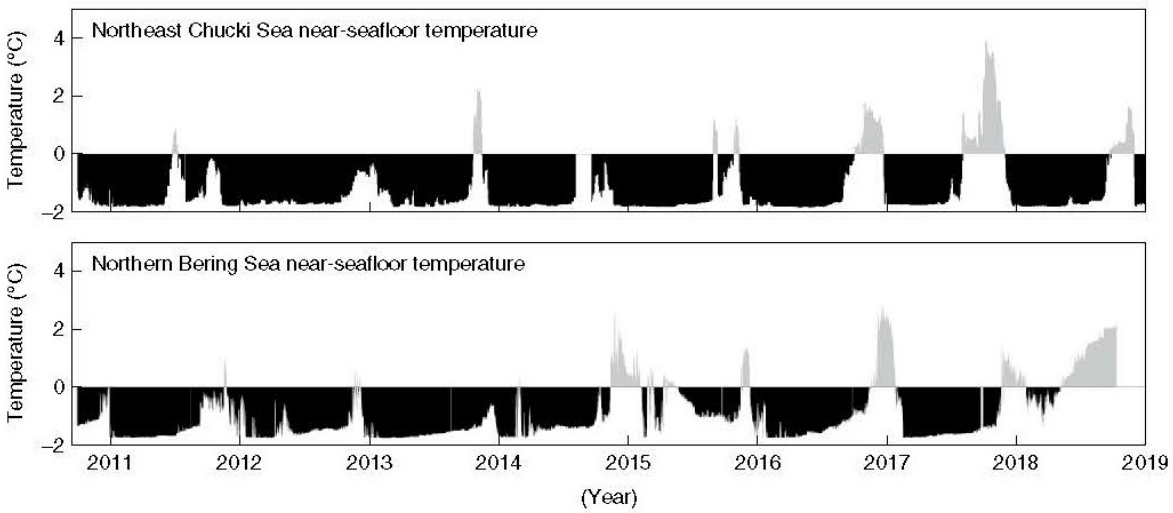

Fig. 2 | Near-bottom water temperatures. in past years, temperatures in important seafloor habitats remained below 0 °C for most of the year, whereas in recent years, an increasing number of months exhibited temperatures well above 0 °C. The mooring locations are indicated by gold stars on Fig. 1.

was not a passing oddity of brief consequence to social-ecological systems, but a sign of what is to come.

In early January 2017, the sea-ice edge had barely progressed south of the Bering Strait and for the entire winter its extent remained at least 2×10^5 km^2 below the long-term average. In June, ship-based observations found that the near-bottom ocean temperatures in the Bering Strait were nearly 4 °C, which are over 3 °C and four standard deviations warmer than the 1991–2016 June mean[2]. By June, the eastern Chukchi shelf was already mostly sea-ice free (Fig. 1). In early December 2017, the ice edge was over 1,000 km north of its climatological mean position near St Lawrence Island.

There was no sea ice in the Bering Strait in February 2018 and southerly winds forced a large ice retreat again in February 2019[23]. Waters in Norton Sound exceeded 10 °C before the end of June 2018 and the cold pool was again minimal by late summer.

Reduced ice cover and warmer seas probably impacted primary production by influencing thermal, light and stratification conditions. In the spring of 2018, the bloom was delayed in the southern Bering Sea due to a lack of freshwater input from melting sea ice, and chlorophyll concentrations were one-order-of-magnitude lower than usual; however, in the northern Bering Sea the ice-associated bloom was early and extensive[24]. Furthermore, the

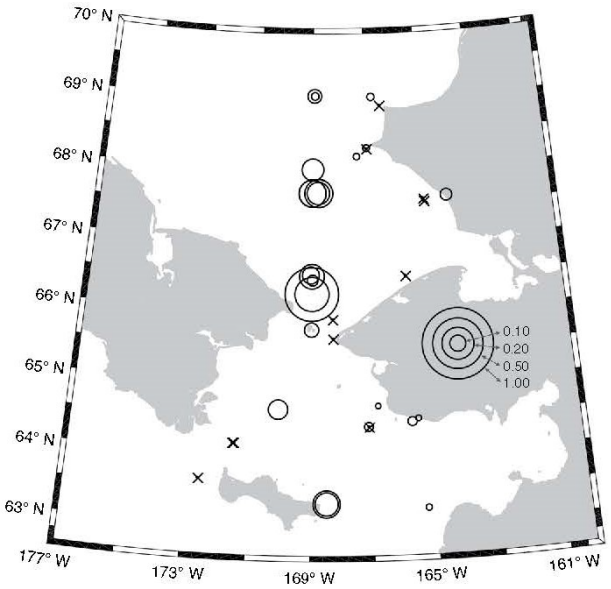

Fig. 3 | Seawater concentrations of domoic acid (nmol kg^{-1}), June 2017. Crosses indicate samples in which no toxins were detected.

detection of domoic acid in shipboard water samples (Fig. 3) and saxitoxin in a few stranded and harvested walruses from Bering Strait villages led to concern about harmful algal blooms and food safety from Indigenous residents, although analytical challenges make the impact difficult to determine[25].

Changes in species distributions had already been observed this century, but not to the extent observed in 2017. The copepods *Calanus glacialis/marshallae* were found that year to be remarkably low in abundance relative to 2012–2015 and multispecies epibenthic biomass in the southern Chukchi Sea also exhibited a pronounced decline relative to comparable collections in 2004, 2009, 2012 and 2015 (Fig. 4). By contrast, acoustic-trawl surveys indicated that age-zero Arctic cod abundance was dramatically higher in the Chukchi Sea in 2017 when compared with previous surveys: backscatter in the northern Chukchi Sea (67° N to 71.5° N) was 5.6 times greater than in 2013 and 16.3 times greater than in 2012 (Fig. 5), but the fish had low energy content. In surface trawl surveys in the northern Bering Sea, the catch per unit effort for juvenile pink salmon (*Oncorhyncus gorbuscha*) was two times greater during 2017 than previous years (Fig. 4); they return as adults in the following year, and during 2018 they returned to Norton Sound in much greater numbers than expected[26]. Adult walleye pollock (*Gadus chalcogramma*), Pacific cod (*Gadus macrocephalus*) and northern rock sole (*Lepidopsetta polyxystra*) biomass in bottom trawl surveys increased in the northeastern Bering Sea during 2017, probably due to northwards movement of these fishes in the absence of the Bering Sea cold pool[27].

In offshore waters, the total number of seabirds declined from 2012–2017 in the southern and northern Bering Sea, but densities were above the long-term mean in the Chukchi Sea during most of that period. The increase in the Chukchi Sea in 2015–2017 was primarily due to short-tailed shearwaters (*Ardenna tenuirostris*), which feed primarily on euphausiids, and less pronounced increases in piscivorous black-legged kittiwakes (*Rissa tridactyla*) and murres (*Uria* spp). By contrast, planktivorous auklets (*Aethia* sp.) had low densities in the Chukchi Sea in 2017 and 2018; however, their densities increased in the northern Bering Sea in those years[24]. Reproductive success was low for seabirds in the Bering Sea in 2017–2018 and there were mixed-species die offs there and in the Chukchi Sea[24,28], with dead birds emaciated. Notably, the numbers of murres and kittiwakes attending the large Chukchi Sea colony continued to increase[29] at a rate that suggested immigration of piscivorous nesting birds.

In the spring of 2017, bowhead whales, including females with calves, were seen near Utqiaġvik, Alaska, nearly a month earlier than usual and the Utqiaġvik whale hunt recorded the earliest known landing on 13 April. Four bowhead whales equipped with satellite transmitters all wintered (2017 to 2018) in the Chukchi instead of their usual wintering area south of Anadyr Strait in the Bering Sea[30] and a bowhead was recorded singing near Utqiaġvik on 11 January 2018, something that has never been recorded before at that time of year. In 2018 to 2019, the bowheads were again north of the Anadyr Strait in winter. Spotted seal (*Phoca largha*) pups in the spring of 2018 were found in poorer condition (less fat and lower mass/length) than in recent years, and almost no ribbon seals (*Histriophoca fasciata*) were seen during those same surveys, raising the spectre of a failure in the 2018 year class. In the spring and summer of 2018 and 2019, more than 280 bearded (*Erignathus barbatus*), ringed (*Pusa hispida*), spotted and unidentified seal carcasses (primarily young and many emaciated) were reported from beaches mostly in the northern Bering and southern Chukchi seas, nearly five times the annual average from 2014–2017, prompting the National Oceanic and Atmospheric Administration to declare an unusual mortality event[31].

Anomaly or transformation?

Changes in sea-ice extent, water temperature, currents, zooplankton abundance, animal distribution and health, hunting success and other aspects of the ecosystem are noteworthy in themselves, but such large-scale changes could conceivably occur without altering basic relationships among ecosystem components. The investigation of specific mechanisms underlying these changes were not part of the cited studies; however, it is known from other areas—including the southern Bering Sea—that the spring sea-ice break-up spurs a productive phytoplankton bloom and its timing, together with ocean temperatures, determines phytoplankton species composition, carbon export to the benthos and food quality for zooplankton[24]. Changes towards lower-lipid zooplankton reduces over-winter survival of fishes such as salmon and Arctic cod[32], even if they increase numerically in summer due to favourable thermal and oceanographic conditions. Lower zooplankton food quality and increased competition from predatory fish moving north from the Bering Sea might explain seabird and seal mortality.

The ecosystem-wide changes seen in 2017–2019 have the poten- tial to fundamentally reconfigure the Pacific Arctic marine food web. An altered physical environment characterized by warmer waters and a longer open-water season is allowing subarctic species to establish themselves in the Chukchi Sea; seasonally for now, but possibly year-round in the future. Subarctic invaders such as walleye pollock and Pacific cod could fundamentally transform interactions among pelagic species, benthic invertebrates, groundfish, seabirds and marine mammals by exerting strong predation pressure on forage fishes and benthic crab, worm and shrimp communities[10]. Predation pressure from these fishes adds top-down stresses to the bottom-up changes that are associated with altered temperature and primary and secondary productivity. Indigenous hunters may begin to find familiar species of fishes and marine mammals at unusual times of year or unfamiliar species during customary hunting and fishing periods[21].

An interdisciplinary look at the Pacific Arctic marine ecosystem as it changes may provide a rare opportunity to track ecosystem transformation in detail as it unfolds, rather than reconstructing details after the fact. The transformation of an ecosystem may reflect a cascade of sequential changes that take place over multiple

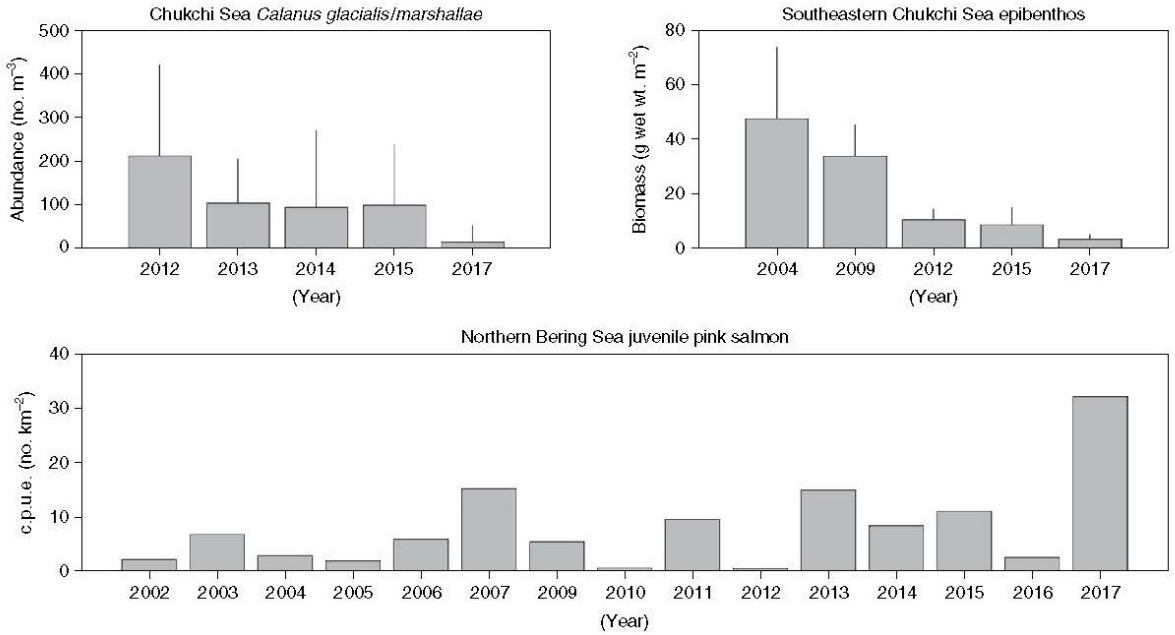

Fig. 4 | Biological changes in recent years. Observations show declines in *Calanus glacialis/marshallae* abundance (upper left) and epibenthic biomass (upper right) in 2017 relative to earlier years, and an increase in catch per unit effort (c.p.u.e.; bottom) for juvenile pink salmon. The upper two graphs show means and s.d. error bars.

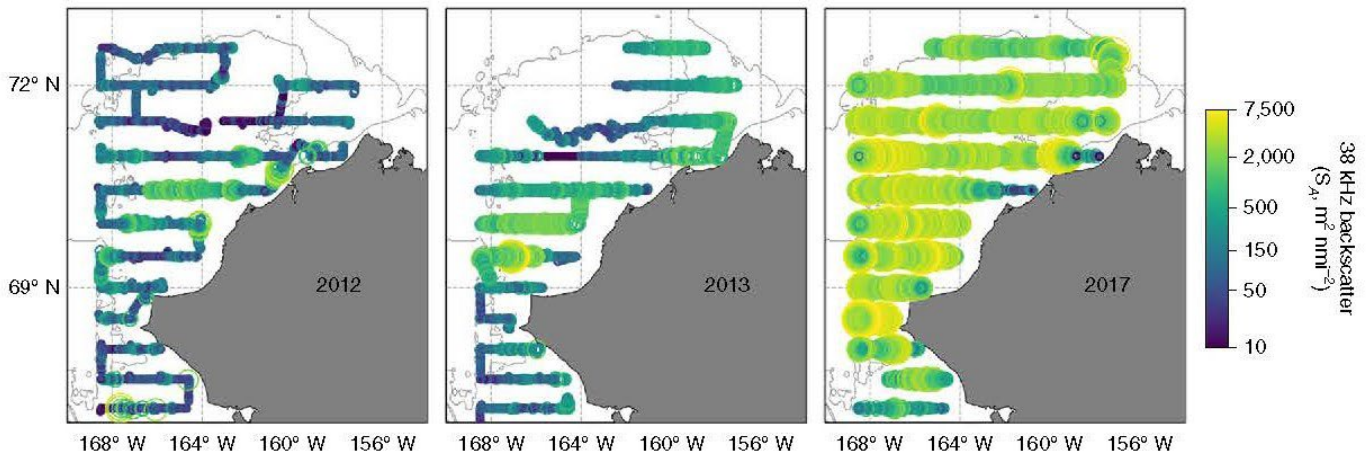

Fig. 5 | Change in Arctic cod abundance. Acoustic surveys indicate that the abundance of age-zero Arctic cod increased substantially in 2017 relative to 2012 and 2013. Trawl sampling indicated that Arctic cod dominated acoustic backscatter in this area in 2012 and 2013 (ref. [50]). This was also the case in 2017 where Arctic cod accounted for 95.4% of fish captured in 33 midwater trawl hauls. Measurements, s_A, are expressed as the nautical area backscattering coefficient[50] at 38 kHz.

years rather than a single shift or tipping point (for example, ref. [33]), although changes to individual ecosystem components may be sudden and dramatic; for example, because of positive feedbacks in the climate system (see ref. [12]), it is possible that 2017 marked the crossing of a threshold that precludes return to the system state that was common just a decade ago. We find that a closely coupled synergy between bottom-up and top-down factors (for example, ref. [34]) seems to best characterize this system's transition and the interactions among these multiple stressors have important implications for understanding any subsequent reorganization. The result would be the transformation of an Arctic marine ecosystem into one that is characterized by subarctic conditions, subarctic species and subarctic interactions (Box 1). The Chukchi Sea may soon resemble the east-central Bering Sea shelf in condition, structure and function, with annual sea ice, warmer bottom water temperatures and ecosystem productivity derived from forage fishes and pelagic zooplankton rather than the benthos. Changes in the historically strong benthic–pelagic coupling have already been observed in the southeastern Chukchi Sea, where overall epibenthic biomass declined by an order of magnitude from 2004 to 2017; the fact that the most abundant taxa were consistent over time may hint at overall changes in ecosystem productivity or pathways rather than specific habitat changes[35,36]. Yet this transformation is more complex than an ecosystem migrating north; for example, the Chukchi Sea would probably retain some characteristics that distinguish it from the Bering Sea shelf, due to higher latitude and downstream location relative to the Bering Strait nutrient supply. How these competing features will combine to create a new state of the Pacific Arctic ecosystem remains to be seen.

In addition to its regional importance, the pattern of change underway in the Pacific Arctic may eventually shed light on the progression of ecosystem transformation more generally[37], which manifests as large-scale alterations in the connections and interactions among species and among physical and biological processes.

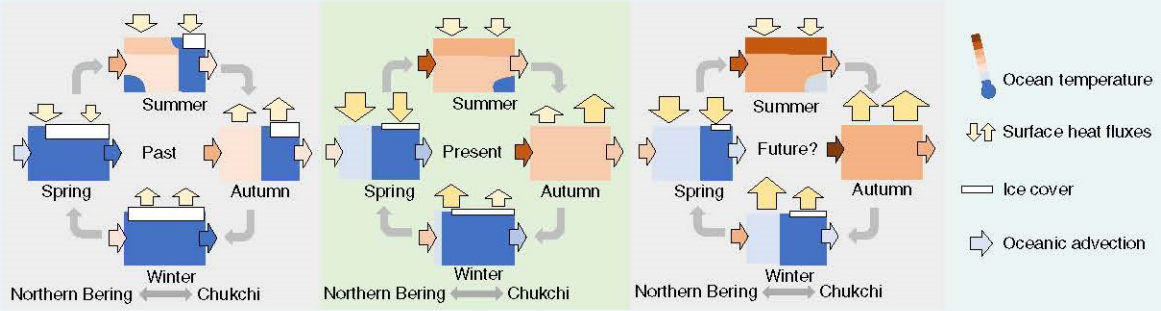
Box 1 | Environmental changes and consequences for the ecosystem and humans

The figure shows the observed and potential future changes in the physical environment, and the following list highlights the observed and anticipated consequences for the biological and human components of the ecosystem:

- Altered timing and magnitude of spring-ice-associated phytoplankton and zooplankton blooms
- Higher frequency of toxic algae blooms
- Increased metabolic and respiration rates
- Seasonally altered distributions of fishes and marine mammals that associate with sea ice
- Seabird reproductive failures and die-offs
- Expansion of subarctic species distributions northwards

New predation pressure on Arctic pelagic and benthic communities

- Migration of commercial fish species away from the southeast Bering Sea
- Less stable ice and altered access to winter subsistence hunting grounds
- Altered seasonality for hunting
- New subsistence food sources
- New management decisions for commercial fishery oversight
- Increased vessel traffic in ice-free waters with associated increased risks of oil spills, marine mammal strikes and noise pollution
- Accelerated coastal erosion and delivery of terrestrial carbon to marine domain



Environmental changes and related consequences. Observed and potential future changes in the physical environment (left and middle panels) in the Northern Bering and Chukchi shelf systems (that is, bottom-up forcing), along with observed and anticipated consequences for the biological and human components of the ecosystem (right panel).

Overpeck et al.[38] suggested the possibility of such a transformation resulting from the removal of perennial ice in the Arctic, although they focused on the before and after states of the system without describing the transformation in between. The pioneering work of Gunderson and Holling[39] recognized that transformation and reorganization are less predictable and less well understood than a simple shift from stability to instability.

What to expect next?

The expectation is for the sea-ice season to further shorten and sea-ice coverage to diminish[40]. Waters will become warmer and stay warm longer into autumn and winter. It is hard to predict how quickly these changes propagate through and persist in the system, and what additional sudden shifts may occur. It is likely, however, that there will be differences in the temporal and spatial scales over which physics and biology change[41]. Physical conditions that were once anomalous may become normal. The biological response will follow but may not carry over across years until species and behaviours that thrive in the new conditions are able to persist. Hunters and fishers will adjust to some degree but may find it necessary to switch the timing or targets of their efforts[42].

Specific trajectories of these changes and their implications for the Pacific Arctic ecosystem, including Indigenous coastal communities, are still unclear. To stay with or ahead of these system transformations rather than reacting to a new state some years from now, some critical unknowns (especially regarding ecosystem relationships) will require further attention and continued monitoring at multiple scales. As sea ice retreats earlier, will some species cling to existing fixed habitats (for example, depositional zones) and remain largely in place while others follow shifting habitats (such as the ice edge)? Will subarctic species be able to flourish and persist in the Chukchi Sea year-round, transforming the ecosystem into a locus of groundfish or pelagic predator abundance? Will increased industrial activity such as shipping combine with climate-driven ecosystem changes in ways that amplify the consequences of either alone[43]? How can coastal communities adjust and adapt quickly enough to retain cultural and nutritional security[44]?

Even in this age of information overload, it is how remarkable how scarce (and thus how valuable) the available data are for mak- ing statistically robust comparisons of today's conditions versus yesterdays; for example, quantifying changes in primary and secondary productivity cannot immediately follow the spring retreat of sea ice because previously the ice itself precluded ship-based measurements at locations and times now ice free. Across the study region, even 15 years of annually collected data is an unusually long time series, and for biological parameters most of these data are confined to summer months; hence, it is important to learn to distinguish surprises from completely new observations.

A cascade of effects through an ecosystem may include tipping points governed by positive feedbacks for individual components, making recovery to the previous structure and function ever less likely (for example, refs. [33,45]). Top-down changes such as increased predation may result from bottom-up changes, such as the removal of thermal barriers to the range expansion of predators. The experience so far in the Pacific Arctic by itself will not resolve these questions, but it does suggest that, with regards to cascades versus

tipping points or top-down versus bottom-up controls (for example, ref. [46]), ecosystem transformation may be a complex matter of 'both and' rather than a simple dichotomy of either/or.

These questions are more than a curiosity[47]. The well-being of coastal communities and the management of human activities in the region—including potential commercial fisheries—depend on reliable information and insight into what is likely to happen next. In Alaskan waters, industrial and research activities are planned in ways to reduce interference with Alaska Native subsistence harvests, and conscientious vessel operators communicate with communities and adjust their plans to avoid areas where hunters are active (for example, ref. [48]). Growing uncertainty about the timing of animal migrations and optimal harvest conditions increases the likelihood of conflict and concerns about food security. Coastal communities are likely to face difficult choices between capitalizing on increased economic opportunity and limiting industrial interference with subsistence activities.

The profound shift in ecosystem state and conditions suggest a new framework is needed to replace the paradigm that served well in recent decades. The Pacific Arctic marine ecosystem transforma- tion is not an isolated case. Social-ecological systems worldwide are facing similar pressures from changing physical conditions, with implications that are increasingly uncertain as transformation propagates through the food web and to human outcomes[49]. Long-term and multiscale data are necessary to detect, examine and respond to such changes. A better understanding of the nature of system transformation will help humans detect transformations earlier, perhaps in time for more effective response or adaptation, even if prevention may no longer be possible.

General Discussion

Environmental Setting

The Arctic IERP proposals were written in 2016, in the midst of the well-documented North Pacific Marine Heatwave (refs; Walsh et al, 2018). Although "the Blob" of warm water was first identified in the Gulf of Alaska (Freeland et al., 2014; Bond et al., 2015) and many dramatic examples of Gulf of Alaska ecosystem impacts were evident at that time and documented in the years since (Piatt et al., 2018, Suryan et al, 2021), anomalous warmth also extended across the Pacific Arctic at this time (Danielson et al., 2020). Little did we know, however, that the northern Bering and Chukchi seas were about to enter a period of unprecedented winter sea ice loss (Stabeno and Bell, 2018; Thoman et al., 2020) and equally as anomalous distribution shifts and changes in abundance of target commercial, non-commercial and subsistence harvest fishes and invertebrates as well as marine mammals (Huntington et al, 2020, Stevenson and Lauth, 2019).

In the Arctic, the main sources of naturally occurring sounds include waves, winds, sea ice, and marine mammals. There is a direct correlation between increasing wind speeds and increasing ambient sound levels over open water. Sound levels tend to be higher for the same wind speed in shallow waters, such as those found in much of the nearshore Arctic, including the northern Bering and southern Chukchi Seas, than in deep waters. With increasing open water, not only is noise from wind and waves increasing but noise from large ships such as tankers, tugs, and fishing vessels may be increasing as they take advantage of the increasing open water season in the Arctic. Vessel traffic through the Bering Strait increased 150% from 2008-2018 and the distance sailed in the Arctic Polar Code Area increased by 160% from 2013-2019 (PAME 2020). Vessels that passed through the Bering Strait from June to November in 2013-2015 included cargo ships, tankers, fishing vessels, research vessels, tugboats, passenger ships, and supply vessels. The sounds from these vessels are relatively low frequency (< 1000 Hz) and in the same frequency band used by many Arctic species including bowhead whales, walrus, bearded, ringed and ribbon seals.

Analysis of a nearly 100-year-long historical record (Danielson et al. 2020) shows that the Bering and Chukchi continental shelves exhibit different trends and multi-year intervals of warm and cold conditions – suggesting that while the Chukchi receives input from the Bering Sea it operates somewhat independently of the Bering's upstream heat inputs: more local processes dominate. Analyses show that the heat engines of both shelves accelerated over 2014-2018, with increased surface heat flux exchanges and increased lateral oceanic heat advection.

In retrospect, it appears that the Arctic IERP field years (2017-2019) encompassed the peak of the thermally anomalous conditions in this particular multi-year phase of regionally warm conditions; they are the only three years in the record with annual mean monthly temperature anomalies of greater than 1.5 °C (Figure 11). Given the likelihood of continued future warming, these years likely represent a preview of what may eventually be considered typical.

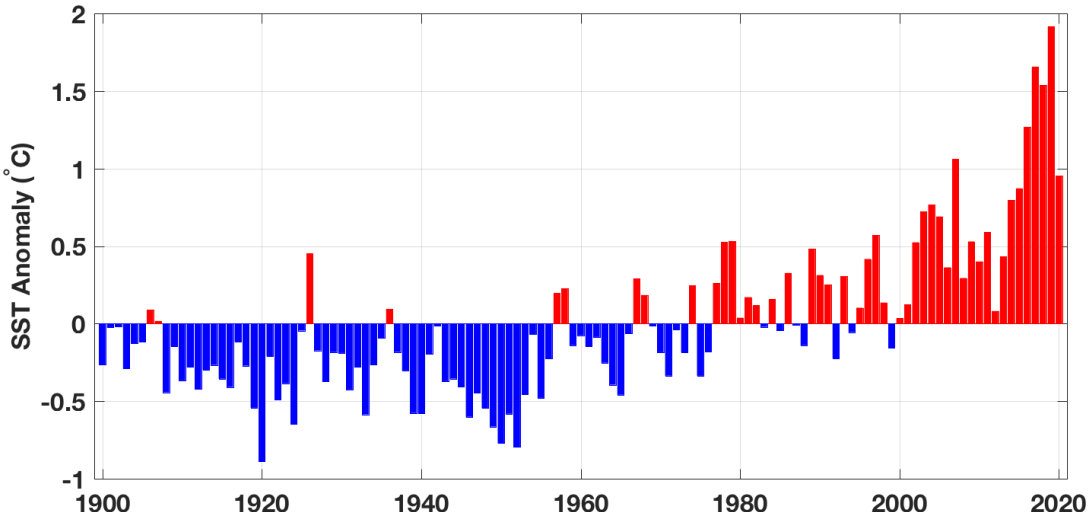

Figure 11. Sea surface temperature (SST) annual mean of all monthly anomalies over 1900-2020 from the Version 5 Extended Reconstructed SST dataset (ERSSTv5). Anomalies are computed relative to the full duration of this 1990-2020 time series. The integration region region for the data shown here extends across the whole of the Northern Bering and Chukchi Seas (60-75 °N, 180-155 °W).

The Over-arching Question

What regulates variations in carbon transfer pathways and how will the changing ice environment alter these pathways and ecosystem structure in the Pacific Arctic and how will a changing environment impact upper trophic level species and human use of the Arctic? Our observations and experiments revealed numerous insights into the character of the bottom-up forcing that helps maintain the Pacific Arctic shelf ecosystem, into how energy (carbon) is routed amongst the various marine system components from microbes to whales, and into how it may change in a warming climate. Temperature clearly stands out as a key factor in the regulation of energy consumption and trophic transfers, but temperature alone is far from the whole answer. The aggregate combination of species abundance and distributions and environmental setting (geomorphology of the Pacific Arctic shelves, large-scale pressure gradients driving mean flows, nutrient supply, strong seasonality in light, ice, winds) combined with the ability of the Pacific Arctic ecosystem to maintain its many services ultimately sets this ecosystem's unique biological character. While this character has never been static in nature, it appears to be crossing thresholds into states that have not previously been observed (Huntington et al., 2020; Ballinger and Overland, 2022). From a marine mammal standpoint, not only is changing sea ice altering habitat for both Arctic and subarctic species (Chapters 1-4), it is also potentially altering the soundscape. An example of this is increasing overlap in acoustically active species such as the subarctic humpback and Arctic bowhead whale (Figure 12).

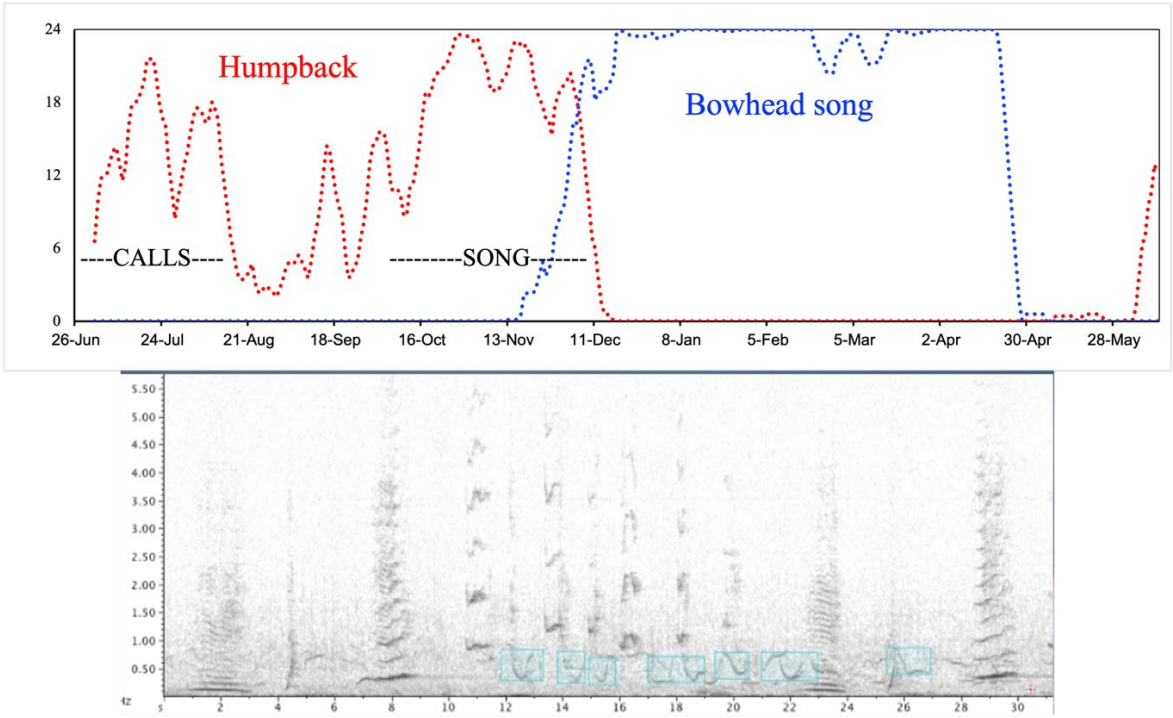

Figure 12. Seasonal occurrence of humpback and bowhead whale songs shows overlap in time and space in Anadyr Strait. In the spectrogram blue boxes highlight bowhead whale song notes in the midst of a humpback whale singing in late November 2017.

Extremely warm conditions from 2017 into 2019 – including loss of ice cover across portions of the region in all three winters – were a marked change even from other recent warm years and may represent a proxy for future decade "normal" conditions. Temperature-controlled respirometry experiments show that benthic oxygen consumption increases significantly (~30%) with warming temperatures and our mooring measurements showed an extended duration of time that the seafloor water temperatures remained 2-6 degrees above the freezing point during these recent warm years. Biological indicators, such as these temperature-dependent benthic respiration rates, suggest that thermal state change exhibits potential to alter ecosystem structure and function (Jones et al., 2021), but our measurements also show that the system exhibits resilient capacity to buffer some of the changes from a bottom-up perspective.

While the environmental alterations represent a bottom-up forcing, recent upper trophic level observations (Stevenson, D.E., Lauth, R.R., 2019; Huntington et. al. 2020, Chapter 7, Stafford et al. Chapter 6) suggest that top-down forcing of the ecosystem will also play a key, and possibly dominant, role in determining future changes to the overall character of the Pacific Arctic ecosystem. For example, the influx of sub-Arctic Pacific Cod and Walleye Pollock exhibit potential to impart a more substantive impact on the benthic community than changes in benthic productivity due to altered pelagic realm export. Sensitivity of the local upper trophic level populations to anthropogenic disturbance (e.g. shipping traffic, noise, see Chapter 5) and intra-species competition represent other potential vulnerabilities.

In aggregate, our results have helped both define and constrain our understanding of the conditions in which the future warmer Pacific Arctic ecosystem will exist. The examples summarized here, and many others in the published manuscripts cited and reprinted in this report, directly contribute to our understanding of how energy in the marine ecosystem is routed now, and how it may change as the

duration of sea ice cover continues to decline. The results of the ASGARD experiments will continue to be analyzed, synthesized, and published in coming years, each further revealing partial answers to the ASGARD and Arctic IERP over-arching question.

Application to Resource Management and Alaska Communities

Coastal Community Concerns

Food security is a paramount concern to residents of coastal communities that depend on a subsistence-based economy. Environmental conditions are changing rapidly, and hunters find themselves dealing with a multitude of factors that can degrade hunt success (Fall et al., 2013). For example, hunters report that their ability to forecast the weather is now at times diminished, fuel costs are high; ice conditions are different and less safe, and game can be less accessible. Hunters are concerned with the impact of vessel traffic on the behavior and location of marine mammals, bycatch from commercial fisheries, and increasing rates of coastal erosion that threaten the placement of entire villages.

Practical applications of our research will directly address issues, questions and concerns posed by coastal community members (e.g., Huntington et al, 2021). These include sea ice conditions and timing; whale, seal and walrus distributions with respect to vessel traffic noises; ramifications of changing climate conditions to the presence and success of marine mammals, clams, crabs, fish, and other animals; and toxic algae blooms that may impact whales and other marine mammals.

Our research allows us to provide scientific lenses through which we can help interpret the causes and consequences of environmental change. As communities continue to adapt – as they have done for millennia – information from scientific studies and scientific observations can help inform community decisions. Such decisions now commonly deal with the practical aspects of addressing climate change impacts to the environment or location availability of subsistence food resources.

Shifting Norms: Management Implications

Perhaps even sooner than many had anticipated, state and federal agencies are confronting resource management issues tied to loss of sea ice and northward-shifting distributions of sub-Arctic marine species. The incursion of Pollock and Pacific Cod into the Bering Strait region – and farther north – demand consideration and a careful assessment of new management actions. Considerations need to include biodiversity, ecosystem structure, and ecosystem function in relation to any potential fishery harvest levels. The recent (since the start of the Arctic IERP) increase of commercial fishing in the Chukchi Sea waters of the Russian Federation suggests that despite insufficient data from the US side of the convention line in the Chukchi Sea, there likely exists significant quantities of Pollock and Pacific Cod on the US side as well. In US waters, any potential fishing activities must consider the cultures and subsistence lifestyles of local indigenous communities, potential impacts of industrial activities (e.g. commercial fishing, oil and gas extraction), potential changes to regional ocean carrying capacity, and resilience of the arctic marine ecosystem (NRC, 2014). An ecosystem-based approach to fisheries management necessitates consideration of food security of the coastal Indigenous communities, their traditional subsistence hunting activities, and conservation of endangered marine mammal and seabird species.

With carbon (or sometimes nitrogen) as the basic currency with which we describe and quantify biological and biophysical interactions - including growth, respiration, energy conversion, energy movement, energy storage and intra-trophic transfers - we need to understand the rate at which carbon is consumed, converted, stored, buried, and relocated. Biophysical numerical models require as inputs sinking rates, growth rates and respiration rates for all important species or functional groups (Stock et al., 2013). As outputs, models predict primary productivity, secondary productivity and biomass. ASGARD data provide spatially explicit measures of the production and respiration rates for the dominant pelagic and benthic species,

along with more basic information about composition, biomass and abundance. Such data will prove critical for advancing spatially and temporally explicit models of ecosystem structure and applying them in appropriate and statistically robust to future scenario projections.

Directions for Future Research

Following a concentrated effort of field work, analysis and publication, further advancements in scientific understanding relies on testable hypotheses and experimental designs that probe the edges of our knowledge base and place our findings into a more complete ecological context. The process of analysis and interpretation of the Arctic IERP results is still ongoing, but a number of future research needs are already apparent. Below, we list a series of specific research directions that are applicable to the entire ASGARD suite of measurements but are targeted to marine mammal and underwater noise data that could further improve our ability to dig deeper into the ASGARD and Arctic IERP guiding questions and could provide management agencies with actionable guidance.

Below, we identify seven study focal areas that would, if addressed, lead to a fuller understanding of the Pacific Arctic ecosystem, its drivers, and future trajectory. All of the below listed studies would fill information gaps and/or needs that resource management agencies could apply to their task mandates.

Ecosystem Status and Change

1. Comparison of ASGARD data to more typical years

Our campaign existed across the two warmest years on record for the study region and are thus not well characteristic of typical conditions found in the first two decades of the 21st century. Repeated measurements in more "normal" years would allow us to better assess our warm phase June month shipboard measurements and year-round mooring measurements.

2. Applying ASGARD measurements to ecosystem models

The ASGARD project was designed in part to provide data useful for the parameterization and/or validation of numerical models. The need for such modeling efforts has not diminished and we now have significant amounts of data that can help bring model studies to a more advanced stage of operation.

3. Non-summer observations

The ASGARD expeditions in June provided valuable data outside of the more typical sampling months of July-September, but seasonal coverage in sampling remains heavily biased to summer and early fall months. Shipboard biological sampling in late fall, winter and early spring could provide data that are important to our understanding during the dark and cold portion of the year. Ecosystem ramification of multiple stressors in the Pacific Arctic Warming, ocean acidification, hypoxia, and increasing vessel traffic and other anthropogenic impacts present the likelihood of unanticipated outcomes due to the nature of nonlinear coupling between multiple stressors. Our ability to assess future ecosystem conditions in the study region depends on improvements in our understanding of how the system as a whole responds to such factors.

4. Management of vessel locations and speeds in the Pacific Arctic region

Increasing vessel traffic poses a risk to protected marine mammal and seabird species. Modeling that assesses potential dynamic and/or adaptive management approaches would improve conservation efforts and reduce the potential for conflict. This need applies year-round due to the different migration timings of the various species of interest, and the fact that vessels are now transiting through the Bering Strait region in all months.

5. Tracking of sub-Arctic species distribution, abundance, and biodiversity

Sub-Arctic species range distributions have been increasing northward in recent decades, and more recent indications show potential for displacement of endemic Arctic species as ranges over

6. Changing phenologies

As the ice, temperature and light conditions change, the timing of species presence, absence, match-mismatch timing with food resources, migration considerations and human interactions all should be assessed with respect to animal behaviors and environmental conditions.

7. Combined US and Russian sector studies

Many data collections end at the international dateline, but the ecosystem is not bound by national boundaries. Studies that bridge both the US and Russian Federation sectors of the Bering and Chukchi seas are needed to gain holistic understanding of the system.

Publications, Presentations, Outreach, and Collaborations

The full ASGARD *Publications* is given in Danielson et al. ASGARD Final Report. Here we include only cruise reports, the passive acoustic and marine mammal ASGARD publications to date, publications in preparation, and other publications that utilize ASGARD data or the participation of the ASGARD marine mammal PI.

- February 2018. AGU/ALSO Ocean Sciences Meeting. Scientific session organization (with DBO and AMBON) and participation: "Linkages Between Environmental Drivers and Structure of Arctic Ecosystems". Session Abstract: Arctic ecosystems are adjusting to rapidly warming temperatures, sea ice loss and a myriad of other factors that are changing with time. Temperature-growth relations, altered seasonality, expanded and contracted range extents, and new trophic pathways may each affect biodiversity, population status of key species, and relations between humans and marine resources. As environmental change continues, can we anticipate how future Arctic ecosystems will compare to those of yesterday and today? Will the effects of a changing climate be the same across various Arctic regions? We welcome presentations from all regions of the Arctic examining rates, processes and mechanistic controls that impart structure on any aspect of the high-latitude marine ecosystem.
- February 2020. AGU/ALSO Ocean Sciences Meeting. Scientific session organization (with DBO and AMBON) and participation: "Ecosystem Structure in a Changing Arctic". Session Abstract: The rate of atmospheric warming in the Arctic is outpacing that of other regions, and is associated with sea ice loss, warming ocean temperatures, changes in the hydrological cycle, and impacted ecosystems. Temperature-growth relations, nutrient cycling dynamics, altered seasonality, changing freshwater balances, expanded and contracted species range extensions, and new trophic pathways may each affect biodiversity, the population status of key species, and relations between humans and marine resources. As environmental change continues, can we anticipate how future Arctic ecosystems will compare to those of the past and present? Will the effects of a changing climate be the same across various Arctic regions? Organizers welcome presentations from all regions of the Arctic examining the drivers, rates, processes, and mechanistic controls that impart structure on any aspect of the high-latitude marine ecosystem.
- February 2020. AGU/ALSO Ocean Sciences Meeting Town Hall organization (with AOOS, USARC and DBO) and participation: "Scientific Responses to an Ever Faster Changing Arctic: Making the Most of our Collective Research Efforts". With the U.S. Arctic experiencing such unprecedented, rapid change, the objective of this town hall was to provide an opportunity for the scientific community to informally discuss causality and linkages across results from recent field work and studies, including if a "new normal" for the Arctic can be determined and what this might look like. We would also like to see proposed actions developed for moving forward with coordinated research efforts, ideas for emerging research. And observing needs, and suggestion or how we can best oorganize ourselves to deliver the data and information products that northern communities, resource managers, industry, first responders, and other decision makers will need.
- December 2021. Acoustical Society of America biannual meeting: "Relationship between vessel speed and sounds levels in the Bering Strait." Abstract: Vessel speed limits have been proposed as a means of reducing underwater ship noise, however it is unclear how effective such a measure would be in the Bering Strait, a natural bottleneck for ships transiting into the Arctic from the Pacific Ocean. In this study, we examine how ship noise varies with vessel type and speed using Automatic Identification System (AIS) data collected from vessels traveling through the strait along with acoustic recordings from three moored hydrophones. We matched recordings with ship noise to individual vessels that passed within 100 km of each hydrophone in June through November 2013–2015. A total of 67 sound files were analyzed, with tug (n = 21) and cargo ships (n = 16) as the most common vessel type observed in our dataset. Sound levels for each vessel were calculated and compared as a function of vessel type and

speed. The results of our study could inform policymakers and managers on the effectiveness of vessel speed limits on reducing ship noise in a sensitive Arctic habitat.

- January 2021. Presentation in “Looking across borders: past, present and future US Russia collaboration in the Bering Sea” during a remote session associated with the Alaska Marine Science Symposium in January 2021.

Synopsis ASGARD project marine mammal studies

Why we did it

Sea ice is one of the defining characteristics of the Arctic Ocean, and while its timing and extent has already undergone significant human-induced changes, it is projected to further decline in the coming years. The ASGARD project was designed to better refine our knowledge of carbon and nutrient dynamics on the northern Bering and Chukchi sea continental shelves in the face of changing sea ice. The fundamental science question we addressed is: What regulates variations in carbon transfer pathways and how will the changing ice environment alter these pathways and ecosystem structure, including that of upper trophic animals, in the Pacific Arctic and beyond?

What we did

The ASGARD study consisted of ship-based and mooring-based studies that collected observations of: heat, salt, nutrients and plankton carried by ocean currents; phytoplankton primary productivity; zooplankton growth/reproduction, respiration and fecal pellet production rates; particle deposition rates from the water column to the seafloor; quality of organic matter deposited to the seafloor; benthic respiration and organic matter decomposition rates; abundance and biomass of benthic microbial and metazoan fauna; distribution of fishes at different life history stages; and underwater sound and seasonal distributions of marine mammals. We sailed to the northern Bering and southern Chukchi shelf in 2017 and 2018 on R/V Sikuliaq, occupying "process" stations at which experimental work was carried out, and "survey" stations at which we collected a reduced set of observations. Moorings were deployed in the water from June 2017 to August 2019.

What we learned and why it matters

Ample supplies of nutrients delivered to the Southern Chukchi Sea through Bering Strait fuel a high level of Chukchi shelf primary productivity during months in which water column light levels are sufficient to maintain phytoplankton blooms. Portions of the region likely exist in a near-perpetual state of patchy phytoplankton blooms from the spring ice retreat all the into the fall. Export fluxes to the benthos are large because large-celled diatoms sink rapidly to the shallow seafloor and because mesozooplankton often are unable to constrain the phytoplankton bloom by grazing. The benthic community carbon consumption and oxygen turnover rates are sensitive to the bottom water temperature and are species- specific. Arctic marine mammals occur more frequently to the west of Saint Lawrence Island than to the east and the overall biodiversity of vocal marine mammals is higher to the west. Further subarctic species were heard well into winter months at all locations. Together, these findings suggest that the future Pacific Arctic ecosystem will adjust in species composition and species abundance in a bottom-up response to environmental change. At the same time, range expansions of sub-Arctic predators into the Chukchi Sea will exert new top-down pressure on both the benthic and pelagic communities. Previously unobserved competition between Arctic and sub-Arctic species will also likely play a role in determining the eventual character of the Chukchi Sea ecosystem. Arctic marine mammals are critical to the food security and cultural and spiritual health of coastal Arctic communities and understanding changes in the timing and diversity of upper trophic bellwether species can be used to understand ecosystem-wide environmental changes.

Arctic Integrated Ecosystem Research Program Final Report

Integrating marine mammal presence into ASGARD: Arctic Shelf Growth, Advection, Respiration and Deposition Rate Experiments

13 June 2022

K.M. Stafford

Table of Contents

Executive Summary

The ASGARD project

The Arctic Shelf Growth, Advection, Respiration and Deposition Rate Experiments projects (ASGARD; NPRB awards A91-99a, A91-00a, A94-00, A98-00a) proposed to address known information gaps that hinder a robustly comprehensive application of an ecosystem-based approach to resource management in the U.S. Pacific Arctic region. An ecosystem-based approach is needed to inform and guide policy-driven actions, but this approach requires synthesis of a detailed knowledge base that at the start of the Arctic IERP effort remained incomplete in three important ways. First, existing data were strongly biased to July through October although important ecosystem processes occur in spring, late fall and winter when access is difficult. Second, while we now understand the basic summer regional biogeography (Sigler et al., 2017), net community production (Codispoti et al., 2013), and drivers of species distributions for some taxonomic groups (Feder et al., 1994; Eisner et al. 2013; Blanchard, 2014; Grebmeier et al., 2015a; Ershova et al. 2015), we had scant information from any season about the fundamental chemical and biological rates that mediate carbon cycling and energy flows through the Northern Bering and Chukchi Sea ecosystem. Third, these knowledge gaps curtailed our ability to model the ecosystem, and our ability to make useful projections for management or policy decisions. Passive acoustic monitoring was added to the ASGARD effort to understand the impacts of changing Arctic on marine mammals and to better understand how drivers from physics to plankton to fish to upper trophic level predators are mediated. Thus, this project is not stand-alone but relies heavily on other ASGARD components (ASGARD; NPRB awards A91-99a, A91-00a, A94-00, A98-00a) to function. The present report draws strongly from the Danielson et al. final report as these projects were intimately linked. Herein we include relevant passages from that report but also focus on the passive acoustic data from ASGARD.

Accordingly, the hypotheses developed under the passive acoustic component of the ASGARD project were:

H-1. *The presence of sub-Arctic marine mammals will be driven by prey availability (fish, zooplankton) that is in turn driven by water mass characteristics*
H-2. *The relationship between ice cover and Arctic species migration from the Bering Sea into the Pacific Arctic can be quantitatively determined by comparing the onset of acoustic detection with ice advance (or formation) from, and retreat towards, the north (in the winter and spring, respectively).*
H-3. *Temperate marine mammal species will move progressively northwards as seasonal ice cover decreases and remain north of Bering Strait longer.*
H-4. *There will be differences in the species and seasonal occurrence of species between the eastern (eastern SLI and US Bering Strait) and western (Anadyr Strait and Russian Bering Strait) recordings. Data from the A3 climate site and the NE Chukchi Ecosystem Mooring site*

help establish if there are northern limits to sub-Arctic species and what the southern limits of Arctic species are.
H-5. *The number of ship passages through both sides of the Bering Strait will continue to increase over time*

Of the above hypotheses, most require much longer-term datasets than were available during the two years of data collection during the ASGARD project. They do, however, point towards the importance of future, long-term year-round data to determine interannual versus climatological changes in the environment. Hypotheses 1 and 4 can be addressed in the short-term from the ASGARD data however hypotheses 2,3 and 5 require longer term monitoring or data collection from extant locations. Data to support the testing of the latter hypotheses were obtained from long-term datasets north of Bering Strait, including the southern (site A3) and northeastern Chukchi Sea (CEO) as well as the western Beaufort Sea (AON).

Summary of Findings

Select key finds and descriptions of novel sample collections that target the proposed hypotheses and that are presented in the chapters of this report include the following highlights.

- Subarctic baleen whales are recorded in the northern Bering and southern Chukchi Seas from late spring into early winter and at times, overlap temporally and spatially with Arctic species • Killer whales are increasingly acoustically recorded in the Pacific Arctic
- Anadyr Strait is a marine mammal hotspot for many species of marine mammal, including both Arctic and subarctic species.
- Ship noise propagation in the Bering Strait region depends on ship size, speed, and ambient noise levels
- Bearded seals are commonly heard when sea ice concentration at the Chukchi Ecosystem Observatory is high. In contrast, walrus are heard at the same location when sea ice concentration is low
- Subarctic fish, birds and mammals are extending their ranges both spatially and temporally in the Pacific Arctic in response to environmental changes

Acknowledgements

We thank Captain Eric Piper, the crew of R/V Sikuliaq, Seward Marine Center shore support, and the Sikuliaq technical support team of Steven Hartz, Dan Nabor and Ethan Roth for their fantastic support throughout the program. Given the size and complexity of our experiments and especially our requirements of extensive climate-controlled incubation space, we believe that no other vessel would have been able to support such a wide array of activities and generate such across-the board successes in our field work.

We thank Bill Wiseman and the National Science Foundation for the addition of funded days at sea in 2017, and UAF's Alaska Sikuliaq Program for major support of ship days in 2017 and 2018. We thank Brendan Smith for accompanying us on the ASGARD cruises and providing photo documentation of our

work and we thank Danielle Dickson and Matt Baker for guidance and support of the project through all of its phases. We thank all of the Arctic IERP funders for sponsoring the program: the North Pacific Research Board (NPRB), the Collaborative Alaskan Arctic Studies Program (formerly the North Slope Borough/Shell Baseline Studies Program), the Bureau of Ocean Energy Management (BOEM), and the Office of Naval Research (ONR) Marine Mammals and Biology Program for funding the main ASGARD proposal and all associated linked studies and gap projects (grants A91-99a, A91-00a, A94-00, A98-00a, A96, A97, A99).

We acknowledge that our field work was conducted on the waters where traditional subsistence harvest activities have been conducted by Inupiaq, Siberian Yupik, and Yupik peoples, and we thank them for their continued stewardship. Out of the field, our research is also conducted at the University of Alaska Fairbanks Troth Yeddha' campus, on the customary homelands of the Lower Tanana Dene. Robert Suydam, Craig George and the Alaska Eskimo Whaling Commission provided valuable guidance for helping us avoid conflict with subsistence harvest activities. We thank Opik Ahkinga of Little Diomede for joining both research cruises and contributing as a valued member of the benthic team and for helping us better understand perspectives of the Bering Strait region residents.

Preamble

The Arctic Integrated Ecosystem Research Program

The Arctic Integrated Ecosystem Research Program (Arctic IERP, 2016-2021) was motivated by the rapid changes occurring in the waters of the northern Bering and Chukchi Seas. While much research has been done in the region, many important questions remain. As a cohesive research endeavor, the Arctic IERP was designed to address a single, overarching question:

How will reductions in Arctic sea ice and the associated changes in the physical environmental influence the flow of energy through the ecosystem in the Chukchi Sea?

The report you are reading now is one of five final reports from the fieldwork phase of the Arctic IERP (a synthesis phase was initiated in 2022 after the completion of the Arctic IERP field-based projects). This preamble provides a brief overview of the Arctic IERP, both to place each final report in the broader context of the whole program, and to encourage readers to examine the other final reports to learn more about the research that was done. More detailed information about the Arctic IERP can be found at https://www.nprb.org/arctic-program.

The spatial domain of interest for the Arctic IERP extended across the Chukchi Sea Large Marine Ecosystem (LME) as redefined by the Arctic Council's Protection of the Arctic Marine Environment (PAME) working group, and the northern Bering Sea (above 61.5° N) as it strongly influences dynamics in the Chukchi Sea from the upstream direction. The main focus has been on the greater Bering Strait region and the Chukchi Sea. The program included the Arctic Basin and Beaufort Sea insofar as processes in the Chukchi Sea are influenced by these adjacent areas.

Development of the Arctic IERP

Before any Arctic IERP research proposals were written, the NPRB administered an assessment program, the Pacific Marine Arctic Regional Synthesis (PACMARS; https://www.nprb.org/assets/uploads/files/Arctic/PacMARS_Final_Report_forweb.pdf), that applied $1.5M provided by Shell and ConocoPhillips to compile and synthesize existing information about the ecosystem and inform research priorities. This assessment included community meetings in 2013 in Savoonga, Gambell, Kotzebue, Nome, and Barrow (now Utqiaġvik), in which representatives from 17 communities between St. Lawrence Island in the Bering Sea and Barter Island in the Beaufort Sea participated. One major area of emphasis that emerged from these community meetings was concern about food security for the region's residents in light of the rapid environmental changes taking place. Results from the scientific assessment and input provided via the community meetings informed the creation of the Arctic IERP. The PACMARS report informed both the IERP Request for Proposals (https://www.nprb.org/arctic-program/request-for-proposals/) and the submitted proposals.

Following a proposal review process, the Arctic IERP formally began in 2016 with funding from the North Pacific Research Board (NPRB), the Collaborative Alaskan Arctic Studies Program (formerly the North Slope Borough/Shell Baseline Studies Program), the Bureau of Ocean Energy Management (BOEM), and the Office of Naval Research (ONR) Marine Mammals and Biology Program. Generous inkind support was contributed by the National Oceanic and Atmospheric Administration (NOAA), the University of Alaska Fairbanks (UAF), the U.S. Fish & Wildlife Service (USFWS), and the National Science Foundation (NSF). This coordinated program was developed in cooperation with the Interagency Arctic Research Policy Committee (IARPC) and the U.S. Arctic Research Commission.

The Research

The Arctic Integrated Ecosystem Research Program (IERP) invested approximately $18.6 million in studying marine processes in the northern Bering and Chukchi Seas in 2017-2021, beginning in the summer of 2017. The research was divided into three main, complementary projects. The Arctic Shelf Growth, Advection, Respiration, and Deposition Rate Experiments (ASGARD) project carried out research in late spring and early summer of 2017 and 2018 aboard R/V Sikuliaq. The Arctic Integrated Ecosystem Survey (Arctic IES) conducted fieldwork aboard R/V Ocean Starr in late summer and early fall 2017 and 2019. In addition to the vessel-based surveys, sub-surface moored sensors were deployed to gather biophysical information continuously from June 2017 to September 2019.

In addition to the vessel-based work, a team of Arctic residents and social scientists, including members from eight communities in the North Slope and Northwest Arctic Boroughs and the Bering Strait region, met several times during the project to assess and analyze Indigenous observations and experiences with various types of change occurring in the region from Savoonga to Utqiaġvik. This group also compiled an annotated bibliography of Traditional Knowledge or Indigenous Knowledge (available through the data portal described below), to help researchers from other components of the Arctic IERP find information relevant to their studies.

Prior to the commencement of fieldwork, meetings were held in the three hub communities of Nome, Kotzebue, and Utqiaġvik. Scientists from the Arctic IERP and NPRB staff met with community members from each region to discuss the research purpose and plans. Research plans were also shared and discussed at meetings of the Alaska Eskimo Whaling Commission (AEWC), the Indigenous Peoples Council for Marine Mammals (IPCoMM), and with the Tribal Councils of Gambell and Savoonga on St. Lawrence Island. One result of these meetings was a shift in timing of the ASGARD cruises from May until June as well as a shift in timing and survey regions for the Arctic IES cruises, to avoid conflicts with subsistence hunting activities during what is traditionally the time for walrus hunting. Another result was the creation of communication protocols to avoid conflicts by alerting coastal communities to the presence of research vessels and adjusting the ships' routes to avoid areas where hunting was taking place. These communication protocols included regular radio broadcasts and daily emails to community members throughout the research area.

Results from the research are published in a growing list of peer-review journal articles, as well as cruise reports that provide contemporary accounts of the cruises, and many social media postings that are available through the NPRB website. Data are publicly available as described below.

Collaborations

The NPRB collaborated and coordinated with several other U.S. agencies and organizations that fund Arctic marine research. NPRB staff worked closely with the U.S. Interagency Arctic Research Policy Committee (IARPC) and the U.S. Arctic Research Commission. As the Arctic IERP was developed, the NPRB secured commitments for collaboration from 22 existing research projects that were detailed in Appendix A of the request for proposals, and made connections with new projects as they were funded.

International researchers also collaborated with the Arctic IERP via the Pacific Arctic Group (PAG), the North Pacific Marine Science Organization (PICES), and the Intergovernmental Consultative Committee (US/Russia - bilateral) as well as collaborations developed by individual investigators. PAG participants, including researchers from Canada, China, Japan, Korea, Russia, and the United States, have coordinated their cruise plans to sample standard stations in the Chukchi and Beaufort Seas termed the Distributed Biological Observatory (DBO). The Arctic IERP contributed to this effort. US-Russian data sharing initiatives were hosted in San Diego in 2016 and Vladivostok in 2017 to promote collaboration and exchange and to facilitate collaboration and synthesis of data and trends of patterns observed in the US and Russian waters in the northern Bering and Chukchi seas (PICES Press, Volume 26, Issue 1). ICC collaborations and other connections also brought scientists from the Russian Federal Research Institute of Fisheries and Oceanography (VNIRO), the Russian Pacific Scientific Fisheries Research Center (TINRO), and Hokkaido University to the US to participate in the Arctic IES cruises and co-author results. This collaboration is expected to connect research interests within respective EEZs (Russia/US) of the Chukchi Sea.

COVID-19

While the fieldwork of the Arctic IERP was completed before the outbreak of COVID-19, the final meeting of researchers in November 2020 was changed from an in-person event to an online format. Other plans for in-person events, such as meetings in hub communities within the US Arctic region (Nome, Kotzebue, and Utqiaġvik), were cancelled. Laboratory work and some collaborations were postponed or cancelled due to COVID-related restrictions and concerns. The NPRB made supplemental funds available to assist researchers with unanticipated expenses due to the pandemic. The overall productivity of the Arctic IERP was likely not greatly reduced, due both to good fortune in the fieldwork being completed and to the collaborative relationships that had been built or strengthened during the program.

Data Portal

Axiom Data Science, Inc. provided data management support to the Arctic IERP throughout the field program. Axiom staff assisted the scientists in authoring metadata and publishing the datasets to public archives. The data collected by the Arctic IERP are publicly accessible at https://arcticierp.dataportal.nprb.org/

General Introduction

ASGARD Background & Scientific Rationale

As a changing climate and sea-ice retreat progressively expose the Chukchi Sea to a longer open water season, society will confront new resource management issues. These include the future of the cultures and subsistence lifestyles of local indigenous communities, potential impacts of industrial activities (e.g. commercial fishing, oil and gas extraction), potential changes to regional ocean carrying capacity, and resilience of the Arctic marine ecosystem (NRC, 2014).

An ecosystem-based approach is needed to inform and guide policy-driven actions but this approach requires synthesis of a detailed knowledge base that today remains incomplete in three important ways. First, existing data are strongly biased to July through October although important ecosystem processes occur in spring, late fall and winter when access is difficult. Second, while we now understand the basic summer regional biogeography (Sigler et al., submitted), net community production (Codispoti et al., 2013), and drivers of species distributions for some taxonomic groups (Feder et al., 1994; Eisner et al. 2013; Blanchard, 2014; Grebmeier et al., 2015a; Ershova et al. 2015), we have scant information from any season about the fundamental chemical and biological rates that mediate carbon cycling and energy flows through the ecosystem. Third, these knowledge gaps curtail our ability to model the ecosystem with even a basic level of confidence – and our ability to make useful projections upon which we can base management or policy decisions.

The ASGARD project addressed the above limitations by:

1. Coordinating and collaborating with other ongoing projects, including participating in ship-of opportunity sampling later in those years; and
2. Carrying out year-round biophysical mooring deployments.

With this approach, we gathered critically missing information required for modeling and follow-on synthesis activities, such as sought by Gibson and Spitz (2011) and Whitehouse et al. (2014). As shown in this report, some of these synthesis analyses have already been begun in the course of our initial publication efforts. Although the Arctic IERP program as a whole has advanced our understanding, the analyses that we might approach today include new questions that were not well appreciated just a few years ago when the program began.

The Arctic is experiencing rapid and extreme changes. The Pacific Arctic Region (PAR), which includes the Bering Strait region, and Chukchi and Beaufort Seas, is a bellwether for these changes with sea ice extent and thickness decreasing and freshwater and heat content increasing (i.e. Stroeve et al. 2012, Woodgate et al. 2012). The biological responses to these extreme physical changes are complex but may result in a shift in the northern Bering Sea and Bering Strait from an Arctic-type ecosystem to a subarctictype ecosystem (Grebmeier et al. 2006b, Grebmeier 2012). One way to monitor changes in, or impacts on, an ecosystem is to observe the response of a suite of upper trophic level species such as sea birds and marine mammals via changes in occurrence and/or distribution (Moore et al. 2014). For instance, the PAR ecosystem "reorganization," from benthic- to pelagic-based, might negatively impact marine mammal species that rely on sea ice for habitat (e.g. Ice seals, walrus, bowhead whales) and/or benthic infauna for food (e.g., walrus, gray whales, some ice seals) via a reduction in habitat and prey abundance (Grebmeier et al. 2006a). Other species, however, such as sub- Arctic "summer whales" may benefit from increased access to northern habitat and pelagic prey species (Moore and Huntington 2008, Clarke et al. 2013).

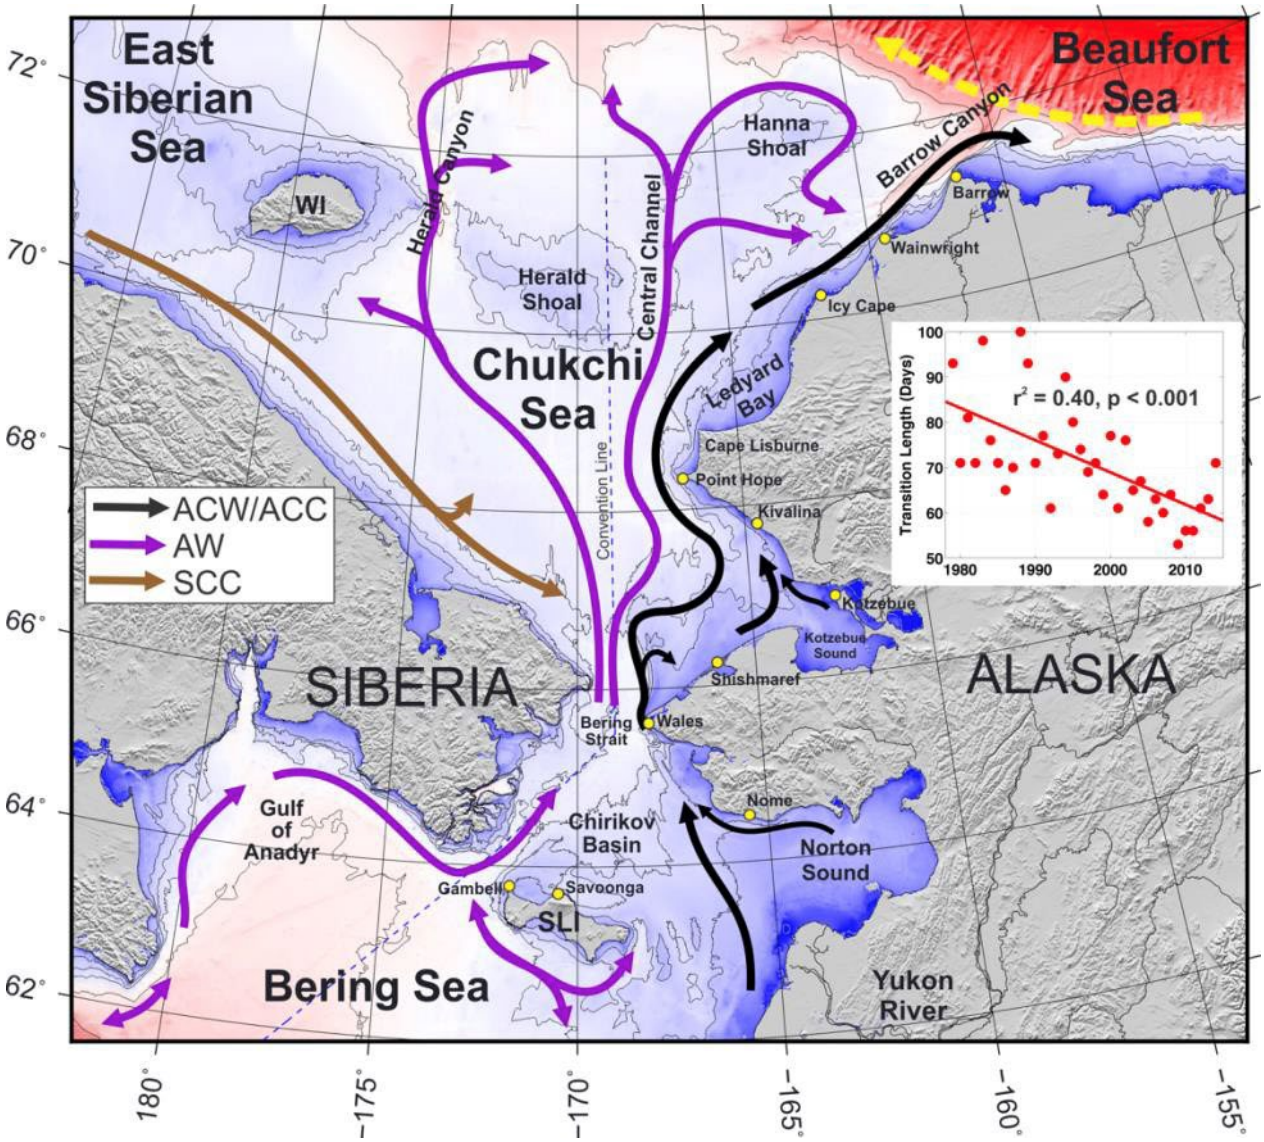

Figure 1. Map showing place names, persistent current systems, bathymetry (color shading). Inset: Decline in the regional duration of the annual spring sea-ice retreat, computed as the time between 80% and 20% ice cover (Map provided by Seth Danielson).

While the risk of potential competition for resources from sub-Arctic species expanding northwards is poorly understood (Clarke et al. 2013), integrating upper trophic level species with environmental data can provide insight into those environmental drivers result in increased competition. Further, assessment of impacts of increased human activities in the arctic (marine resource extraction and increased shipping) requires improved basic marine mammal population information (Reeves et al. 2013). Finally, there is concern among native Alaskans who live in the villages of the Arctic that environmental changes may result in changes in distribution of, and access to, species that are important for subsistence.

As the only oceanic gateway between the Pacific Ocean and the Arctic, the Bering Strait and Chukchi Sea are regions where climate change and changing anthropogenic utilization may have sizeable impacts on local marine fauna, and where changing fluxes of marine mammals to the Arctic can be confidently observed. The PAR is home seasonally to vocal Arctic species such as bowhead and beluga whales; bearded, ribbon and ringed seals; and walrus. Bowhead whales are currently listed as endangered species and walrus have been proposed for a "threatened" listing due to decreasing sea ice cover in the Arctic. In the summer, the northern Bering and Chukchi Seas provide habitat for fin, humpback, minke, gray and right whales (Clarke et al. 2013). Gray whales are regularly seen in the PAR and there have been recent sightings of humpback and fin whales north of the Bering Strait but relatively little is known of the northern limits of distribution for these "summer" whales.

The Bering Strait acts as a gateway for migration of animals between the Pacific Ocean and Bering Sea and the Pacific Arctic. The Bering Strait region is ice covered (i.e. those closed to marine mammals which need access to the surface to breathe) in the winter and "reopens" in the late spring, thereby influencing the migratory patterns of many marine mammal species (e.g., bowhead, beluga and gray whales, ice seals). Traditionally viewed as simply a route through which animals migrated, it is slowly becoming clear that marine mammals may spend significant portions of the summer and autumn in the PAR if prey is available there (Clarke et al. 2013; Lowry et al. 1980).

Flow from the Pacific advects nutrients and plankton into the Arctic Ocean, supporting very high levels of seasonal productivity that differ in the eastern and western PAR. The Bering Strait is the only source of Pacific inflow to the Arctic and has been the focus of ongoing research seeking to characterize circulation in the Arctic in light of global climate change (e.g., Aagaard al. 2006; Woodgate et al. 2005a, b; Woodgate et al. 2006, 2012). Pacific waters are a key source of nutrients for the Arctic Ocean (e.g.,
Walsh et al 1989), Therefore, in the PAR has important implications for Arctic biology, circulation, and the global freshwater budget (Woodgate et al. 2005b, 2006, 2012) and for the feeding success of marine mammals (Berline et al. 2008, Eisner et al. 2013). Differences in the physical oceanographic environment from east to west suggest that monitoring both sides of the PAR is critical to fully understanding changing ecosystem dynamics.

Changes in the timing and extent of annual sea ice influence the community ecosystem dynamics of this region. Ecosystem composition is affected directly via opening or closing of the strait and indirectly through the export of primary production to the shallow benthos (Grebmeier et al. 2006b). If the retreat of seasonal sea ice continues to shift the subarctic-Arctic temperature front, then community composition in the northern Bering and Chukchi Seas is likely to change, if not permanently, then seasonally (Overland and Stabeno 2004; Grebmeier et al. 2006a).
The PAR is home to native Alaskan and Russian communities that rely on marine mammals for subsistence. A recent workshop held in Nome, Alaska (Cooper 2010) identified the most pressing scientific questions to be addressed in the Bering Strait region from the perspective of local stakeholders (village inhabitants). Of highest priority for this group was increased monitoring of marine mammals, via visual and acoustic observations, because Arctic species and food security are integral to their nutritional cultural and spiritual subsistence.

As seasonal sea ice continues to diminish, ambient noise levels from shipping and seismic exploration will increase. As the Northern Sea Route and Northwest Passage become viable Pacific-Atlantic shipping routes, every ship along this route will pass through Bering Strait. The number of ships that used the Northern Sea Route increased dramatically from 4 in 2011 to 200 in 2013. This will lead to an inevitable increase in ambient noise levels at the low frequencies used by baleen whales, thereby decreasing the range over which they communicate and increasing the possibility of ship strikes (Clark et al. 2009; Hatch et al. 2012).

One means of assessing changes in marine ecosystems (the physical environment can be measured directly) is to examine the distribution of fauna that are directly influenced by such changes (Moore et al.
2014). As the top of short Arctic food webs, marine mammals can be considered sentinels of environmental change (Moore 2008; et al. 2014). Changes in cetacean abundance and distribution have been shown in conjunction with short and long time scale climate events in the north Pacific (Benson et al. 2002; Fiedler 2002; Croll et al. 2005) and Bering Sea (Stafford et al. 2010). Passive acoustic sampling is extremely robust, and can detect the presence of vocalizing marine mammals continuously (24 hours a day) in any weather conditions over weeks to months, over a distance of some 20-30 km and is a proven sampling method in waters offshore Alaska (Moore et al. 2006, 2012), including the Beaufort Sea and Chukchi Seas (Hannay et al. 2012, MacIntyre et al 2013; Stafford et al. 2007, 2013).

Species-specific characteristics of marine mammals vocalizations allow for unambiguous identifications based on acoustic signatures (Thomson and Richardson 1995). Therefore, acoustic monitoring can provide the ability to determine which species are present at a given time, and how species composition changes across seasons in the Bering and Chukchi Seas. For instance, gray whales, which have recently been regular summer visitors to the western Beaufort Sea, were detected

even in mid-winter in 2003-2004 by use of acoustic recordings (Stafford et al. 2007) and fin and humpback whales have been recorded in the Chukchi Sea (Delarue et al 2013; Hannay et al. 2013).

At present, the Arctic Ocean has relatively low ambient noise levels in winter due to ice cover that reduces wind waves (Milne and Ganton 1964; Roth et al. 2012) and in summer primarily due to the lack of commercial shipping, which has increased ambient noise levels significantly in other oceans (MacDonald et al. 2008). The reduction in seasonal sea ice and expansion of the open water season will change the seasonal ambient noise cycles of the Arctic. In late summer and fall, as the Northwest Passage and Northern Sea Route become viable Pacific-Atlantic shipping routes, every ship along this route will pass through Bering Strait resulting in increased ambient noise levels at the low frequencies used by baleen whales. In addition to anthropogenic increases in noise, the longer open water season and increasing storminess of Arctic regions (Overland et al. 2014; Thomson and Rogers 2014) will also lead to higher noise levels. Increases in ambient noise levels elsewhere have been shown to decrease the range over which marine mammals can receive signals, increase stress levels and change behavior (Richardson et al. 1986; Hatch et al. 2012; Rolland et al. 2012). While these reactions can be difficult to discern, longterm ambient noise data can be used to monitor ship passages, industrial exploration, and storms. Integration of acoustic detections of marine mammals is increasingly being used to understand correlations between habitat variables, prey, and marine animal presence. These include the use of generalized linear models, generalized additive models and time series analysis among others in order to determine what environmental factors most influence the presence of animals. In this manner, it may be possible to predict how the behavior of different species will change under changing environmental conditions (Baumgartner and Fratantoni 2008; Stafford et al. 2009, 2013; MacIntyre et al. 2015*;* Baumgartner et al, 2014).

In the shallow waters of the Chukchi and northern Bering Seas, low frequency acoustic signals from marine mammals (fin, bowhead, gray whales) are unlikely to transmit more than 20 km and higher frequency signals (from ice seals and beluga whales) will likely only be detected 5-10 km away. Therefore, the same signals will not be detected on multiple hydrophones. Each instrument will thus record signals local to the mooring area allowing comparison of the three proposed locations over the same time scales. When data from similar instruments deployed in Bering Strait and north of the Strait (Figure 1) are contributed, we will have coverage of all gateways between the Pacific and the Arctic Ocean. This will allow us to map migratory pathways and timing of the different species that use the Pacific Arctic.

By deploying acoustic recorders on biophysical oceanographic moorings, we can examine relationships between the physical and biological drivers in the PAR and quantify the animal fluxes in a manner that allows the investigation of seasonal and interannual change and understand the levels of underwater noise in the Arctic.

The ASGARD project is a coordinated ensemble of vessel- and mooring-based process studies consisting of physical, chemical, biological, and biogeochemical rate measurements that are designed to better constrain our understanding of carbon and nutrient dynamics of the northern Bering and Chukchi sea continental shelves.

Project Objectives

The ASGARD program was designed to address the NPRB Arctic Program's overarching questions outlined in their Request for Proposals: "How do physical, biological and ecological processes in the Chukchi Sea influence the distribution, life history, and interactions of species or species guilds critical to subsistence and ecosystem function? How might those processes change in the next fifty years?"

O-1: *Deploy hydrophones on 3 moorings in the northern Bering and Chukchi Sea.*

- Multi-electronique Aural M2 hydrophone packages were deployed on ASGARD moorings N1, N2 and N4 and were supplemented by data from a site north of Bering Strait (A3) and in the western Beaufort Sea (AON).

O-2*: Document the inter-seasonal and inter-annual presence of vocal marine mammals in the Pacific Arctic Region and compare of acoustic detections in the eastern, western, and central PAR.*

- Passive acoustic data from the ASGARD moorings as well as A3 and AON were analyzed for the presence of vocal marine mammals to determine geographic variability in the presence of different species.

O-3: *Integrate oceanographic drivers with acoustic detections to better understand how the physical environment influences the biological inhabitants of that environment*

- Deployment of hydrophones on biophysical moorings provides concurrent *in situ* data for comparing the physical environment with marine mammal presence. These analyses are ongoing.

O-*4:* *Collaborate with other ASGARD PIs to develop an integrated understanding of the ecosystem components of the Pacific Arctic Region from physical forcing through to upper trophic level consumers.*

- Meetings and collaborations with IERP colleagues resulted in two peer-reviewed publications (Huntington et al. 2020, Stafford et al. 2022) and on-going synergies for projects in the Pacific Arctic.

Approach

The ASGARD study consisted of ship-based and mooring-based studies designed to integrate with other proposed field, modeling, and human dimensions efforts. We selected the following focal measurements to help us address our main science question:

- Advective fluxes of physical, biotic and abiotic components of the water column
- Phytoplankton primary productivity
- Zooplankton growth/reproduction, respiration and fecal pellet production rates
- Particle deposition rates from the water column to the seafloor
- Quality of organic matter deposited to the seafloor
- Benthic respiration and organic matter decomposition rates
- Abundance and biomass of benthic microbial and metazoan fauna
- Distribution of fishes at different life history stages (NPRB Award A98-00a)
- Underwater sound and seasonal distributions of marine mammals (NPRB Award A94-00)

This report includes the overall goals of ASGARD with a specific focus on the inclusion of passive acoustic recording instrumentation on three of the ASGARD moorings and participation in the two research cruises. We sailed to the northern Bering and southern Chukchi shelf in 2017 and 2018 (Figure 2) on *R/V Sikuliaq*. In each year, working south to north, we first occupied ten "process" stations (yellow squares in Figure 2). As the ship visited the process stations, we paused to deploy and/or recover moorings (Figure 2) that recorded year-round time-series. Throughout the cruise we collected continuous underway navigational, ocean surface, ocean profile, and meteorological data and marine mammal observations (Figure 3) to provide additional environmental context for subsequent analyses.

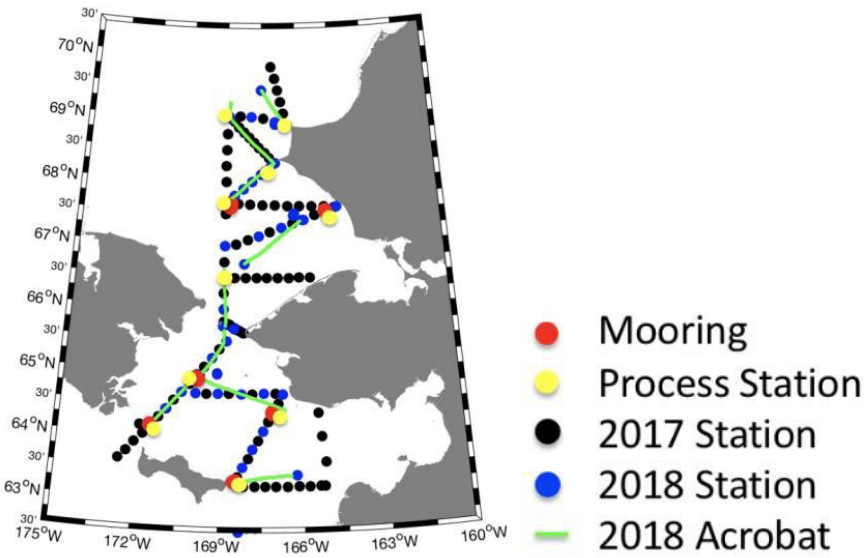

Figure 2. Location of field effort. Most 2018 stations (blue circles) were also occupied in 2017 (black circles). Some circles were shifted slightly on the map to reduce overlap.

The mooring array (Figure 2) consists of four biophysical moorings south of Bering Strait, two moorings in the southern Chukchi Sea plus the NPRB Long-Term Monitoring Program NE Chukchi Sea Ecosystem Mooring located on the southern flank of Hanna Shoal near Barrow Canyon. Together, these seven moorings allowed us to examine cross-shelf differences between the AW and ACW regimes and physical and biogeochemical changes imparted as the waters flow across the shelf into the Arctic. These instruments recorded year-round to reveal time histories of: nutrient and phytoplankton concentrations and fluxes; the bifurcation of flow to either side of St. Lawrence Island and the influence of regional winds on the upstream structure and partitioning of water masses feeding Bering Strait; conditions in Anadyr Strait, in the nexus of the most important zone at which subsurface nutrients are mixed to the surface as they arrive at Chirikov Basin and Bering Strait; AW and ACW properties and advection rates; phytoplankton blooms, sinking organic matter fluxes and their relationship to advective supply, light, ice thickness and the retreating ice edge; bottom sediment resuspension with respect to water and ice motion and ambient noise.

In addition, we aimed to contribute to the graduate educations of PhD students, including two students partially funded by the project and students not requiring financial support from ASGARD, but who participated in our cruises and collected data for use in their externally-supported research. We sought to strengthen existing and build new collaborations with national and international partners. We had cruise involvement of outreach specialists to help us communicate our science to targeted stakeholders and the public. We strengthened our ties to the coastal communities by participating in numerous co-management and other Alaskan Native Organization meetings, including Tribal Council consultations and the incorporation of a local observer on board our research cruises.

Field Expeditions

ASGARD field efforts (Figures 2 and 4) are documented in two detailed scientific cruise reports (Danielson et al., 2017; 2018) and one community observer report (Ahkinga, 2017) that are available at the NPRB Arctic IERP website https://www.nprb.org/arctic-program/about-theprogram/ The cruises took place in June 2017 and June 2018. We joined the Arctic EIS component of the IERP for final mooring recoveries in August 2019. Weather conditions and cruise timing allowed us to occupy more survey stations in 2017 than in 2018.

Emerging Stories

This report documents ASGARD project activities and results through the end of the initial phase of research and analysis (2016-2021). We were successful in collecting data that has been and will be applied to all of our focal objectives and hypotheses and as shown below, we addressed each from different vantage points. At the same time, we have only scratched the surface of the vast suite of potential results that the rich Arctic IERP dataset will yet reveal.

The *Results* section chapters document observations, and analyses that use data collected in the ASGARD field effort and were written in support of helping fill the three main information gaps identified in the ASGARD proposal (i.e., seasonal data gaps, rate measurements, and model parameterization/validation data) and guiding science question (i.e., ecosystem change in the face of diminishing sea ice). These chapters include graduate student dissertation chapters, and peer-reviewed journal articles (published and in preparation) that were written in support of the ASGARD project proposal and the Arctic IERP Integrated Work Plan (NPRB, 2016).

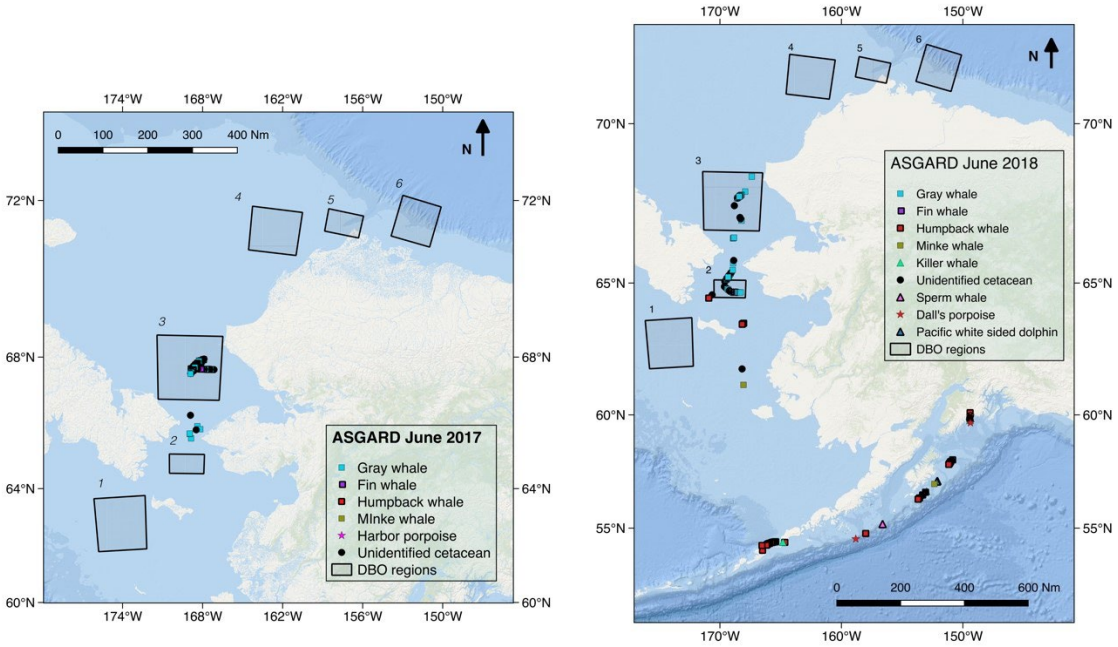

Figure 3. Left panel shows marine mammal sightings during the ASGARD 2017 cruise as well as Distributed Biological Observatory locations. Right panel shows sightings from the 2018 cruise.

Chapters are organized as follows. Chapters 1-4 concentrate on marine mammal occurrence and environmental conditions (physics and biology) and their temporal and spatial variability. Chapters 1-3 present information on the seasonal and spatial occurrence of marine mammals in the ASGARD study area and northwards and the interaction of these with environmental conditions. Chapter 4 examines the long-term changes in marine mammals at the Chukchi Ecosystem Observatory. Chapter 5 presents information on the underwater soundscape and ship noise contributions to the Bering Strait region. Chapter 6 is a review of changes in subarctic upper trophic level distributions. Chapter 7 (cited as Chapter 19 in the Danielson report) raises the question of whether this highly productive ecosystem could be in the midst of a significant ecological transformation.

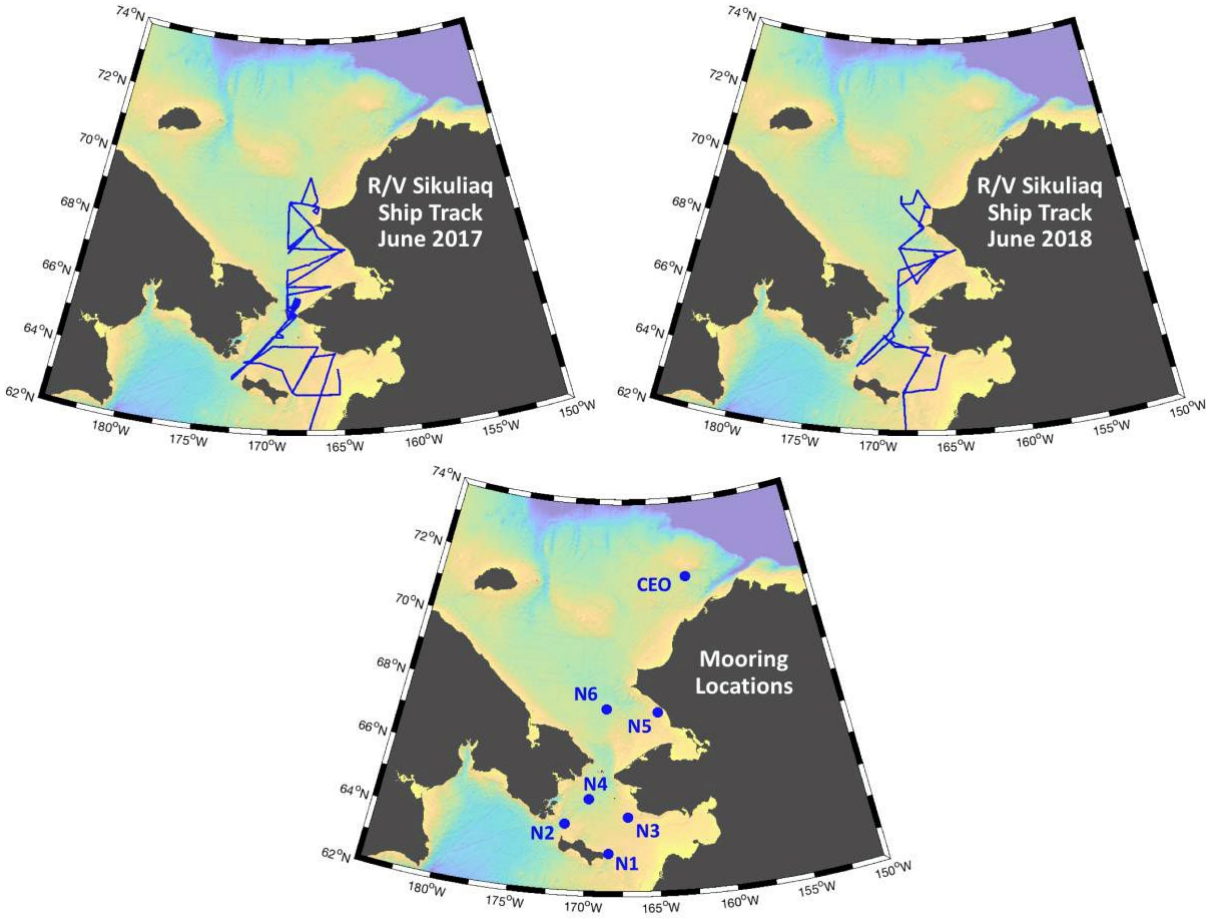

Figure 4. Vessel track lines (blue) for cruise SKQ2017-09S (June 2017, upper left), SKQ2018-13S (June 2018, upper right) and year-round mooring locations (blue circles, bottom). Identifying names for ASGARD moorings N1-N6 and the Chukchi Ecosystem Observatory (CEO) mooring cluster are labeled.

Results

The integration marine mammal presence into the ASGARD program using visual surveys on the two cruises and passive acoustic data on three of the 6 ASGARD-specific moorings as well as on the CEO (Fig 4) resulted in 3 peer-reviewed publications (Huntington et al. 2020, Moore et al. 2022, Stafford et al. 2022), an Honours thesis (Mottu 2022), PhD dissertation chapter (Escajeda et al. *in revision*), and additional in preparation collaborations (Stafford and Danielson and Stafford et al., in prep).

Chapter 1: Changes in gray whale phenology and distribution related to prey variability and ocean biophysics in the northern Bering and eastern Chukchi seas

Moore SE, Clarke JT, Okkonen SR, Grebmeier JM, Berchok CL, Stafford KM (2022) Changes in gray whale phenology and distribution related to prey variability and ocean biophysics in the northern Bering and eastern Chukchi seas. PLoS ONE 17(4): e0265934

Abstract

Changes in gray whale (*Eschrichtius robustus*) phenology and distribution are related to observed and hypothesized prey availability, bottom water temperature, salinity, sea ice persistence, integrated water column and sediment chlorophyll a, and patterns of wind-driven biophysical forcing in the northern Bering and eastern Chukchi seas. This portion of the Pacific Arctic includes four Distributed Biological Observatory (DBO) sampling regions. In the Bering Strait area, passive acoustic data showed marked declines in gray whale calling activity coincident with unprecedented wintertime sea ice loss there in 2017–2019, although some whales were seen there during DBO cruises in those years. In the northern Bering Sea, sightings during DBO cruises show changes in gray whale distribution coincident with a shrinking field of infaunal amphipods, with a significant decrease in prey abundance ($r = -0.314$, $p<0.05$) observed in the DBO 2 region over the 2010–2019 period. In the eastern Chukchi Sea, sightings during broad scale aerial surveys show that gray whale distribution is associated with localized areas of high infaunal crustacean abundance. Although infaunal crustacean prey abundance was unchanged in DBO regions 3, 4 and 5, a mid-decade shift in gray whale distribution corresponded to both: (i) a localized increase in infaunal prey abundance in DBO regions 4 and 5, and (ii) a correlation of whale relative abundance with wind patterns that can influence epi-benthic and pelagic prey availability. Specifically, in the northeastern Chukchi Sea, increased sighting rates (whales/km) associated with an ~110 km (60 nm) offshore shift in distribution was positively correlated with large scale and local wind patterns conducive to increased availability of krill. In the southern Chukchi Sea, gray whale distribution clustered in all years near an amphipod-krill 'hotspot' associated with a 50-60m deep trough. We discuss potential impacts of observed and inferred prey shifts on gray whale nutrition in the context of an ongoing unusual gray whale mortality event. To conclude, we use the conceptual Arctic Marine Pulses (AMP) model to frame hypotheses that may guide future research on whales in the Pacific Arctic marine ecosystem.

gray whale nutrition in the context of an ongoing unusual gray whale mortality event. To conclude, we use the conceptual Arctic Marine Pulses (AMP) model to frame hypotheses that may guide future research on whales in the Pacific Arctic marine ecosystem.

Introduction

Arctic and sub-arctic marine ecosystems are changing much faster than predicted [1]. Since the advent of satellite records in 1979, sea-ice areal extent has diminished by about 50% at the September minimum, with a roughly 75% year-round reduction in thickness of multi-year ice. This fundamental shift has not been linear in the Pacific Arctic region; rather, there were dramatic step-changes of sea-ice loss in late summer 2007 and 2012, and in winter 2017, 2018 and 2019 near Bering Strait [2]. Ocean temperatures have risen across the Arctic, driven both by increased solar insolation that is no longer reflected back into the atmosphere by sea ice and by transport of warm ocean water from the south into sub-arctic and arctic regions [3]. In the Pacific Arctic region, the loss of sea ice has been accompanied by ocean warming and freshening [4, 5], with 2014–2018 marking a period of increased ocean-atmosphere heat exchange coincident with unprecedented low ice cover [6]. The combination of sea-ice loss and warmer seawater has reset the clock on ecological processes in the Pacific Arctic [7], with the Bering Strait region described as in a state of transformation [8]. Compared to the late 1990s, primary production is initiated earlier in spring, with enormous blooms sometimes encountered under thin sea ice resulting in an overall 57% increase in net productivity [9]. Changes in primary productivity vary at regional and local scales, with production in the Chukchi Sea the highest in the Pacific Arctic region [10]. The biophysical impacts of reduced sea ice, increased ocean temperatures and primary production, combined with shifting atmospheric and ocean dynamics, can drive swift and fundamental changes near the base of marine food webs, the trophic level important to gray whales.

Gray whales are unique among mysticete whales in that they can suction sediment from the sea floor and effectively sieve out the infaunal prey on their short, coarse baleen leaving distinctive mud plumes at the surface (Fig 1A). Gray whales are also capable of efficiently feeding on epi-benthic prey swarms, pelagic zooplankton aggregations (Fig 1B), and even fish roe at the sea surface [11]. In the northern Bering and Chukchi seas, gray whales commonly feed on infaunal amphipods [12, 13], although epi-benthic and surface swarms of euphausiids (*Thysanoessa* spp.; hereafter, krill), eurisid amphipods (*Pontogeneia makarovi*), or cumaceans (*Diastylus glabra*) are sometimes the targeted prey [14, 15]. Reports on fine-scale feeding behavior at coastal study sites offshore Vancouver Island, Canada describe the ease with which gray whales can switch between various prey species based upon availability and sometimes size [16, 17]. While apex predators, such as marine mammals and birds, are now commonly recognized as ecosystem sentinels [18], gray whales were one of the first cetacean species so described. Specifically, evidence of connections between changes in gray whale phenology and distribution with shifts in their environment were summarized for six environmental factors, including oceanographic indices (i.e., Pacific Decadal Oscillation and El Nino Southern Oscillation), sea ice loss (N Bering) and thinning (W Beaufort), and shifts in infaunal and epi-benthic prey availability [19]. Taken together, these observations made a compelling case for gray whales as effective sentinels of ecosystem alteration in North Pacific and western Arctic ecosystems.

The Distributed Biological Observatory (DBO) was initiated in 2010 to provide standardized sampling to investigate biological responses to the rapid physical changes ongoing in the

Pacific Arctic marine ecosystem (Fig 2A) [20]. An opportunistic marine mammal watch was included in the standard DBO protocol to assess the capacity of marine mammal and other upper trophic level (UTL) species to act as sentinels of ecosystem variability and reorganization [21, 22]. Like fishes and seabirds, marine mammals rely on finding dense aggregations of prey to forage successfully. As a result, shifts in their ecology (i.e., phenology, distribution, and abundance) can signal changes in marine ecosystem trophic structure, which are in turn reflected physiologically by changes in diet and body condition [23]. In addition to sightings during DBO cruises, a robust program of marine mammal research has been conducted in the Pacific Arctic region, comprised of year-round Passive Acoustic Monitoring (PAM) of species-specific calls [24] and seasonal broad-scale Aerial Surveys of Arctic Marine Mammals (ASAMM) [25]. Changes in baleen whale phenology and seasonal distribution have been described based upon some of these data, with correlations to biophysical processes [26, 27] and details on prey availability included when possible [13, 28].

Here, we identify changes in gray whale phenology and seasonal distribution, based upon a compilation of information from the DBO, PAM, and ASAMM programs. We then relate

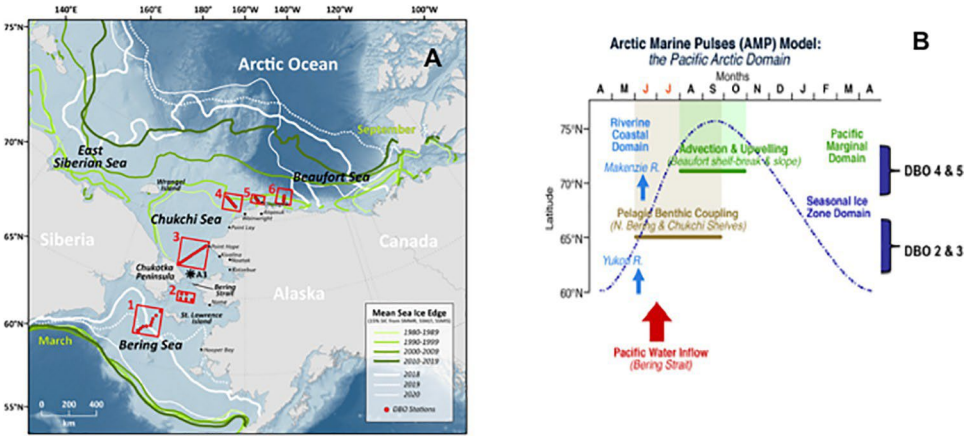

Fig 2. The Distributed Biological Observatory (DBO) and mean sea ice edge in the Pacific Arctic (A, revised from [10]), and a schematic of the conceptual Arctic Marine Pulses model (B, revised from [29]) depicting links among biophysical aspects of the Pacific Arctic marine ecosystem. The mean sea ice edge depicts the 15% concentration threshold using SMMR, SSM/I and SSMIS satellite data. All sea ice edge contours north (south) of Bering Strait represent September (March) conditions for three decadal periods (green) and annually for 2018, 2019 and 2020 (white).

https://doi.org/10.1371/journal.pone.0265934.g002

those shifts to changes in ocean biophysics that likely impact availability of their prey, including pelagic-benthic coupling, advection, ocean warming and freshening, and large and local-scale wind forcing. The conceptual Arctic Marine Pulses (AMP) model combines these biophysical factors into a regional framework (Fig 2B) [29]. We use the AMP model to contrast the advection and pelagic-benthic coupling drivers active in the Bering Strait region (DBO regions 2 & 3) to those factors combined with seasonal sea ice retention and wind-forcing dynamics in the northeastern Chukchi Sea (DBO regions 4 & 5) to investigate how these processes influence gray whale prey availability. Notably, the inclusion of long-term measures of infaunal crustacean abundance and species composition in DBO regions 2–5 provides direct evidence of, and fosters insights into, the impacts of shifting ocean biophysics on gray whale prey. The potential effects of observed and inferred prey alteration on gray whale nutrition are discussed in the context of an unusual mortality event that began in 2019 resulting in *ca*. 10-fold increase in annual number of stranded gray whales [30]. We close with suggested hypotheses that might guide future research on the ecology of gray and other baleen whales and enhance their capacity to act as sentinels of ongoing transformation of the Pacific Arctic marine ecosystem.

Methods

Gray whale passive acoustic and visual sampling

Our assessment of gray whale phenology, defined here as timing of arrival and departure from the Bering Strait region, is based on detection of their distinctive knock-like 'bongos' or 'Class 1 calls' [31]. Gray whale 'moans' or 'Class 3 calls' [31] were also included when detected with 'bongo' calls and when there were no accompanying humpback sounds with which they could be confused. Data were recorded on instruments deployed in or near DBO regions 2 and 3 (NM1 and PH1 on Fig 4A) from 2012–2019 as part of an extensive marine mammal PAM program [24]. Instruments were set to record on a duty cycle of 30% to extend battery life for a full year, with a sample rate of 16384 Hz for an effective bandwidth of 10–8192 Hz, which is sufficient to record all known gray whale signals [31]. Daily call detections were binned in 10-minute increments and normalized by recording effort, resulting in call histograms which depict the percent of calling activity/day, rather than an actual count of calls recorded. We examined histograms of gray whale calling activity at each site to identify phenological changes in annual pattern.

Our summary of gray whale distribution is based on sightings made during: (a) marine mammal watches on 22 DBO cruises (S1 Table), and (b) the broad scale ASAMM program conducted in the northeastern Chukchi Sea from 2009–2019 [25]. On DBO cruises, a visual watch for marine mammals was conducted during daylight hours when the ship was transiting between sampling or mooring stations, augmented by scans around the ship each hour when the ship was on station. An observer trained in marine mammal species identification used naked eye and handheld binoculars to scan a 120˚ arc forward of the ship (abeam, to +30˚ of the bow) out to the horizon. When two people were available to stand watch, the full 180˚ arc forward of the ship was scanned to the horizon. The watch stander was often assisted by other scientific party personnel and the ship's crew. The watch was curtailed when sea state exceeded Beaufort 05 (wind speed ~25kts, 12.8 m/s), or visibility was reduced to < 1km by precipitation or fog. Although DBO cruise tracks and ship speeds were similar among years, sighting rate (whales/km) could not be calculated due to variability in watch effort. Thus, while sightings from DBO cruises provide data on gray whale presence, especially in the Bering Strait region, these data are not included in statistical analyses.

During the ASAMM program, line-transect aerial surveys were conducted from July through September using twin engine aircraft outfitted with left- and right-side bubble windows. The study area encompassed the northeastern Chukchi Sea from 67˚N to 72˚N, and east of 169˚W, an area inclusive of DBO 3–5. Dedicated observers stationed at each window reported all marine mammal sightings and associated environmental conditions to a data recorder. Sightings of large whales were briefly circled over to confirm species identity, group size, behavior, and presence of calves. Surveys were conducted whenever weather conditions allowed (i.e., sea state ≀Beaufort 05; cloud ceiling consistently >335 m). Offshore transect lines were oriented perpendicular to the coastline to allow sampling across isobaths and prevailing currents, and to best assess marine mammal density gradients; a coastal transect was flown *ca*. 1-km offshore to better document nearshore habitat.

To examine changes in gray whale distribution in the context of environmental variability, ASAMM data were divided into three geographic areas for analysis: (1) the southern Chukchi Sea, referred to as the Hope Basin area and inclusive of DBO 3; and the northeastern Chukchi Sea, referred to as the (2) Wainwright and (3) Peard Bay areas, inclusive of DBO regions 4 and 5. Gray whale sighting rates were calculated for each area as the number of gray whales seen/offshore transect kilometer by month (July, August, September) and year (S2 Table). Effort and sightings on the coastal transect were not included in monthly SR analyses to avoid bias towards nearshore areas. All ASAMM data are publicly available at fisheries.noaa.gov/resource/data/1979-2019-aerial-surveys-arctic-marine-mammals-historical-database; databases used for analyses include versions 1979_2011_v3_36, 2012_2014_v0_28, 2015_2017_v22, and 2018_2019_v6.

Gray whale prey and environmental variability

Environmental factors relevant to the influence of pelagic-benthic coupling on gray whale infaunal prey were evaluated based upon a multi-decadal record of macrobenthos and sediment dynamics [32], with special focus on stations dominated by crustacean species at the start of the 2010–2019 time series [32, 33]. In brief, stations in DBO regions 2–5 were designed to sample sediments across localized areas of high benthic productivity and biomass. Stations in DBO regions 3, 4 and 5 were oriented along diagonal transects, while those in DBO 2 sampled along latitudinal transects. South of DBO 3, a series of stations (designated UTN, for University of Tennessee), were oriented roughly parallel to the International Date Line (IDL) from 66.5ºN to 68ºN latitude. Over the 2010–2019 period, small adjustments were made to sampling design in DBO regions 2 and 4. Specifically, In the DBO 2 region, the four original times series stations (UTBS) were augmented from 2016 onwards by the addition of three stations (BCL6c, DBO2.7, UTBS2A) to expand the spatial extent of sampling. In the DBO4 region, station placement was changed from six stations along a single transect line to six stations on three shorter transect lines (shown as DBO4 O, N, and n; Fig 5) to improve sampling the patchy distribution of benthic fauna in that area. At all stations, replicate sediment samples were collected using a 0.1 m^2 weighted van Veen grab. Sediments were sieved onboard through 1 mm mesh screens, with the retained macrofauna preserved with 10% buffered seawater and formalin for post-cruise taxonomic identification and analysis of abundance and wet weight biomass. The analysis of infaunal prey for gray whales focused only on the Class Crustacea, which is comprised primarily of amphipods, with a very minor (< 1%) inclusion of isopods and cumaceans. Additional details of sampling and analysis methods are provided in [32].

Gray whale infaunal crustacean prey were analyzed with attention to changes in species composition and abundance in response to trends in sea ice loss, ocean temperature, salinity, and measures of chlorophyll *a* both in the water column and in surface sediment. Spatial

interpolation was accomplished using geographical information system software [34]. Specifically, the Geostatistical Analyst Wizard Inverse Distance Weighting (IDW) tool in ESRI's ArcGIS Desktop v.10.8.1 was used with default settings to produce an interpolated surface map based on abundance of the class Crustacea per station for the years 2010 to 2019. Temporal patterns in crustacean abundance and Spearman's rho rank correlation analysis was used to determine correlations of crustacean abundance over time using JMP™ Pro 15.2.0 (www.jmp.com). Most macrofaunal data sets for the 2010–2019 period are available at the Arctic Data Center (ADC) DBO project page (https://arcticdata.io/catalog/portals/DBO/Data)), and the NOAA National Centers for Environmental Information (NCEI) website (https://www.ncei.noaa.gov/), although some replicate samples could not be included due to Covid limitations on laboratory work. To clarify data included this paper, a summary of crustacean abundance is listed by cruise number, station and date is provided supplemental S3 Table. Of note, the environmental data used for statistical analyses in relation to crustacean abundance listed in S3 Table are available at the aforementioned ADC and NCEI data archives for the associated cruises.

Environmental factors potentially indicative of the influence of advection and circulation on gray whale epi-benthic and pelagic prey availability were evaluated through application of an iterative correlation analysis (ICA) method [35, 36]. The ICA method is a supervised machine learning tool that uses, in the present case, a multiyear time series of gray whale SR derived from ASAMM data as a training set to identify a statistically similar interannual time series of either (i) a seasonally-averaged environmental factor (e.g. volume, heat, freshwater transports) measured at the 'climate mooring' north of Bering Strait [4; mooring A3], or (ii) local- to large-scale (Bering-Chukchi-Beaufort region) wind regimes derived from daily sea level wind products available at the National Centers for Environmental Prediction (NCEP)/National Center for Atmospheric Research [37]. For an environmental factor with time series information at a single location (e.g. transport at mooring A3), ICA identifies the seasonal start and end dates for which correlations between seasonally-averaged transports and gray whale SRs are statistically significant. For an environmental factor with time series information at multiple locations (e.g. NCEP winds), ICA identifies the seasonal start and end dates that maximize the ocean area north of the Bering Sea shelf break over which correlations between seasonally-averaged winds and gray whale SRs are statistically significant. Results for both single and multiple location ICA are summarized in the form of a heat map matrix that identifies the best-fit start and end dates from a range of candidate seasonal averaging periods.

Results

Changes in gray whale phenology and distribution

Acoustic detections. A change in gray whale acoustic activity was observed in the northern Bering Sea (DBO 2) where the period of calling activity extended from late May through November in 2012–2015, shortened to late May to mid-September in 2016, and followed by a near cessation of call detections in 2017–2019 (Fig 3A). In the southern Chukchi Sea (DBO 3), consistent calling activity extended from mid-June through October in 2012–2015. In 2017 call detections ended a month earlier (September), and there was a near cessation of calling activity throughout 2018–2019 (Fig 3B). These changes in calling activity suggest that gray whales departed DBO regions 2 and 3 earlier each year after 2016 and 2017, respectively.

Visual detections. Gray whales were seen during marine mammal watches on DBO cruises in all years (Fig 4A). Areas where gray whales were commonly seen included the northern Bering and southern Chukchi Seas, and waters offshore Wainwright and along the coast between Pt. Franklin and Pt. Barrow. While DBO cruise tracks were similar among years,

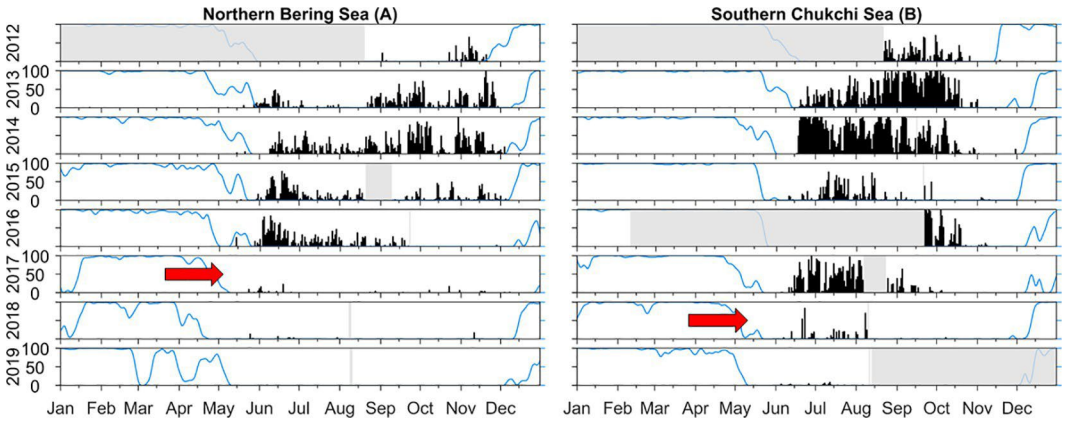

Fig 3. Gray whale annual calling activity in the northern Bering (A) and southern Chukchi (B) seas, 2012–2019. Black bars show gray whale calling activity, blue lines represent seasonal ice cover and grey shading indicate periods for which data are unavailable. Red arrows denote dramatic drop-off in calls coincident with 2017–2019 winter sea ice loss event. Hydrophone locations are shown in Fig 4 - DBO map.

https://doi.org/10.1371/journal.pone.0265934.g003

timing and platform operations varied, limiting inferences that can be drawn from these data for lack of SR calculations. Of note, however, is that gray whales were consistently seen in the northern area of DBO 2 and near the central and western-most sampling stations in DBO 3 (Fig 2A), as well as west of the International Date Line (IDL) in years that ships had access to those waters (2009, 2010, 2012). Also, in contrast to the PAM data, gray whales were seen in DBO regions 2 and 3 in 2017–2019 after the aforementioned loss of winter sea ice in those areas.

The ASAMM data provide the means to relate gray whale distribution to survey effort north of 67˚N and east of 169˚W in the Chukchi Sea. Over the eleven-year study period, there were 1,333 sightings of 2,358 gray whales from July through September, with most whales seen in south-central and northeastern Chukchi Sea waters (Fig 4B). Interannual variability in SR

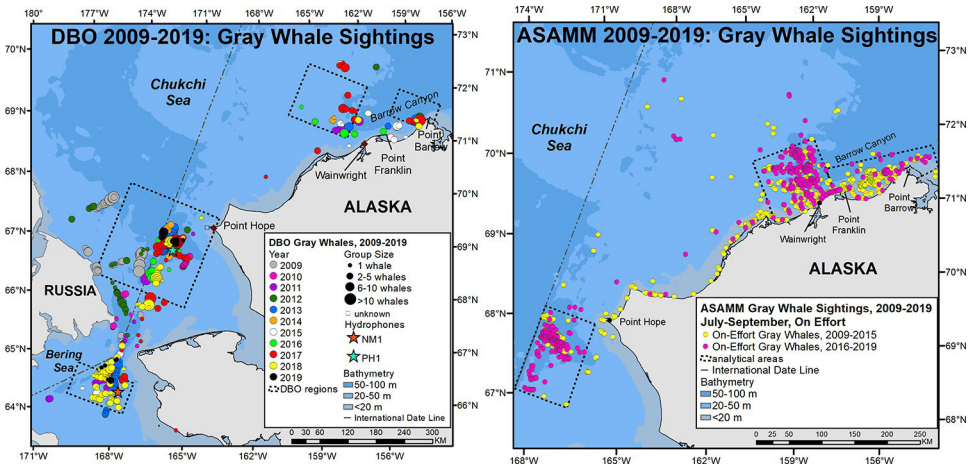

Fig 4. Gray whale distribution from sightings made during marine mammal watches on DBO cruises, and the broad scale Aerial Surveys of Arctic Marine Mammals (ASAMM) program, 2009–2019. Dashed lines depict boundaries of DBO regions and analytical areas, respectively. Gray whale sighting rates (SR = whales/km) in analytical areas were calculated solely from ASAMM data. ASAMM data are publicly available at fisheries.noaa.gov/resource/data/1979-2019-aerial-surveys-arctic-marine-mammals-historical-database. Databases used for maps include versions 1979_2011_v3_36, 2012_2014_v0_28, 2015_2017_v22, and 2018_2019_v6.

for the entire study area ranged from a high of 2 whales/100km in 2018 to a low of 0.5 whales/100km in 2010 (Table 1). In 2015, there was a *ca*. 110 km (60 nm) shift in gray whale distribution away from the coastal habitat between Pt. Franklin and Pt. Barrow to waters offshore Wainwright and near the head of Barrow Canyon. In the south-central Chukchi Sea, gray whale distribution clustered in a benthic trough 'hotspot' southwest of Pt. Hope in all years, with sightings extended further south after 2015. Since gray whales spend much of their time feeding while in the Chukchi Sea, these changes in distribution and associated shifts in SR were examined (i) with reference to observed changes in infaunal crustacean prey abundance and community composition from benthic sampling, and (ii) by correlation of sighting rates from ASAMM data with environmental factors associated with availability of epi-benthic and pelagic prey, as described in the next two sections.

Changes to infaunal crustacean abundance, community composition, and associated environmental factors

Our multi-decadal record of infaunal crustacean abundance provided the means to directly track changes to gray whale infaunal crustacean prey in productivity hotspots in the northern Bering and eastern Chukchi seas (Fig 5). The area of highest gray whale prey abundance is in the south-central Chukchi Sea, near the northernmost UTN and the western-most DBO3 stations and extends west of the International Date Line (IDL). Two smaller centers of prey abundance occur in DBO regions 4 and 5 in the northeastern Chukchi Sea. Conversely, the DBO 2 region, which used to encompass a well-documented gray whale prey hotspot in the northern Bering Sea, now is relatively 'cool' with only moderate measures of infaunal crustacean abundance.

The clearest change in gray whale prey during the 2010–2019 period was a significant decrease ($r = -0.314$, $p < 0.05$) in amphipod abundance in the DBO2 region (Table 2; Fig 6). Especially notable was the decline in crustacean abundance at the northwest sampling sites starting in 2015 and the nearly complete absence of crustacean prey at southwest sampling stations after 2012 (Fig 7). Of note, this decline in crustacean abundance represents a continuation for gray whale prey loss this region, which began in the late 1990s [32].

In the southern Chukchi Sea, comparatively small-bodied amphipod species from three families were found in the DBO 3 region, where gray whales are often seen feeding from both vessel and aircraft platforms. There was no significant trend in infaunal crustacean abundance

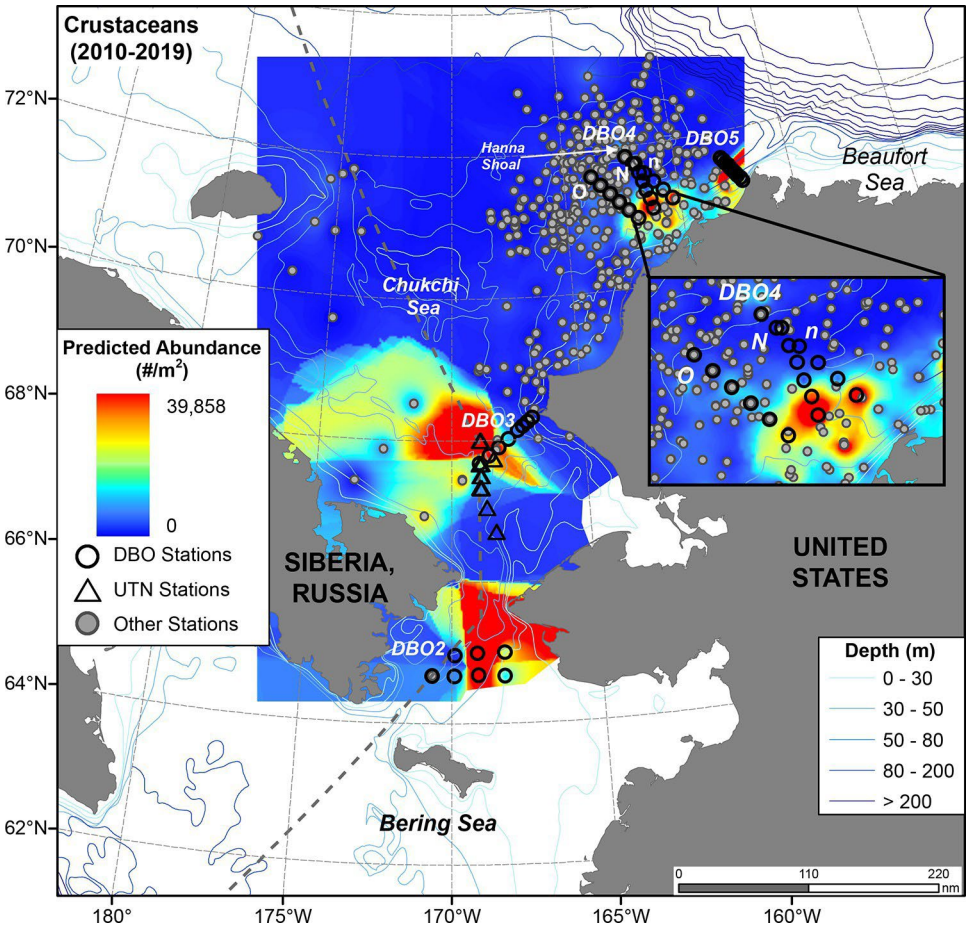

Fig 5. Distribution of infaunal crustacean abundance (#/m^2) at all stations where macrofauna were sampled during the period 2010–2019 in the northern Bering and eastern Chukchi seas. Key: open circles = DBO stations, open triangles = UTN stations, and closed gray circles = all remaining stations. Note that DBO4 has 3 transect links: O = original line 1, n = new line 1, and N = new line 2. The spatial interpolation map was made using the Geostatistical Analyst Wizard Inverse Distance Weighting (IDW) tool in ESRI's ArcGIS Desktop v.10.8.1 (ESRI 2020) with default settings. See S3 Table for DBO sampling site information and crustacean abundance data. The remainder of the all station crustacean abundance data are available at Arctic Data Center DBO data portal <https://arcticdata.io/catalog/portals/DBO/Data>.

https://doi.org/10.1371/journal.pone.0265934.g005

in this region, with the highest crustacean abundance consistently observed in the hotspot sampled by the UTN 7 and SEC 3 and 4 stations (Figs 6 and 7). Notably, although abundance remained stable over time, there was a shift in community composition, whereby the northernmost stations of the DBO 3 hotspot are now dominated by *Pontopoporeia femorata* (F. Pontoporeidae), which replaced the *Byblis* sp. (F. Ampelicidae) in the mid-2000s and has remained the dominant crustacean species since that time; meanwhile the small F. Isaeidae amphipods have remained second in abundance throughout the last decade.

In the northeastern Chukchi Sea, feeding gray whales were seen where both comparatively large infaunal amphipods (F. Pontoporeidae) and a variety of small infaunal crustacean species (F. Isaidae., F. Phoxochelidae) were found in a localized area along the eastern flank of Hanna Shoal in DBO 4 (Fig 5, Table 2). The infauna at all 6 stations in the time series were equitable in abundance (Fig 6), but there was notably higher amphipod abundance in 2016 and 2017 at the DBO 4.2N station (Fig 7) on the east flank of Hanna Shoal and close to the head of Barrow Canyon. In DBO 5, both the larger amphipods (F. Ampeliscidae) and smaller amphipods (F.

Table 2. Changes in infaunal crustacean community composition and abundance coincident with bottom water temperature and salinity, sea ice persistence (days from Sept-to Sept), and integrated water column and sediment chlorophyll in DBO regions 2–5 for the period 2010–2019.

https://doi.org/10.1371/journal.pone.0265934.t002

Isaeidae and F. Phoxocephalidae) and cumaceans (F. Leuconidae*)* were abundant along the narrow shelf nearshore (Table 2). Although there was no significant trend in infaunal crustacean abundance in the DBO 5 region (Fig 6), there was an indication of a local increase in abundance near the head of Barrow Canyon at the BarC 6 station in 2015 and especially in 2017 (Fig 7). Unfortunately, sea ice cover in 2018 precluded sampling the DBO5 stations and sorting of 2019 samples is in progress.

A summary of changes in environmental factors associated with the sampling of infaunal crustaceans provides context, but no simple answers, as to why there was a significant change in abundance only in the DBO 2 region (Table 2). Sea ice persistence has *decreased* in all DBO regions 2–5, while integrated water column chlorophyll increased only in the DBO2 region, suggesting an enhanced pelagic food supply in waters north of St. Lawrence Island. In contrast, seasonal variability in water mass nutrient content in the eastern Chukchi Sea (i.e., DBO 3–5) influences chlorophyll and productivity measurements over the open water season (see Frey et al, this volume). Notably, sediment chlorophyll increased only in DBO 2 and DBO 4. This suggests food supply to infaunal crustaceans has increased in those regions, making the *decline* of amphipods in DBO 2 unexpected and indicating that some combination of environmental factors is driving abundance. In reviewing those factors, we note that bottom water temperature has increased in all regions except DBO 5, accompanied by increased bottom water salinity in DBO 2 (Table 2). Bottom water salinity was variable across the DBO3 transect from nearshore to offshore stations, resulting in no trend. Bottom water became significantly fresher in DBO 4, likely due to increasing sea ice melt and perhaps freshwater pulses from the south. There was no change in bottom water salinity in DBO 5, likely due to the seasonal complexity of Barrow Canyon ocean dynamics.

Environmental factors related to gray whale epi-benthic and pelagic prey availability

Since gray whales also feed on epi-benthic (e.g. mysids, cumaceans [11]) and pelagic (e.g. krill [14]) prey, integrative correlational analyses (ICA) were used to investigate drivers of Chukchi Sea circulation (regional wind forcing and transport through Bering Strait) that can alter prey availability and thereby influence whale distribution and sighting rates (SR). In the northeastern Chukchi Sea, interannual changes in gray whale monthly distribution and SR depict a shift in foraging away from the nearshore Peard Bay area (2009–2014) to offshore waters near the head of Barrow Canyon in the Wainwright area (2015–2019; Fig 8). The shift in distribution and SR is most evident for the month of July, with a near-abandonment of the Peard Bay area in August and September. To investigate this shift, combined annual July-August-September (JAS) SRs for Wainwright (W) and Peard Bay (PB; Fig 9A) were used to create a 2009–2019 time series of fractional SR, ($W_F = W_{JAS}/(W_{JAS} + PB_{JAS})$. This served as the ICA training set (Fig 9B) to identify periods of seasonally-averaged winds within the Bering-Chukchi-Beaufort domain that were significantly correlated ($r > 0.60$, $p<0.05$, $df = 9$) with the fractional SR. The ICA heatmap shows three loci, all with start dates in early June (Fig 9C), with averaging periods of: (i) ~21 days (end date late June; best fit indicated by diamond symbol), (ii) ~45 days (end date late July), and (iii) ~100 days (end date mid-September). The resulting wind regimes were similar for all three loci in that the action center is the region north of ~70˚ N and that statistically-significant variability primarily occurs with the E-W component of the wind field. These results suggest foraging conditions for epi-benthic and pelagic prey are relatively better in the Peard Bay area when late-spring and summer winds are easterly and persistent (warm color shading) over the northern Chukchi and southern Beaufort (Fig 9D). Conversely, gray whale foraging on epi-benthic or pelagic prey (e.g. krill) is likely better in the Wainwright area when late-spring and summer winds are weak, variable (cool color shading), or westerly (Fig 9E).

Interannual variability in gray whale monthly distribution and SR in the Hope Basin area depicts a more stable situation. Sightings were clustered around a quasi-stationary front associated with a bathymetric trough southwest of Pt. Hope, with a southern extension of sightings evident in the combined July distribution (Fig 10). Of note, there were very few gray whales seen in 2009–2013, likely due in part to limited survey effort in those years (S2 Table). Except for 2015, the combined annual JAS SR for gray whales in the Hope Basin area was consistently higher from 2014–2019 than for the years 2009–2013. Notably, an ICA for the Hope Basin area showed no clear relationship with winds over the Bering-Chukchi shelf region. Combined monthly SR showed intra and interannual variability, with peaks in July (2017 and 2019), August (2014 and 2017), and September (2014 and 2016) (Fig 11).

Interannual variations in gray whale SR in the Wainwright, Perd Bay and Hope Basin analytical areas were used as ICA training sets to identify time series of monthly-averaged transport at the A3 'climate' mooring site (see Fig 2A) north of Bering Strait. ICA results indicate that winter-to-early-spring volume, heat, and freshwater transports are positively correlated

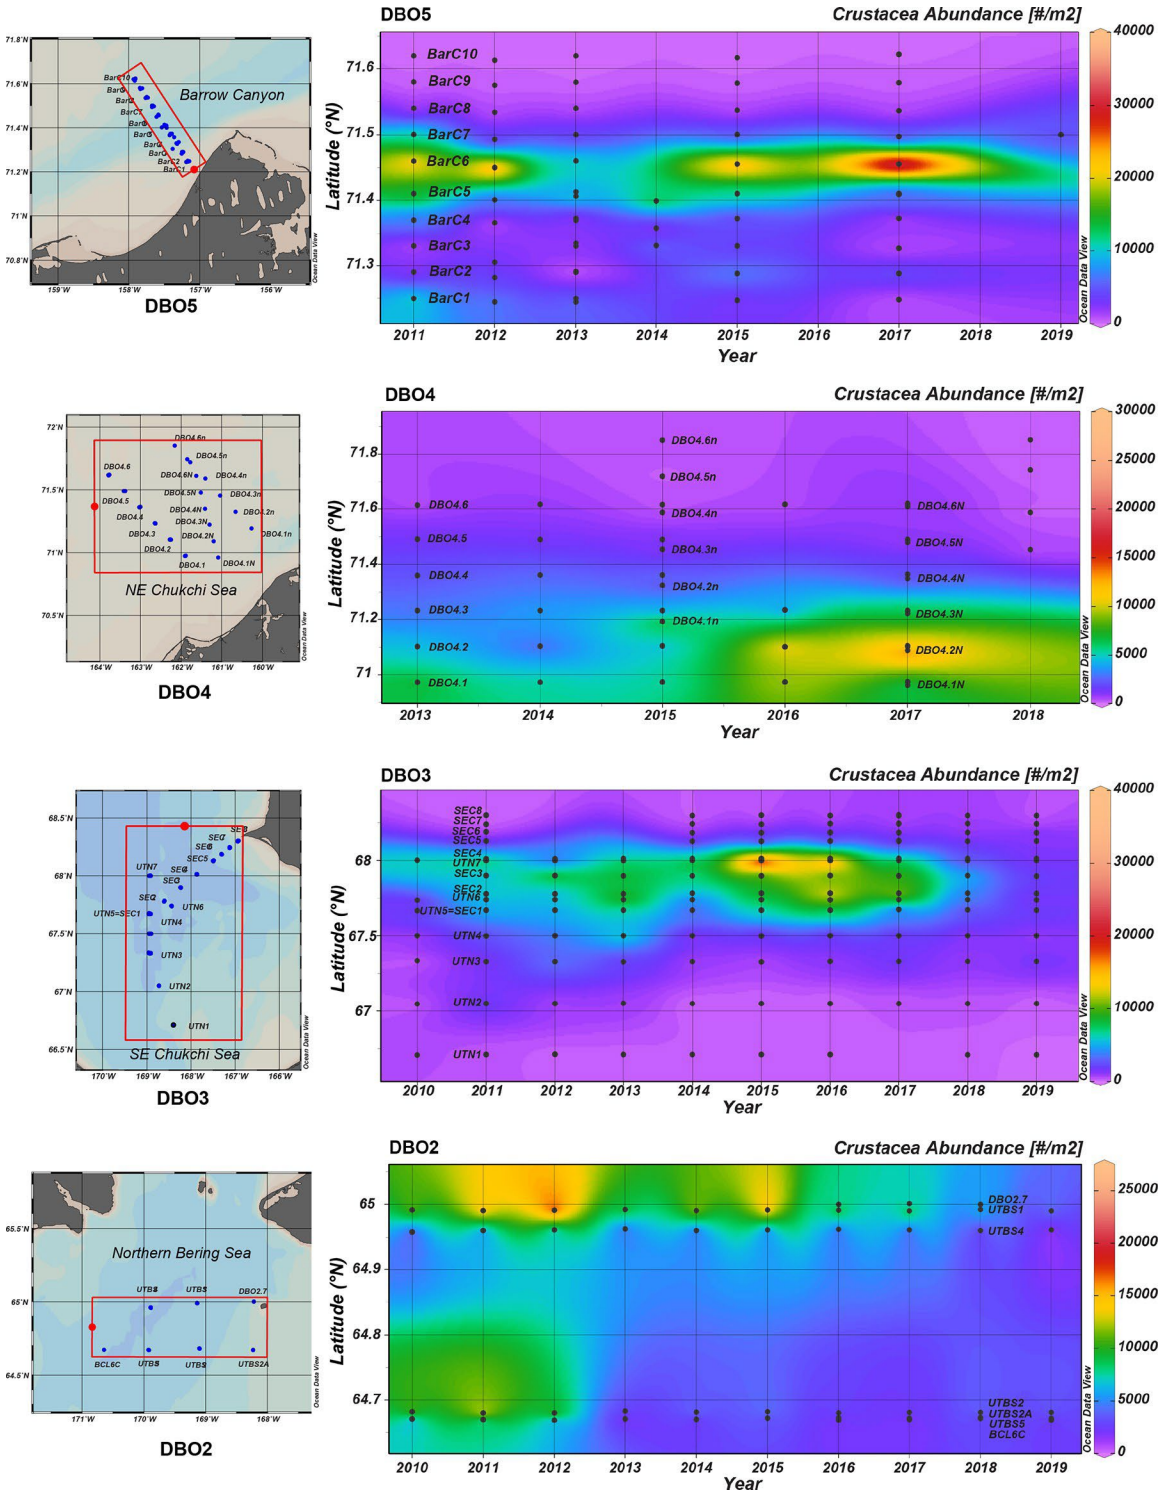

Fig 7. Time series of macrofaunal crustacean abundance at stations in DBO regions 2–5 over the 2010–2019 period. Figures are aligned from south to north over a latitudinal gradient with the red bounding boxes surrounding time series stations in each DBO region. The crustacea summary data plotted in this figure are provided in S3 Table and the Arctic Data Center DBO project page (https://arcticdata.io/catalog/portals/DBO/Data). All crustacean data in each DBO region were plotted using Ocean Data View software under a CC By license; see Methods for details of stations included in the visualization.

https://doi.org/10.1371/journal.pone.0265934.g007

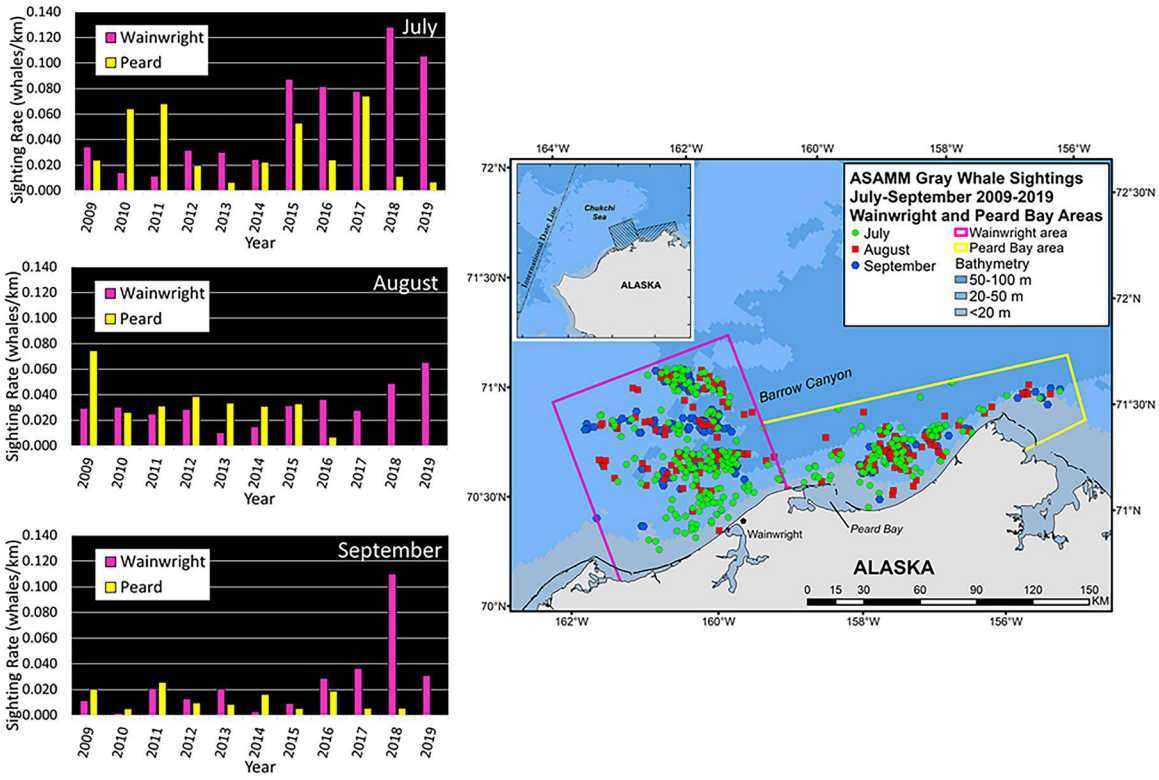

Fig 8. Interannual variability in gray whale monthly distribution and histogram of sighting rates (SR) for Wainwright and Peard Bay analytical areas in the northeastern Chukchi Sea, 2009–2019. Inset map shows the location of Wainwright and Peard Bay areas relative to the ASAMM study area. ASAMM data are publicly available at fisheries.noaa.gov/resource/data/1979-2019-aerial-surveys-arctic-marine-mammals-historical-database. Databases used for maps include versions 1979_2011_v3_36, 2012_2014_v0_28, 2015_2017_v22, and 2018_2019_v6.

https://doi.org/10.1371/journal.pone.0265934.g008

with the combined JAS SR in the Wainwright area and negatively correlated with combined JAS SR in the Peard Bay area (Table 3). In the Hope Basin area, interannual variations in August and September SR were negatively correlated with volume, heat, and freshwater transports. Notably, the negative correlations for the September SR were associated with 10-12-month time-averages of transport compared to the 1 to 4-month averages of transport found in other comparisons.

A summary of results relating variability in gray whale sighting rates (SR) to circulation drivers (A3 transport and winds), bathymetry, and likely whale prey highlights contrasts among the three analytical areas in the Chukchi Sea (Table 4). Notably, transport at A3 is correlated with gray whale SR in each of the regions, while a contrasting pattern of high and low SR can be correlated with alternate wind patterns only in the Peard Bay and Wainwright areas. In sum, bathymetry and transport appear to be drivers of gray whale pelagic prey in the Hope Basin area (inclusive of the DBO 3 region), while bathymetry, transport and wind forcing play a role in the northeastern Chukchi Sea (inclusive of DBO 4 and 5).

Discussion

Historical overview of gray whale ecology

Gray whale ecology in the northern Bering and Chukchi Seas has been the focus of intermittent research since the late 1960s, which provides a foundation upon which to interpret the

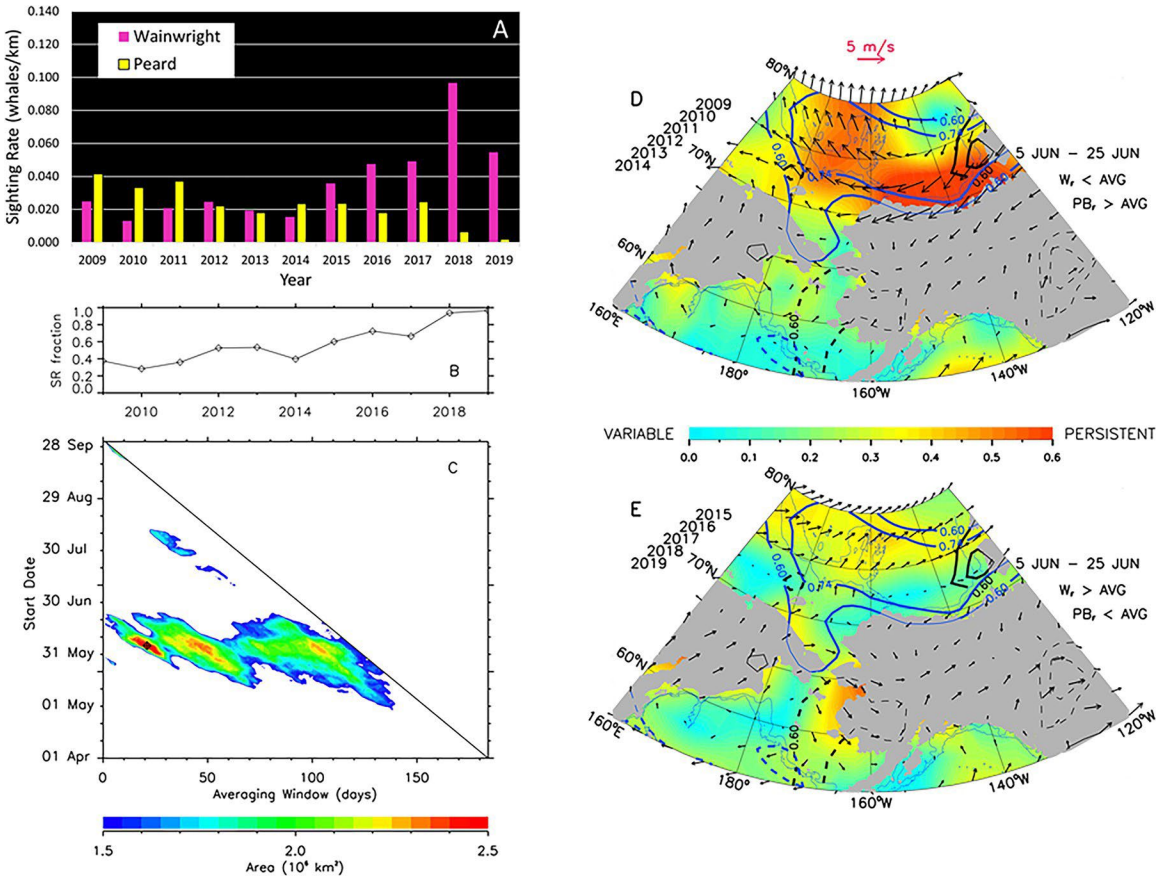

Fig 9. Relationship between gray whale sighting rates (SR) and wind forcing, including: Histogram of combined average July-August-September SR in the Wainwright and Peard Bay analytical areas (A); Wainwright area SR fraction (B); ICA heat map showing the area of the Bering-Chukchi-Beaufort ocean domain over which correlations between the SR fraction and time-averaged winds are statistically-significant ($r > 0.602$, $p<0.05$; $df = 9$, two-tailed test) (C); mean atmospheric circulation from 5 June to 25 June for years in which the Wainwright SR fraction was less than average and the Peard Bay SR fraction was greater than average (D); mean atmospheric circulation from 5 June to 25 June for years in which the Wainwright SR fraction was greater than average and the Peard Bay SR fraction was less than average (E). Mean wind vectors plotted at every 2nd ith grid point. Color shading indicates wind directional constancy, with correlations between SR fraction and U-component winds (blue contours) and V-component winds (black contours) statistically significant at $r = 0.60$ ($p < 0.05$) and 0.74 ($p < 0.01$).

https://doi.org/10.1371/journal.pone.0265934.g009

changes in their phenology and distribution reported here. For example, maps from Russian surveys from 1968–1982 show a near-continuous gray whale distribution along the Chukotka peninsula, with clustered aggregations of hundreds of whales in the coastal and central south-western Chukchi Sea [38]. Likewise, in a review of Russian research associated with commercial whaling, gray whales were reported as commonly seen feeding on benthic and epibenthic organisms in shallow waters along the Chukotka peninsula where prey concentrations were greater than 100 g/m^2, with distribution extending northwestward to the Eastern Siberian Sea and a very large aggregation (~2000 whales) encountered roughly 160 km offshore between 67˚40-68˚15'N and 169˚40'-172˚W during a 1980/81 expedition [12]. Stomach contents from whales taken in Mechigmensky Bay in 1980/81 contained roughly 122 benthic species [39], with various species of amphipods the most common in occurrence by percentage; e.g. *Pontoporeia femorata* (57.9%), *Ampelisca macrocephala* (53.9%), *Byblus longicornis* (51.3%) and *Lembos arcticus* (47.3%) Similarly, a satellite tracking study of 9 gray whales offshore Chukotka in late summer 2006 found that whales remained in shallow (< 30m) nearshore waters (< 5 km from coast) and were likely feeding on dense aggregations of amphipods [40].

Inset map shows the location of the Hope Basin area relative to the ASAMM study area. ASAMM data are publicly available at fisheries.noaa.gov/resource/data/1979-2019-aerial-surveys-arctic-marine-mammals-historical-database. Databases used for maps include versions 2012_2014_v0_28, 2015_2017_v22, and 2018_2019_v6.

https://doi.org/10.1371/journal.pone.0265934.g010

While maps from 1975–1980 surveys offshore Alaska depict comparatively few gray whale sightings in the southeastern Chukchi Sea, there is a distinct distribution cluster in what is now called the DBO 3 'hotspot' area [41]. Conversely, the distribution of gray whales in the northern Bering Sea was extensive, with a dense cluster of sightings extending north from St. Lawrence Island through Bering Strait. This dense summertime distribution of gray whales in the DBO 2 area continued at least through the mid-1980s [42, 43], but by the early 2000s gray whale sightings were comparatively sparse and shifted northward following a shrinking pattern of amphipod distribution [44, 45]. In the northeastern Chukchi Sea, focal areas for gray whale distribution in the 1980s included coastal waters between Icy Cape and Pt. Barrow, with a cluster of sightings near Hanna Shoal northwest of Wainwright [42]. There are no year-round acoustic data for the Bering Strait region in 1980s, but gray whales were reported in the northern Bering and Chukchi Seas from May through at least mid-October, with some whales seen as late as December seemingly following the seasonal cycle of sea ice retreat and formation [12, 41].

Changes in gray whale phenology

Gray whale phenology, as described by patterns of calling activity in the Bering Strait region, suggests little change in late May arrival times from 2012–2016 in the northern Bering Sea (DBO 2), and through 2017 in the southern Chukchi Sea (DBO 3). Departure dates inferred from a drop in calling activity changed dramatically thereafter, shifting from November to

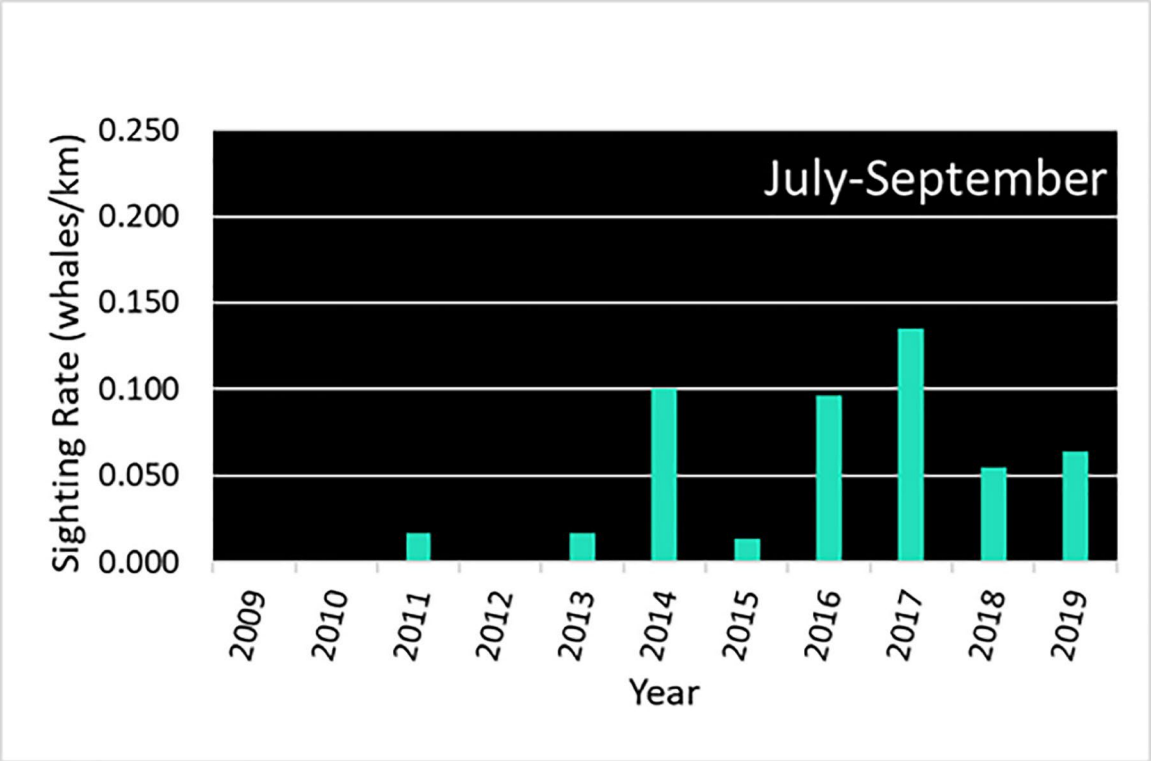

Fig 11. Gray whale combined July-August-September sighting rates (SR) in the Hope Basin area in the southern Chukchi Sea, 2009–2019. ASAMM data are publicly available at fisheries.noaa.gov/resource/data/1979-2019-aerial-surveys-arctic-marine-mammals-historical-database. Databases used for maps include versions 1979_2011_v3_36, 2012_2014_v0_28, 2015_2017_v22, and 2018_2019_v6.

https://doi.org/10.1371/journal.pone.0265934.g011

mid-September in 2016 (DBO 2) and from October to September in 2017 (DBO 3). This shift towards earlier departure dates and shorter residency periods culminated in a near-absence of calling activity in years 2017–2019 (DBO 2) and in 2018–2019 (DBO 3). This drop in calling activity in each region after 2017 and 2018 suggests that gray whales may have abandoned formerly prime foraging areas coincident with the anomalous 2017–2019 winter sea ice loss event [46]. Alternatively, because gray whale acoustic activity was based on detection of only two call types [31, Class 1 and 3], the drop in call detections could reflect changes in age-class composition or behaviors associated with those signals, rather than whale departure.

Table 3. Coefficients of linear correlation between 1 to 12- month time-averaged transport at mooring A3 (Woodgate 2018) and gray whale July-August-September (JAS) sighting rates (SR).

	Volume transport	Heat transport	Freshwater transport
Wainwright JAS SR (df = 9)	**0.799**, 3-month avg (Feb-Apr)	**0.932**, 3-month avg (Feb-Apr)	**0.829**, 3-month avg (Feb-Apr)
Peard Bay JAS SR (df = 9)	Not significant	**-0.766**, 1-month avg (Jan)	*-0.683*, 4-month avg Jan-Apr
Hope Basin Aug SR (df = 4)	*-0.880*, 1-month avg (Feb)	*-0.866*, 4-month avg (Jun-Sep, prior year)	*-0.871*, 1-month avg (Feb)
Hope Basin Sep SR (df = 4)	**-0.962**, 11-month avg	**-0.994**, 10-month avg	**-0.991**, 12-month avg
	Sep prior year -Jul	Nov prior year-Aug	Aug prior year-Jul

Table 4. Summary of bathymetry, gray whale prey and circulation drivers (transport and winds) used in iterative correlation analyses with Gray Whale (GW) Sighting Rates (SR) for three analytical areas in the northeastern Chukchi Sea.

Analytical Area	Bathymetry	Gray whale prey (see Table 2)	Transport @ A3 (see Table 3)	Winds over northern Chukchi Sea (see Figs 8, 9)
Peard Bay	Coastal shelf (20-40m deep)	Benthic species: amphipods cumaceans	**JAS GW SR**	**JAS GW SR**
	GW distributed along shore from Peard Bay to Point Barrow (Fig 4B)		negatively correlated with average winter transports	**High 2009–2014** Strong & persistent ENE winds in northern Chukchi in summer interrupt delivery of krill to head of Barrow Canyon, thereby making amphipods more accessible than krill
Wainwright	Offshore shelf	Benthic species:	**JAS GW SR**	**JAS GW SR**
	(40-50m deep)	amphipods, east flank of Hanna Shoal & near head of Barrow Canyon; increased abundance 2015–2017 (Fig 7)	positively correlated with average winter transports	**High 2015–2019**
	GW distribution clustered at the head of Barrow Canyon, NW of Wainwright (Fig 4B)	Pelagic & epi-benthic species: krill, possibly other spp.		Weak & variable winds in the northern Chukchi in summer promote the convergent delivery of krill to the head of Barrow Canyon
Hope Basin	Inflow shelf (~40m deep)	Benthic species: amphipods, in trough 'hotspot'	**August GW SR** negatively correlated with winter or preceding summer transports	ICA results not significant
	GW distribution localized over 50-60m trough SW of Point Hope; southward extension along central channel in 2014, 2018, 2017 (Fig 5B)	Pelagic & epi-benthic species: krill, at frontal system coincident with trough slope (Bluhm et al. 2007)	**September GW SR** negatively correlated with long-term average transports	

JAS = combined July-August-September SR.

https://doi.org/10.1371/journal.pone.0265934.t004

Sightings of gray whales in the Bering Strait region during DBO cruises conducted from July-October suggest that the abrupt changes in calling activity may indicate a modest (*ca*. 30–40 km) shift in distribution away from the recorder locations, rather than a substantial change in gray whale phenology. While propagation modeling has not been conducted at this site, evidence from modeling studies elsewhere in the Bering Sea [47] suggests that gray whale calls are not likely detected beyond a radius of about 35km (20nm). So, for example, a shift of whales northward to the remaining amphipod beds in DBO2 or westward toward the DBO 3 hotspot near the IDL could take them out of detection range of the recorder. However, because the clear truncation in gray whale calling activity coincided with anomalous wintertime sea ice loss event in 2017–2019, this potential shift in phenology and/or distribution is noteworthy. Future deployments of recorders near the remnant amphipod beds in DBO2, or the benthic trough hotspot in DBO3 could help resolve some of the uncertainty regarding shifts in gray whale phenology in the Bering Strait region.

Gray whale infaunal prey abundance, community composition, and environmental factors

Since 2010, the abundance of infaunal crustaceans that gray whales feed upon has significantly declined only in the DBO 2 region. This decline has been ongoing since the late 1980s [42, 43] leaving a reduced area of the northern Bering sea suitable for gray whale foraging. This change is concomitant with a shift in sediment quality due to faster currents, with the finer sediments required for tube building by *A*. *macrocephala* found only where current speed is reduced by land mass constriction south of Bering Strait [45]. Of note, the decline of infaunal crustaceans in DBO 2 is also coincident with an increase in polychaetes and bivalves [32, 33]. Collectively, these data suggest a physiological sensitivity of the dominant amphipods to warming

conditions in the DBO 2 region, with the potential to be outcompeted by organisms more tolerant of seawater changes and able to take advantage of increasing integrated and sediment chlorophyll carbon sources.

While there was no decline in infaunal crustacean abundance in DBO 3, a shift in dominant species was observed. Specifically, *Byblis* spp. (F. Ampeliscidae) was dominant from 1984–2004, but is now largely absent there, although it continues to be abundant in the DBO 5 region. The larger amphipod *Pontoporeia femorata* (F. Pontoporeidae) is now the dominant species in the northern portion of the DBO 3 hotspot, continuing to provide a benthic prey base for gray whales in the 'hotspot' area where they also appear to feed on advected krill [14]. Infaunal crustacean abundance in DBO regions 4 and 5 remained stable and without major changes in dominant fauna, at least through 2017.

Environmental factors and pelagic-benthic coupling

What has influenced the changes or stability of the infaunal crustacean communities across the DBO 2–5 sites? On the face of it, the lack of change to infaunal crustacean abundance in DBO regions 3, 4 and 5 seems inconsistent with a fundamental tenant of the pelagic-benthic coupling model whereby loss of sea ice results in reduced organic carbon from ice-associated algae dropping to the sea floor and thereby cutting food supply for benthic macrofaunal communities [48]. Yet, our observations show that surface sediment chlorophyll increased as sea ice persistence decreased in DBO regions 2 and 4 (Table 2). Notably the significant decrease in sea ice persistence was associated with a significant increase in integrated water column chlorophyll only in DBO 2, although satellite observations indicate increasing productivity north of Bering Strait. These observations support the idea that changes in the timing and magnitude of water column primary production play an important role in carbon transfer to the seafloor [32]. Previous studies indicated that primary production is highest in the northern Bering Sea (DBO 1–2) in April/May, with a production peak north of Bering Strait (DBO 3) in June followed by peak production in the northeastern Chukchi Sea (DBO 4–5) in July [49]. Recently, however, pelagic primary production north of Bering Strait has increased in June and July [9, 50], which may be mismatched with the arrival of zooplankton grazers thereby leaving phytoplankton production to fall to the seafloor and feed benthic macrofauna. This effect on pelagic-benthic coupling may be especially true in the DBO 3 hotspot where deposition is greatest [51]. However, recent sediment trap results indicate that the early season breakup of sea ice at the DBO2-4 sites resulted in shorter periods of chlorophyll and diatom fluxes, thus potentially reducing the biological pump [52], emphasizing the importance of advective carbon to sustain northern DBO sites.

Clearly other environmental factors, such as sea ice thinning [10], increase in ocean heat and freshwater in the Chukchi Sea [5, 6], and changing sediment grain size associated with variability in current speed [32, 33, 45] are also influencing benthic macrofauna community structure. Specifically, increased water temperatures in DBO regions 2–4 is likely affecting the distribution of benthic species, as has been reported for the northeastern Atlantic where *Ampelisca* spp. have extended their distribution northward with warming seawater [53]. Of note, DBO5 stations in Barrow Canyon do not show increased bottom water temperatures, likely due to its dynamic nature and the seasonally variable water masses reported there [54]. Finally, increasing bottom water salinity since 2019 in DBO2 is perhaps indicative of a stronger Anadyr water signal at depth that may also influence nutrient availability to surface waters by mixing upward of AW after storm events. By comparison, DBO4 in the NE Chukchi Sea shows a decrease in bottom water salinity and a decline in integrated chlorophyll a, likely a response to reduced brine production with declining sea ice and variable nutrient content.

Changes in gray whale distribution related to pelagic prey availability

Changes in gray whale distribution based on sightings were evident in the northeastern Chukchi Sea, and somewhat less so in the southern Chukchi Sea. Analyses of the ASAMM data show a mid-decade southwestward shift in distribution of roughly 110 km (60 nm), from coastal waters between Pt. Franklin and Pt. Barrow to waters offshore Wainwright. High gray whale sighting rates (SR) in the coastal Peard Bay area (2009–2014) were associated with strong and persistent easterly winds over the northern Beaufort-Chukchi region, while high SR in the Wainwright area (2015–2019) were associated with weak and variable winds that are conducive to krill remaining on the shelf over winter [28]. Winter-spring transports of volume, heat, and fresh water through Bering Strait were positively correlated with gray whale SR in the Wainwright area and negatively correlated with SR in the Peard Bay area (Table 4). This lagged relationship implies an advective timescale of ~4–6 months for biophysical signals to travel from Bering Strait to Barrow Canyon, which roughly comports with results from drifters traveling along that path in 90 days [55]. The heat signal, in particular, invites speculation that zooplankton development and survivability are enhanced in years with greater transport ultimately leading to improved summer foraging conditions near the head of Barrow Canyon. When krill remain on the northern Chukchi shelf, we postulate that they are subsequently aggregated via the convergence of northern Chukchi currents which promotes gray whale foraging near the head of Barrow Canyon. Although we have no confirmatory evidence (e.g., feces, stomach contents) that gray whales feed on krill in this area, they have been seen skim feeding on krill (Fig 1B) in association with foraging bowhead whales east of Pt. Barrow [28].

Changes in gray whale distribution in the southern Chukchi Sea were evaluated analytically using ASAMM data and, for waters south of 67˚ N, sightings during DBO cruises which provide qualitative information. Both data sources confirmed a strong and consistent aggregation of gray whales at a prey hotspot associated with a 50–60 m trough in the central Chukchi Sea. Furthermore, sightings during DBO cruises showed that this feeding hotspot extends across the international date line, with additional sighting of gray whales common along the Chukotka coast and associated with the western boundary of the central channel.

Implications for the Gray Whale Unusual Mortality Event (UME)

In 2019, a gray whale UME was declared when the number of dead animals found stranded on beaches along their migration route between Alaska and Mexico increased roughly ten-fold [30]. A similar UME occurred in 1999–2000 and the emaciated condition of some of the dead whales during both events suggested starvation or nutritional deficit as a likely cause [30, 56]. Notably, ship strikes, entanglement in fishing gear, and predation by killer whales (*Orcinus orca*) contributed to the death toll during both events, while mortalities due to disease and biotoxins could not be clearly identified [57].

Whether or not gray whales were nutritionally stressed due to a change or reduction in prey availability related to environmental forcing, and/or to increased competition for food resulting from their burgeoning population size, remains a pivotal question with regard to both UME events [58]. The 1999–2000 UME closely followed the powerful 1997–1998 El Niño, while the onset of the 2019 UME was subsequent to extreme ocean heat events in the North Pacific and Gulf of Alaska from 2014–2016 [59], as well as the aforementioned ocean warming and wintertime sea ice loss that persisted in the northern Bering and Chukchi Seas from 2017–2019. The latter event was contributory to a mass mortality of seabirds [45] and likely influenced an ice seal UME [60].

The record on infaunal crustacean communities presented here shows that while gray whale benthic prey abundance declined in the northern Bering Sea from 2010–2019, it remained stable in the Chukchi Sea. Specifically, a significant decrease in amphipod abundance was observed in the DBO 2 region of the northern Bering Sea, a decline that extends a trend that began in the mid-1980s [45]. Conversely, there was no decrease in infaunal crustacean prey abundance evident in DBO regions north of Bering Strait, although there was a shift from a smaller (*Byblis* spp) to a larger (*Pontoporeia* spp) dominant amphipod species in the DBO 3 region. Meanwhile, iterative correlational analyses support the hypothesis that, due to changes in wind-driven circulation, gray whales may be finding more opportunities to feed on krill near the head of Barrow Canyon in the northeastern Chukchi Sea.

While changes in gray whale prey, either among benthic infauna or between benthic and pelagic species, will have nutritional ramifications, it seems unlikely that a change in diet alone would result in a dramatic upsurge in mortality. In other words, from the perspective of gray whale prey abundance, our observations provide context but not causation for poor nutritional condition of gray whales that feed north of Bering Strait. Conversely, if a portion of the gray whale population exhibits feeding-site-fidelity to the northern Bering Sea, that could result in nutritional stress for those animals. Indeed, there is evidence at the local scale that biophysical events that impact gray whale prey availability can lead to changes in phenology, a reduction in feeding, and signs of poor body condition. This was the case in 2005 when late spring ocean conditions off the Oregon coast markedly decreased abundance of epi-benthic mysids leaving the small population of gray whales that feed there over summer with a nutritional deficit [61]. A subsequent study showed body condition of whales in these whales responded to upwelling conditions along the Oregon coast, with animals in 'good' condition following strong upwelling years (2013–2015) and in comparatively 'poor' condition following years of weak upwelling (2016–2018) [62].

The AMP model as a framework for future research

The Pacific Arctic marine ecosystem is in a state of transformation as it responds to amplified planetary warming [8]. In constructing the conceptual AMP model, we purposely imbedded mechanistic features such as transport through Bering Strait, pelagic-benthic coupling, advection, and upwelling as key drivers that influence biological outcomes in the region (Fig 2B) [29]. The challenge is to elucidate how these biophysical drivers interact in this productive inflow shelf system. Results from this and past studies suggests that this question may be best approached by investigating factors that (i) drive aspects of pelagic benthic coupling in the northern Bering and southern Chukchi Seas (DBO 2 and 3), and (ii) influence downstream advection, upwelling and ocean circulation dynamics in the northeastern Chukchi Sea (DBO 4 and 5). This type of approach was used to develop a mechanistic model for the persistence of benthic 'hotspots' in DBO regions 1–5, showing that those in regions 2, 3, and 5 rely on carbon supplied from upstream biological production, while those in regions 1 and 4 were supplied by local production [63]. As in past studies focused on macrofaunal biomass [32, 33], our observations of changes in infaunal crustacean prey abundance in DBO regions 2 and 3 suggest that the timing and magnitude of water column primary production, bottom water temperatures, bathymetric channeling, sediment grain size and the responses of other macrofaunal species may be as important as sea ice persistence in influencing pelagic-benthic coupling dynamics that lead to benthic community transitions.

The AMP conceptual model provides a rudimentary framework to guide future research aimed at elucidating changes in both benthic and pelagic realms of the Pacific Arctic. In the benthic realm, a focus on linking sea ice metrics [10] to biophysical data will provide a clearer

picture of their combined influence on productivity and community structure [33]. The addition of sediment trap data [52] can add additional detail to track pelagic-benthic coupling processes in the region. A key question for the Pacific Arctic region is: how important are krill as prey for upper trophic level predators? This requires investigating the more ephemeral prey aggregations in the epi-benthic and pelagic realm. The ICA results presented here suggests that the offshore shift of gray whale distribution after 2015 may have been influenced in part by the availability of krill in the northeastern Chukchi Sea. While this speculation builds on research focused on bowhead whale (*Balaena mysticetus*) foraging on krill in adjacent waters of the western Beaufort Sea [28], we have no direct evidence that gray whales are feeding on krill. Seabirds can also act as sentinels of krill availability, especially short tailed shearwaters (*Puffinus tenuirostris*) who feed on these advected prey in the northeaster Chukchi Sea more often now in the 1980s [64]. Using both marine mammal and bird species as ecosystem sentinels can alert researchers to changes in the pelagic realm across a broad range of space and time related to each species natural history [22] and we advocate for their continued inclusion in DBO and other ocean observatory protocols.

Acknowledgments

We thank the captains and crews of the research vessels that provided safe operations and space for a marine mammal observer on the DBO research cruises. We appreciate the passive acoustic team from AFSC and CICOES who manually analyzed data from recorders on moorings in DBO2 and DBO3: Eric K. Braen, Stephanie L. Grassia, Eliza G. Ives, Daniel F. Woodrich, and Dana L. Wright. We thank the marine mammal observers, pilots, mechanics, programmers, flight followers, and organizations that enabled ASAMM surveys to be conducted safely and effectively, in particular Megan Ferguson, Amelia Brower, Amy Willoughby, NOAA Aircraft Operations Center, and Clearwater Air, Inc. The scientific results and conclusions, as well as any views or opinions expressed herein, are those of the author(s) and do not necessarily reflect those of NOAA or the Department of Commerce. Reference to trade names does not imply endorsement by the National Marine Fisheries Service or NOAA. JMG thanks past and current support staff at CBL for technical assistance, especially Stephanie Soques and Alicia Clark, and Alynne Bayard for GIS mapping and data analytics. Finally, we thank Dr. Karen Frey (Clark University) for providing Fig 2A, and Dr. Leigh Torres (OSU) and an anonymous reviewer for constructive comments that guided improvements to the final manuscript.

Chapter 2: Acoustic Behaviour and Vocal Repertoire of Transient Killer Whales (*Orcinus orca*) in the Bering Strait and Southern Chukchi Sea

This chapter is the result of a Marine Biology Honours thesis of Abigail Mottu at St. Andrews University, Scotland. It will be revised and submitted as a peer-reviewed manuscript:

Mottu, A, Oswald JN, Wallace EE and Stafford KM. *in prep*. Acoustic detections of transient killer whales in the northern Bering and southern Chukchi Seas. Global Climate Change Biology

Abstract

In the Pacific Arctic, Killer whales (Orcinus orca) are historically classified as three genetically, morphologically, and acoustically distinct ecotypes: residents, offshores, and transients. Despite recent studies reporting an apparent increase in transient killer whale sightings in the Bering/Chukchi/Beaufort seas, there is still a lack of acoustic analysis of this phenomenon. Transient killer whale calls were recorded using passive acoustic data from three moored autonomous recorders in the Bering Strait and the southern Chukchi Sea from September 2009 to December 2018. An unsupervised neural network was used to categorize these calls into specific categories in order to generate a vocal repertoire of transients in this area. This identified 29 discrete, pulsed calls in the vocal repertoire of this transient population, which showed little apparent overlap with other described repertoires of transients. This study provides the first acoustic catalogue of transient killer whale calls in the Bering Strait and the southern Chukchi Sea.

180011049

1. Introduction

Many social animals have evolved complex vocal repertoires to facilitate a range of interactions, including, but not limited to, group cohesion, predator avoidance, and mating (Elie and Theunissen, 2016; Gall and Manser, 2017; Charlton et al., 2018). For example, the repertoire of Common Bottlenose Dolphins (*Tursiops truncatus*) consists of signature whistles in which an individual produces a distinctive whistle type that broadcasts the owner's identity (Janik and Sayigh, 2013). More broadly, vocal repertoires will typically vary interspecifically and can aid researchers in developing quantitative methodologies for studying these animals' location and behavioural attributes (Janik and Knörnschild, 2021). For marine mammals, understanding vocal repertoires is of particular importance because visual surveys can only detect a fraction of the animals present. This limited detection ability is because surveys are often constrained by bad weather, limited to daylight hours, and the overall sighting opportunities are solely when the animal(s) surfaces (Mellinger et al., 2007; Gillespie, 2019). Additionally, tagging methodologies are more expensive, short-lived (tags detach after roughly 25 days), and give information only on select individuals (Newman and Springer, 2008).

To combat these limitations, an increasing number of studies rely on Passive Acoustic Monitoring Methods (Mellinger et al., 2007). Recent technological advances have made Passive Acoustic Monitoring (PAM) a widely accessible, low-cost, and non-invasive way to understand species' spatiotemporal distribution and abundance since it capitalizes on distinct cetacean vocalizations used for different behaviours (Gillespie, 2019; Mellinger et al., 2007; Van Parijs et al., 2009; Hannay et al., 2013; Sousa-Lima et al., 2013). Some species, like killer whales (*Orcinus orca*), exhibit distinct, intraspecific vocalizations, which makes them an ideal candidate

180011049

for passive acoustic methodology (e.g. Deecke et al., 2010; Thomsen et al., 2001; Filatova et al., 2015; Emmons et al., 2021).

Killer whales are found in every ocean worldwide, making them the most widely distributed cetacean (Myers et al., 2021). Killer whales' overall success in occupying a range of ecological niches can be attributed to the intraspecific variation of hunting techniques derived from morphological and acoustic differences (de Bruyn et al., 2012). This intraspecific differentiation is not limited to geographically delineated areas but can also be found in sympatric populations. There are three described ecotypes of killer whales in the Pacific Arctic: residents, transients, and offshores. Despite inhabiting the same geographic region, these three ecotypes are all reproductively isolated from one another and differ in various ways (Hoelzel et al., 2007). Resident killer whales ascribe to a tight matrilineal social structure, are fish specialists, and display high site fidelity (home ranges < 200 km) (Deecke et al., 2010; Ford et al., 1998; Fearnbach et al., 2013). Transient killer whales feed primarily on marine mammals, have a much more fluid social structure than residents, in which it is more common to spread from their original pod, and have presumably large home ranges spanning from the Aleutian Islands to Barrow, Alaska (Ford et al., 1998; Baird and Whitehead, 2000; Clarke et al., 2013). Much less is known about offshore killer whales, but they are presumed to feed primarily on sharks and fish and spend time along the continental shelf (>15 km offshore) (Dahlheim et al., 2008). In addition to the differences in preferred prey, social structure, and geographic range, these three ecotypes all differ acoustically.

Sound is used by killer whales for foraging and social interactions, such as maintaining group cohesion (Madrigal et al., 2021; Ford and Fisher, 1983). Killer whales produce distinct sounds for different functions. These vocalizations can be placed into three discrete categories: whistles,

180011049

echolocation clicks, and pulsed calls (Ford, 1989; Barrett-Lennard et al., 1996; Riesch and Deecke, 2011; Deecke et al., 2005; Samarra et al., 2010; Filatova et al., 2012; Deecke et al., 2010; Ford and Fisher 1983; Filatova et al., 2015). Whistles are typically non-pulsed tonal sounds that are used for socializing, close-range interaction, and possibly food sharing (Ford, 1989; Riesch et al., 2006; Riesch and Deecke, 2011). Whistles produced by resident and transient killer whales differ in duration, end frequency, and maximum frequency (Thomsen et al., 2001; Riesch and Deecke, 2011). More recent studies have found that killer whales also produce high-frequency whistles ranging up to 75 kHz. It is still unclear the purpose of these ultrasonic whistles, but they have a higher degree of directionality and are presumed to be used for private communication (Samarra et al., 2010; Andriolo et al., 2015; Simonis et al., 2012). Echolocation clicks are short, broad-spectrum pulses of sound. These clicks are primarily used for hunting since they provide information to the individual emitting the signal about the target animal (Ford, 1989; Barrett-Lennard et al., 1996). Offshore and resident killer whales use echolocation clicks to forage, whereas transients rarely echolocate (Ford, 1989; Deecke et al., 2005). Pulsed calls (hereafter referred to as “calls”) are the most common form of killer whale vocalization. They are used for group recognition and behavioural coordination (Ford, 1989; Deecke et al., 2005). Calls vary in pitch across these three ecotypes in which offshores have the highest minimum frequency, followed by residents, then transients (Foote and Nystuen, 2008). In general, calls are highly stable and, in many studies, are further categorized into discrete call types (Sharpe et al., 2017; Ford and Fisher, 1983; Ford, 1991; Madrigal et al., 2021; Filatova et al., 2012; Deecke et al., 2010). Recently, multi-part calls, in which a singular call contains a high- and low-frequency component, have been described in resident and transient populations (Filatova et al., 2015; Madrigal et al., 2021). In residents, these are thought to aid in maintaining contact and

monitoring the position of individuals when pods are mixed (Filatova et al., 2015). This comparison of killer whale sounds across ecotypes illustrates that transients vocalize significantly less often than their counterparts. This finding has been attributed to ecotypes differences in preferred prey types. Since transient killer whales' preferred choice of prey are marine mammals, it is therefore suggested that they rarely vocalize to avoid prey eavesdropping (Deecke et al., 2005).

The distinct differences in killer whale vocalizations can be explained by the fact that they are socially learned behaviours. This creates dialects between ecotypes despite no geographical boundaries. (Ford 1991; Deecke et al., 2010; Yurk et al., 2002; Filatova et al., 2012). Evidence suggests even greater acoustic divergence within these ecotypes into subpopulations known as acoustic clans (Ford 1991). Acoustic clans are collections of pods that have shared call types between their group-specific repertoire. In residents, this acts as a reflection of maternal lineage (Ford, 1991; Yurk et al., 2002; Deecke et al., 2010; Miller and Bain, 2000). While it is much more thoroughly understood in residents, there is evidence that suggests that transients also exhibit clan structure (Ford and Ellis, 1999; Sautilus et al., 2005; Sharpe et al., 2017). A study on the genetics of killer whales in this area indicated the presence of three subpopulations of transients: West Coast transients, Gulf of Alaska transients, and AT1 transients (Barrett-Leonard, 2000). Further studies have demonstrated that beyond varying genetically, these populations exhibit different acoustic behaviours. Deecke (2003) explored calls from West Coast transients in which he described a repertoire difference between the California population, and the British Columbia and Southeast Alaska population. Sautilus *et al* (2005) described 14 discrete calls in the AT1 transient subpopulation and found no matches with neither the West Coast nor Gulf of Alaska transient subpopulations (Deecke et al., 2005). A more recent genetic analysis of

180011049

transients in the Gulf of Alaska population suggests that this described subpopulation can actually be divided into five further subpopulations (Parsons et al., 2013). Sharpe *et al* (2017) supported these findings, providing the first extensive catalogue of group-specific call types in the western Gulf of Alaska: Western Aleutian Islands; Pribilof Islands; Eastern and Central Aleutian Islands. The authors described 36 call categories in which only six were attributed to more than one region, suggesting that each region has its own repertoire of distinct call types and can in turn be deemed an acoustic clan (Ford, 1991).

Current stock assessments of transient killer whales group together the Gulf of Alaska, Aleutian Islands, and the Bering Sea populations together in one stock (Allen and Angliss, 2012). However, recent findings suggest that these should be considered subpopulations (Parsons et al., 2013; Sharpe et al., 2017). Madrigal *et al* (2021) was the first study to provide a repertoire in which they confirmed the presence of transient Killer Whales north of Pribilof Islands (off of Point Hope, Alaska), providing acoustic support for this subpopulation hypothesis. The acoustic catalogues outputted by Sharpe *et al* (2017) and Madrigal *et al* (2021) resulted in no exact matches, which could either be due to inconsistent methodologies or they could possibly indicate different subpopulations of transients in these two locations.

While Madrigal *et al* (2021) is the first and only study to analyze transient killer whale repertoires north of the Pribilof Islands, numerous studies suggest that there has been an increase in transient killer whale sightings in these more northern areas (Frost et al., 2012; Hannay et al., 2013; Clarke et al., 2013; Stafford, 2019). Frost *et al* (1992) reported an unusual number of killer whales in the southeastern Bering Sea in 1989 and 1990. Twenty years later, Clarke *et al* (2013) found six sightings of 37 whales just north of the Bering Strait region in the southern Chukchi Sea. Even more recently, Stafford (2019) found a marginally significant increase in killer whale

sightings in the fall months just north of the Bering Strait in the southern Chukchi Sea. All of these indicate that these sightings are presumably transient killer whales.

Over the past several decades, the Arctic has warmed at twice the global rate, which has a range of chemical, physical, and biological consequences, namely affecting sea ice extent (Grebmeier, 2012). The Bering Sea is one of the most productive marine ecosystems worldwide, with a host of climatic, biological, and oceanographic interactions (Woodgate, 2022). Recently, the Bering Sea has been deemed a "hotspot" for the effects of climate change (Sigler, 2010). The Bering Sea has been especially vulnerable to climate change because the region's productivity relies on the seasonal change of sea ice extent. For example, there is supposed to be roughly 500,000 km^2 of ice in April, which supports a wide range of trophic levels, acting as a platform for seals and serving as a space for primary production. In April of 2018, there was only 61,704 km^2 of sea ice, which is about 10% of the normal amount (Hansen, 2018). These observations were supported by Jones *et al* (2020), who found that sea ice conditions in the Bering Sea in 2018 were the lowest in the past 5500 years. A similar phenomenon has also been documented in the Chukchi Sea. In the Chukchi Sea, the open-water season now extends from mid-June to late November, an expansion of about 42 days over the past 30 years, indicating that sea ice in the region is becoming annual rather than perennial (Stafford, 2019). While negative for many species, Moore and Huntington (2008) ran a model to understand the resilience of different Arctic marine mammals when faced with sea ice loss and found that certain species, like the killer whale, are more adaptable to these changes and may be able to extend their range into more northern areas. This has been described in the Hudson Strait area, where an increase in killer whale sightings was suggested to be correlated with a decline in sea ice (Higdon and Ferguson, 2009). This also corresponds with the increase of sightings in the Bering Strait and the

Chukchi Sea, as noted above. A further change in oceanographic conditions has the potential to have a large effect on the ecosystem dynamics in these areas.

Through the Bering Strait, the Bering Sea acts as the only connection between the Pacific and the Arctic Ocean, making it the ideal study location (Woodgate, 2022; Hansen, 2018). The lack of detailed acoustic analysis in the Bering Strait and southern Chukchi Sea is partially due to; (a) a lack of dedicated effort until recently and (b) difficulties assessing this area. Long-term passive acoustic monitoring is a helpful tool that can monitor and assess killer whales without the need for a full-scale survey. However, for this methodology to be effective, a repertoire needs to be defined. While it is suggested the transient killer whales are expanding to these more northerly areas, due to the limited studies, the population that is exploiting this niche is not definitively known. As suggested by Sharpe *et al* (2017), transients may exhibit regional repertoires, and therefore analyses need to be carried out on a regional basis to figure out what population is moving to this region. This study aims to investigate the spatiotemporal distribution of transient Killer Whale calls in the Bering Strait and southern Chukchi Sea and characterize these calls into distinctive categories to describe a regional repertoire. Given the outcomes of the resilience model from Moore and Huntington (2008) and an increase in transient Killer Whale sightings in the Bering and Chukchi Seas, this study hypothesizes that the occurrence of calls will be greater in more recent years. Within this, this study hypothesizes that call occurrence varies by recorder location, year, and month. Like Madrigal *et al* 2021, this study also takes place partly in the Chukchi Sea, and therefore it is hypothesized to have similar call categories. Furthermore, this study hypothesizes that year, month, and recorder location will affect call type occurrence. This study will be the first to describe an acoustic catalogue of transients in the Bering Strait to increase our knowledge of the spatiotemporal distribution of killer whales in this highly

180011049

productive and changing area. The repertoire produced from his study will be able to be used as a baseline for future acoustic studies in this region.

2. Methods

2.1.Data Collection

Continuous passive acoustic data were collected from three moored autonomous underwater recorders (AURAL-M2 hydrophones, Autonomous Underwater Recorder for Acoustic Listening-Model 2, Multi-Électronique, Inc.; sensitivity of −154 dB re 1 V/µPa and 16-bit resolution) managed by the National Oceanic Atmospheric Association (NOAA) and the Applied Physics laboratory at the University of Washington (NOAA, 2022). These three moorings were positioned in different locations within the Bering Strait and southern Chukchi Sea: one in the centre of the Bering Strait on the east side of the Diomede Islands (A2), one in the centre of the eastern channel (A4), and a central strait location approximately 35 km north of the strait in the southern Chukchi Sea (A3) (Figure 1).

180011049

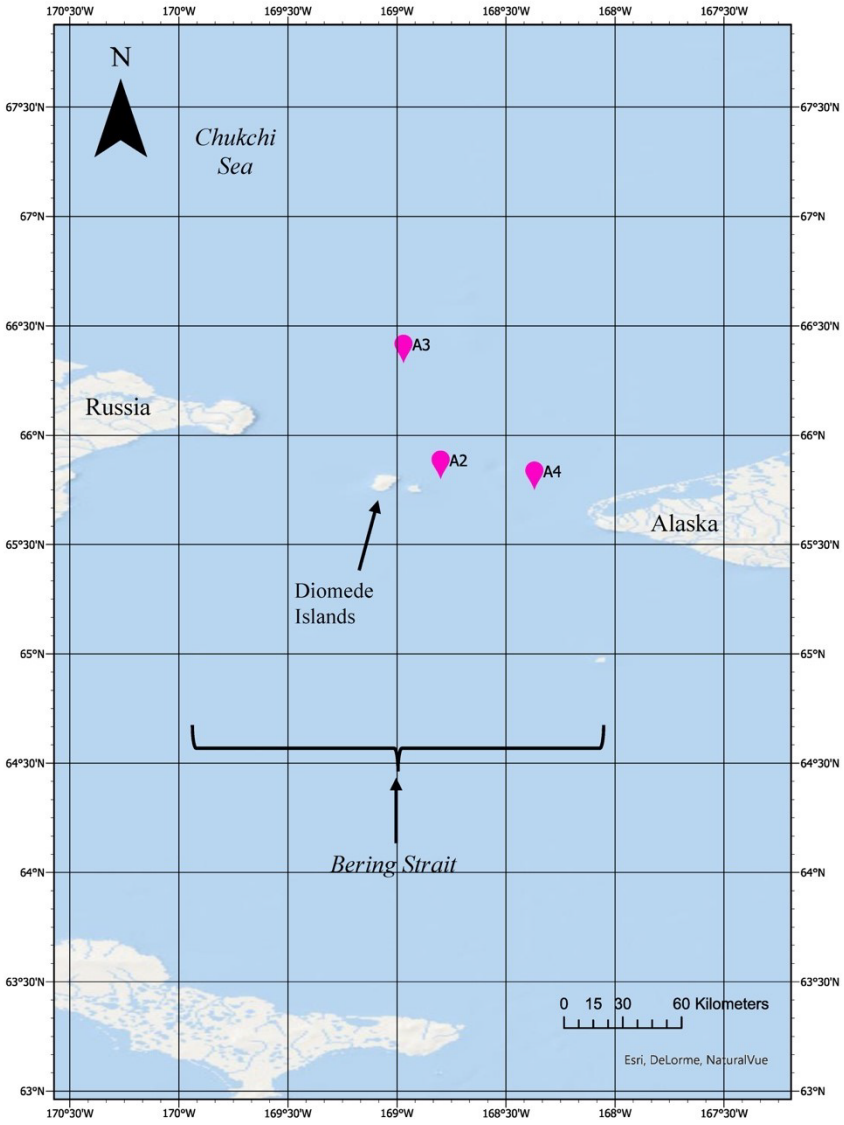

Figure 1. Map of the study region and the three moored autonomous recorders. The Diomede Islands are located roughly mid-strait in between the western and the eastern channel. A2: 65.8°N, 168.80°W; A3: 66.33°N, 168.97°W; A4: 65.75°N, 168.37°W. Scale bar of 60 km.

These hydrophones collected data from September 2009 through December 2018. While data was sampled at 8192 Hz or 16384 Hz, only files samples at 16384 Hz were used for further

180011049

analysis. Files sampled at 8192 Hz (2013, 2014, 2015) were disregarded since the spectrograms generated would not cover the typical range of killer whale calls (1-6 kHz) (Ford 1989; Samarra et al., 2016). This is because, in order to represent a sound accurately, samples taken need to be twice every wavelength. When sound is represented on a spectrogram, it appears as half the sample rate. So, recordings sampled at 8192 Hz would only generate spectrograms reaching 4 kHz and, therefore would potentially not provide an accurate representation of the range of killer whales.

2.2.Call Extraction

Recordings that were previously identified as transient killer whales were analyzed (NOAA, 2022). Acoustic recordings were aurally and visually inspected using the RAVEN 2.0.1 sound analysis program (Cornell Laboratory of Ornithology, NY) to examine spectrograms (512-point FFT, 16 kHz bandwidth, 10-second window). Calls were annotated and deemed either quality 1, 2, or 3. For a call to be considered quality 1 it must have been traceable, meaning it had to have a clear start and end, have little to no overlap of other calls or noise, have the majority of sidebands be visible, and was clearly audible. A sideband is how the pulse repetition rate of a call is displayed on a spectrogram. It appears as a series of harmonics bands that vary depending on the pulse repetition rate of the signal (Watkins, 1967). For a call to be deemed quality 2 it must have also been traceable meaning it must have had a distinguishable start and end, visible but not necessarily distinct sidebands, could have some overlap between other calls/noise, and be audible. Quality 3 calls were untraceable meaning that they did not have a clear start or end, overlapped with other calls/noise, and were only faintly audible. Due to the fact that quality 3 calls were, by definition, difficult to discern from other calls and background noise, they were

180011049

not included in any further analysis. The annotated quality 1 calls from RAVEN were then used for further analysis in PAMGuard 1.15 (Gillespie et al., 2008). The ROCCA (Real-time Odontocete Call Classification Algorithm) module in PAMGuard 1.15 was used to trace the lowest frequency component of quality 1 calls (Gillespie et al., 2008, Oswald and Oswald, 2013). Once a call contour was traced, ROCCA extracted the time and frequency points along with 56 additional variables that describe frequency (Oswald and Oswald, 2013; Oswald et al., 2021). Refer to Appendix A in Oswald and Oswald (2013) for more information regarding the details and meanings of the ROCCA output variables. For the purpose of this analysis, six of the variables that were measured by ROCCA were examined: (1) minimum frequency (Hz), (2) maximum frequency (Hz), (3) call duration (sec), (4) beginning frequency (Hz), (5) end frequency (Hz), (6) median frequency (Oswald et al. 2007, Oswald and Oswald, 2013). These variables were selected in accordance with similar studies so comparisons could be drawn accordingly (Madrigal et al., 2021).

2.3.Test of Interrater Reliability

An interrater reliability test was conducted to ensure the quality criteria assigned to the calls (1, 2, or 3) were defined well and consistently applied. The methodology for this was adapted from Riesch and Deecke (2011). A subset of 23 randomly chosen transient killer whale calls was used to confirm my initial classification of quality ratings. Spectrograms (512-point FFT, 16 kHz bandwidth, 10-second window) of transient killer whale calls were presented to four naïve observers. Out of the 23 chosen calls, eight calls were quality 1, eight were quality 2, and six were quality 3. All calls were printed on separate sheets of paper containing one spectrogram each (standardized 4-second window for each spectrogram shown) and presented in random

180011049

order. Observers were asked to divide the calls into three different quality categories based on defined criteria. A Kappa Statistic was used to test for interobserver reliability.

2.4.Call Type Categorization

Time-frequency call contours from ROCCA were organized into different call types using ARTwarp. ARTwarp is MATLAB-based software that uses an unsupervised adaptive resonance theory neural network and dynamic time-warping to group contours into categories (Deecke and Janik, 2006). Dynamic time warping is an algorithm that allows limited compression and/or expansion of the time axis to allow for maximum frequency overlap with the reference contour (Deecke and Janik, 2006). To be placed into a category, a call had to have a similarity index (vigilance parameter) of 81.24% to the reference contour. When a contour is undergoing categorization, it is compared to all the reference contours, and it is put in the first category that exceeds the similarity index, and then the reference contour is subsequently readjusted accordingly. A new reference contour is generated if the contour does not exceed the similarity index. It is these reference contours that make up the described call repertoire.

2.5.Call Type Comparison with Previous Literature

Madrigal *et al* (2021) created an acoustic catalogue of transient killer whale calls off of Point Hope, Alaska. The repertoire defined six main call types: multi-part, flat, upsweeps, downsweeps, modulated, and single modulated calls. Flat calls have a linear contour; Upsweeps have an ascending call contour with a lower start frequency than end frequency; Downsweeps have a descending call contour with a higher start frequency than end frequency; Modulated calls refer to calls that have more than one inflection point (i.e. at least two modulations; and Single modulated calls are calls that have only one inflection point (Madrigal et al., 2021). The current study only focused on pulsed calls, not multi-part; therefore, that call category was not used in

180011049

any further analysis. To see if similar categorization is possible in the Bering Strait and the Chukchi Sea, reference contours from ARTwarp were manually organized into the five described call types.

2.6.Statistical Analysis

Descriptive statistical metrics were analyzed using SPSS (IBM, 2017), in which call incidence by location, year, and the month was examined. To understand whether the occurrence of all calls varied with location, year, and time of year (month), a general linear model was used. *Recorder* and *Year* were both included as factors, and *Month* was included as a continuous variable. To combat the issue of the two locations recording at different times, the data was aggregated by month and then merged back into the main data file.

$$\text{full model} = calls \sim recorder + year + month$$

For a more thorough comparison, the years 2009, 2010, and 2012 specifically were analyzed since calls were detected in the same months across both recorders. The same model was used as described above, just with the filtered set of data.

Due to the high number of calls found in 2017 and 2018 at mooring A3, calls in these two years were compared. They were analyzed using a general linear model to see if there was a relationship between year and number of calls recorded.

$$\text{full model} = calls \sim year + month$$

A general linear model was also used to further understand whether specific call types occurred more commonly at a specific location and/or time (year and/or month). Call category refers to the outputs generated from ARTwarp. *Year* and *Recorder* were both included as factors and

180011049

Month as a continuous variable. Since the two recorders sometimes varied in what months and years data was recorded, the data was aggregated by month and then merged back into the main data file.

$$\text{full model} = callcategory \sim recorder + year + month$$

ANOVA tests were run to assess variable significance for all described linear models. Model analysis was performed using R 4.0.3 programming language with base and "dplyr" packages (R Core Team, 2020; Wickham et al., 2008).

Averages of the time and frequency parameters of flat, downsweep, upsweep, modulated, and single modulated calls were respectively extracted. These were used to compare against those described in Madrigal *et al* (2021). Independent sample T-tests were used to compare the six variables examined in this study with those reported in those of the call types reported in Madrigal *et al* (2021).

3. Results

A total of 107 hours from 353 audio files collected in 2009, 2010, 2012, 2017, and 2018 were processed (Table 1). 1670 calls were annotated in RAVEN and given a quality rating of 1 (n=600) or 2 (n=1070). A singular call was detected at recorder A4. Because this recorder had so few calls, it was not included in further analysis. The interrater reliability for the raters was found to be Kappa = 0.77 ($p < .0.001$), suggesting the definitions for calls were sufficient in describing quality. 600 high-quality (quality 1) calls were extracted in PAMGuard using the ROCCA module for further analysis.

180011049

Table 1. Summary of the location of recorders, the years, and months where and when files were recorded. The number of calls initially annotated in RAVEN (quality 1 and 2 calls) and the number of calls extracted (quality 1) in PAMGuard using ROCCA corresponds to each recorder by year and month. The one call extracted from the A4 recorder is listed; however, it was not used in subsequent analysis.

Mooring	Location	Year	Month	Number of Calls Annotated (RAVEN)	Number of Calls Extracted (PAMGuard)
A2	65.8°N, 168.80°W	2009	September	12	2
			October	8	1
		2010	August	1	0
			September	188	58
			November	15	0

			Total	**1670**	**600**

3.1.Spatiotemporal distribution of all calls

The occurrence of killer whale calls at the two recorders was significantly dependent on month ($p<0.0005$) but not on recorder location ($p=1$) or year ($p=0.58$) ($F_{6,1662}=277.2$, $p<0.005$, adj $R^2=0.49$). Out of all 1669 calls, the most calls were annotated in the month of September (44.1%), followed by November (29.4%) (Figure 2). Even when separating call occurrence by the mooring, September had the most calls in both locations (A2: 85.2%; A3: 36.2%). When analyzing call occurrence during years where both moorings had recordings (2009, 2010, 2012) there were more calls are found at A2 (n=271) than A3 (n=215) (Figure 3). Within this subset,

180011049

year was a significant predictor of call occurrence ($F_{4,481}$=120.2, p<0.001, adj R^2=0.50). When analyzing call occurrence at mooring A3 in 2017 and 2018, more calls were recorded at the A3 mooring in 2018 (n=789) than in 2017 (n=394); however, this finding was not statistically significant ($F_{2,1180}$=592.5, p=0.181, adj R^2=0.50).

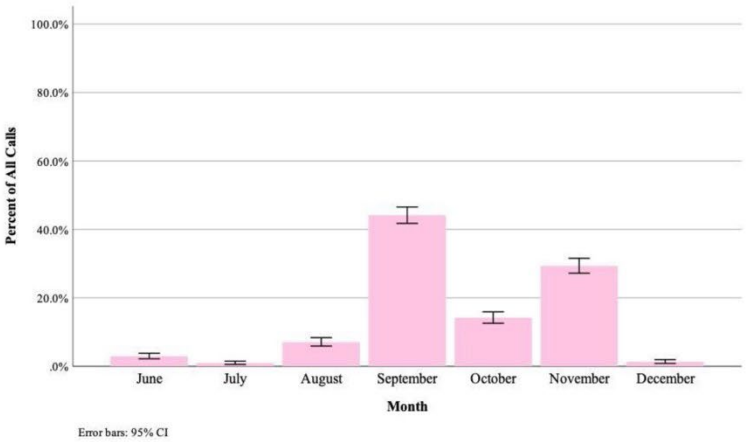

Figure 2. Percentage of overall call occurrence by month ± 2 standard error.

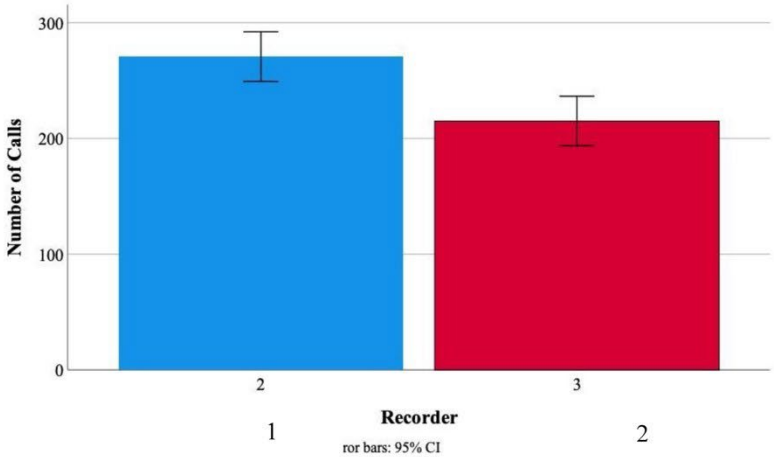

Figure 3. Total number of calls recorded at A2 mooring (blue) and A3 mooring (red) in 2009, 2010, and 2012 ± 2 standard error. $F_{4,481}$=120.2, p<0.001, adj R^2=0.50.

180011049

3.2. Categorizing Call Types

ARTwarp grouped the 600 traced calls into 29 types (Figure 4).

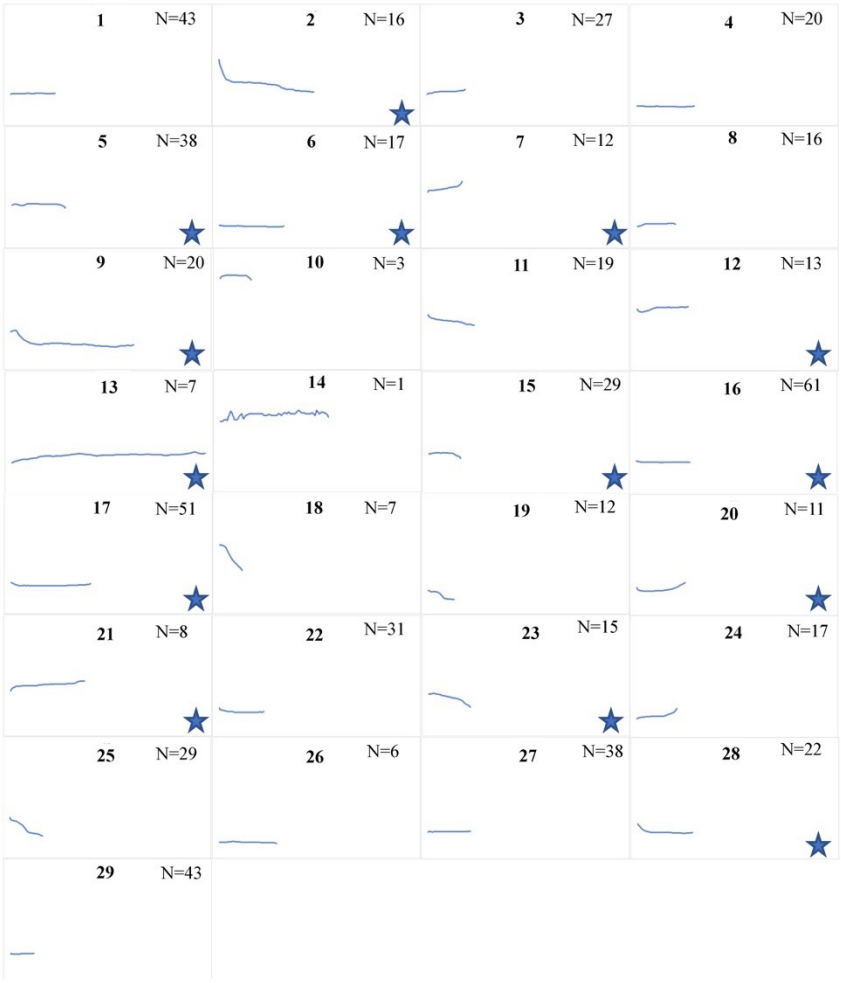

Figure 4. Reference contours of transient killer whale calls as outputted from ARTwarp. Time on the X-axis (0-19.6 seconds) and Frequency on the Y-axis (0-3600 Hz) are consistent for all plotted reference contours. N values refer to the number of calls that were sorted into each respective category. Stars indicate that call type was found at both A2 and A3 moorings.

All call types occurred at A3 whereas only call types 2, 5, 6, 7, 9, 12, 13, 15, 16, 17, 20, 21, 23, 28 occurred at A2 (Figure 4). Whether a certain call type is recorded is significantly

180011049

dependent on recorder location ($p<0.001$), month ($p<0.001$), and year ($p<0.001$) ($F_{6,593}=14.9$, $p<0.001$, adj $R^2=0.12$).

The four most common call types were 16 (n=61, 10.2% of calls), 17 (n=51, 8.5% of calls), 29 (n=43, 7.2% of calls), and 1 (n=43, 7.2% of calls) (Figure 5). Out of all calls found at recorder A2 (n=70), call 16 comprised 11.4% (n=8) and call 17 comprised 21.4% (n=15). Calls 1 and 29 were not detected at recorder A2. Out of all calls found at recorder A3 (n=530), call 16 made up 10% (n=53), call 17 made up 6.8% (n=36), call 1 made up 8.1% (n=43), and call 29 also made up 8.1% (n=43). Call 17 was the only one of these common calls recorded in every study year. Call 17 was recorded in September (n=28, 54.9% of all recordings of Call 17), October (n=5, 9.8%), and November (n=16, 31.3%). Call 16 was found in every study year except 2009. This call type was recorded in August (n=2, 3.2% of all recordings of Call 16), September (n=14, 22.9%), October (n=5, 8.2%), and November (n=40, 65.6%). Call 29 was found in 2010, 2017, and 2018. This call type was recorded in August (n=24, 55.8% of all recordings of call 29), September (n=15, 34.9%), and November (n=4, 9.3%). Call 1 was found in 2010, 2017, and 2018. This call type was recorded in September (n=6, 13.9% of all recordings of call type 1), October (n=5, 11.6%), and November (n=32, 74.4%).

180011049

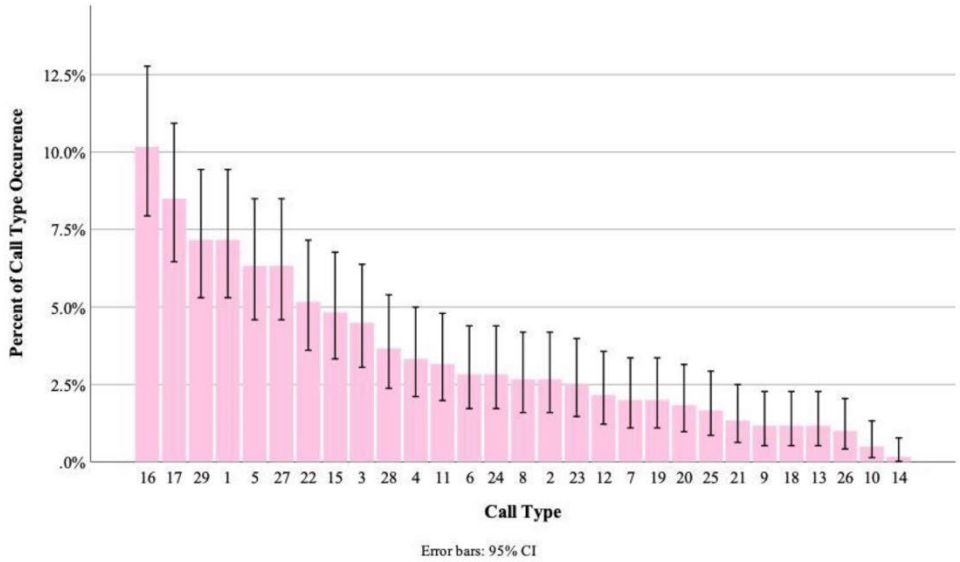

Figure 5. Percentage of overall call type occurrence ± 2 standard error. The x-axis is organized in ascending order from most common (Call 16, n=61, 10.2% of all calls) to least common (Call 14, n=1, 0.06% of all calls)

3.3.Call Types Comparison with Previous Literature

To compare the call structures of transient killer whales between the current study and Madrigal *et al* (2021), call types produced by ARTwarp were visually sorted into five broad call categories (flat, upsweep, downsweep, modulated, single modulated). Each broad category described contained several different ARTwarp reference contours that are referred to hereafter as subcategories. Table 2 shows the number of subcategories generated in the current study compared to Madrigal *et al* 2021.

180011049

Table 2. Comparison of the number of subcategories generated in the current study and those generated in Madrigal *et al* (2021).

	Current Study	Madrigal *et al* (2021)
Flat	9	6
Downsweep	6	4
Upsweep	8	6
Modulated	3	5
Single Modulation	3	2
Total	**29**	**23**

Similar to Madrigal *et al* (2021), flat calls were the most common call type described in the current study (n=310, 51.6%). However, the frequency parameters in the current study were different compared to Madrigal *et al* (2021) (Table 3). T-tests comparing the frequency and duration parameters of each call type between studies showed that most were significantly different from one another (Table 3). Upsweeps were similar to those described by Madrigal *et al* (2021), in which the only two significantly different variables were start frequency ($t(178)=-5.19$, $p<0.001$) and minimum frequency ($t(178)=-3.35$, $p<0.001$).

180011049

Table 3. Summary of variables measured in ROCCA (mean ± standard deviation). Rows in green correspond to measurements from Madrigal *et al* (2021). P-values from independent samples t-test are italicized and placed with respective call types.

Call Type	Duration (s)	Start Freq (Hz)	End Freq (Hz)	Maximum Freq (Hz)	Maximum Freq (Hz)	Freq Median (Hz)
Flat (n=310)	0.88 ± 0.55	940.30 ± 368.92	909.92 ± 362.53	790.4 ± 294.57	1057.55 ± 393.05	901.32 ± 325.56
Flat (n=485)	0.82 ± 0.36 *p=0.06*	728 ± 157 *p<0.01*	733 ± 169 *p<0.01*	666 ± 156 *p<0.01*	785 ± 166 *p<0.01*	724 ± 164 *p<0.01*
Downsweep (n=108)	0.86 ± 0.46	1365.04 ± 703.76	1014.52 ± 457.3	905.48 ± 436.23	1485.63 ± 667.88	1114.37 ± 495.99
Downsweep (n=175)	0.95 ± 0.40 *p=0.08*	859 ± 252 *p<0.01*	619 ± 170 *p<0.01*	588 ± 150 *p<0.01*	1006 ± 244 *p<0.01*	799 ± 167 *p<0.01*
Upsweep (n=88)	0.93 ± 0.57	1049.09 ± 536.35	1115.64 ± 606.11	898.91 ± 492.49	1257.09 ± 614.34	1043. 82 ± 538.28
Upsweep (n=92)	0.90 ± 0.52 *p=0.71*	738 ± 201 *p<0.01*	1133 ± 337 *p=0.81*	713 ± 196 *p<0.01*	1178 ± 326 *p=0.28*	958 ± 264 *p=0.17*
Modulated (n=46)	0.99 ± 0.58	1254.26 ± 471.15	1126.26 ± 291.54	976 ± 234.4	1464.35 ± 406.35	1228.52 ± 296.24
Modulated (n=60)	0.88 ± 0.34 *p=0.22*	738 ± 158 *p<0.01*	699 ± 298 *p<0.01*	574 ± 131 *p<0.01*	1067 ± 271 *p<0.01*	787 ± 178 *p<0.01*
Single Modulation (n=48)	0.69 ± 0.29	1142.67 ± 443.99	1067.33 ± 484.52	968 ± 412.95	1300 ± 483.04	1178.33 ± 427.17
Single Modulation (n=31)	0.45 ± 0.21 *p<0.01*	737 ± 178 *p<0.01*	789 ± 235 *p<0.01*	623 ± 168 *p<0.01*	953 ± 226 *p<0.01*	758 ± 201 *p<0.01*

In the current study, downsweeps were the most common call type at recorder A2 (n=26, 37.1%). Flat calls were the most common call type at recorder A3 (n=285, 53.8%). Flat calls were recorded in all years and months of the study. Downsweeps, upsweeps, and modulated calls were recorded every year except for 2009. The least recorded call type, single modulated calls, were recorded in 2009 (n=1), 2017 (n=13), and 2018 (n=34). All call types were recorded in September, October, and November at some point during the study period. Only flat, upsweeps, and single modulated calls were found in June or July.

180011049

4. Discussion

4.1.Call Occurrence

The first aim of this study was to use calls produced by transient killer whales to investigate their spatiotemporal distribution in the Bering Strait and the southern Chukchi Sea. The results presented here demonstrate that calls vary significantly by month but not necessarily by location or year. Aside from 2010, September contained the greatest number of calls in general and within each recorder location. These findings are consistent with sighting data of transient killer whales in the Chukchi Sea, where the highest number of detection days was also in September (Hannay et al., 2013).

In the current study, the location was hypothesized to have a significant effect on call occurrence because of the placement of recorders with respect to relative environmental factors. The Bering Strait is divided into two channels by the Diomede Islands, roughly mid-strait. The western channel is cold, salty, and comparatively more productive than the eastern channel, which tends to be warmer and contains fresher water (Escajeda et al., 2020). In terms of mooring location, A2 is located in the centre of the strait but on the eastern side of the channel, whereas A3 is located ~35 km north of the centre of the strait. Recorder A4 was located further into the eastern channel right in the Antarctic Coastal Current, which is known to be less productive and therefore, it was expected that there would be fewer calls at this location (Escajeda et al., 2020). It was also expected that the A2 mooring would have fewer calls because it is on the slightly less productive side of the channel than the A3 mooring, which had the potential of recording killer whales passing through both channels in the strait. Despite predicting that location would have a significant effect on call occurrence, it did not. A possible reason for this lack of significance could be attributed to the recorders' distance from one another. The recorders are approximately

180011049

57 km from one another, which is within the average maximum distance transients can travel in a straight line each day (95 km/day) (Parsons et al., 2013).

Despite year not being a significant variable in the model, it is worth noting the difference in the number of calls recorded in November in 2017 and 2018. Roughly eight times as many calls were recorded in November 2018 compared to November 2017. Additionally, when undergoing initial spectral analysis in RAVEN, 2018 contained numerous calls that were too messy (overlapping and background noise) to allow for further selection. Nonetheless, since transients do not vocalize often, these finding highlights that there may have been a greater number of transients in the area (Deecke et al., 2005). Further, it is likely that transient killer whale presence is still underrepresented in this region. They are likely underrepresented because of their calling behaviour (or lack thereof), the nature of duty-cycled recorders, and since there was no moored recorder in the western (more productive) channel in the Bering Strait if a transient travelled through this path, then any calls would not have been recorded (Deecke et al., 2005; Rand et al., 2022; Escajeda et al., 2020).

Even so, this study suggests that there is an apparent increase in transients in the Bering Strait and the southern Chukchi Sea in November. A possible explanation for this could be that 2018 had the lowest levels of sea ice concentration on record, meaning the longest ice-free season (Hansen, 2018; Jones et al., 2020). Transients have previously avoided these regions, except in the summer months, because of the heavy concentrations of sea ice posing a risk for ice entrapment and damage to their sizeable dorsal fine (Stafford et al., 2022; Ferguson et al., 2010). So, while transients were historically barred from months during the ‘freeze-up’ period in the Bering/Chukchi Seas, that is potentially no longer the case. The decline in sea ice is not unique to 2018. The Arctic is warming twice that of the global rate creating a range of cascading

180011049

ecological effects, with one of the biggest being a decline in sea ice (Grebmeier, 2012). While negative for many endemic Arctic species, transients are expected to benefit from this reduction in sea ice by exploiting these highly productive regions for longer periods of time (Moore and Huntington, 2008).

This idea has been supported by recent studies where there is a reported increase in transient killer whale sightings in the Bering, Chukchi, and Beaufort seas (Hannay et al., 2013; Clarke et al., 2013; Stafford, 2019). Killer whales moving to these more northerly areas affects ecological dynamics, specifically predator-prey relations. Many endemic Arctic marine mammal species are already quite limited in their ability to cope with the changing climate due to their narrow home ranges and reliance on sea ice for foraging or predator avoidance tactics (Moore and Huntington, 2008; Laidre et al., 2008; Ferguson et al., 2010). The combination of this heightened sensitivity to climate change and the increased presence of a mammal-eating killer whale puts these animals at risk. This phenomenon is more well understood in the Canadian Arctic, where it has been suggested that endemic Arctic species like the narwhals (*Monodon monoceros*), belugas (*Delphinapterus leucas*), and bowhead whales (*Balaena mysticetus*) all alter their behaviour in the presence of killer whales (Matthews et al., 2020). While the implications of killer whale expansion are less well understood in the Pacific Arctic, there is preliminary evidence to suggest that there damaging effects. For example, there is a suspected correlation between an increase in scars on Bowhead Whales in the Bering/Chukchi/Beaufort seas and an increase in killer whales in this area (George et al., 2017). Overall, even though this evidence suggests that transients are moving towards the Bering and Chukchi Seas, it does not explain what population of transients are undergoing this transition.

180011049

4.2.Regional Repertoire

The next objective of this study was to develop a call repertoire of transients in the Bering Strait and the southern Chukchi Sea. The population structure of transients in this area is not well understood, and therefore this call repertoire was then used to attempt to understand what population is found in the Bering Strait and the Chukchi Sea. To achieve this, the described call repertoire was used to examine whether there are similarities in calls between transients in different areas. The current study described a repertoire of 29 different call types. Results from the current study indicate that location, month, and year all influence the occurrence of a specific call type. Different clans of transients travelling through the Bering Strait at different times (yearly or monthly) and following different paths is a plausible explanation for why there is a significant difference in where and when a call type occurs. As suggested above, it is thought that the number of transients found in the Bering and Chukchi Seas is increasing (Hannay et al., 2013; Clarke et al., 2013; Stafford, 2019). Since the Bering Strait is the only connector between the Pacific and the Arctic Ocean, any transient killer whale wanting to move to these colder, more productive waters needs to travel through this passage. It is likely that if different clans of transients are travelling north, they are not all travelling at the same time. Since clans all produce distinct vocal dialects, different travel times and patterns could explain the significance of year, month, and recorder location on call type occurrence. A potential subpopulation moving through the Bering Strait is the Aleutian Islands transient population.

Preliminary satellite telemetry data suggest that it was the Aleutian Island transient population spotted near the edge of the Chukchi and Beaufort Seas (Hannay et al., 2013). However, studies have shown that even within the Aleutian Islands transient population, there are genetic and acoustic differences and, therefore, should be broken down into more

subpopulations (Parsons et al., 2013; Sharpe et al., 2017). This further subdivision of the Aleutian Island subpopulation supports the notion that it is multiple subpopulations travelling through the Bering Strait, which is why different call types are produced at different times and locations.

4.3.Methodological Discrepancies when Comparing to Previous Literature

Within the call categories from ARTwarp, five more broad call type categories were designated: downsweeps, flat, upsweeps, modulated, and single modulation. These categories were taken from Madrigal *et al* (2021), in which the authors defined a repertoire of 6 call categories with 36 subcategories, but since this included multi-part calls, for the purposes of this comparison Madrigal *et al* (2021) defined five call categories with 23 subcategories. The current study produced these five call categories, and the subcategories for this were the initial call categories as outputted in ARTwarp. In the current study, the most common call types were Flat calls and Downsweeps. Similarly, the most common call types in Madrigal *et al* (2021) were Flat calls and Downsweeps. Visual comparison and similar variables were chosen to analyze through ROCCA, which allowed for comparability of these transient repertoires; however, the actual classification methodology for determining call categories was quite different. In the study by Madrigal *et al* (2021), the first step of categorical assignment involved manual categorization into broad categories. Then, a hierarchical cluster in R was used to generate subcategories. Contrastingly, the first step of the category assignment in the current study used ARTwarp. Outputs were then manually sorted into the five call categories described by Madrigal *et al* (2021) to assess potential similarities.

Although the comparisons of these two studies yielded visual similarity, the statistical similarity was lacking. The only broad call type that had more statistical similarity than

180011049

difference was upsweeps (appendix). Despite a few different studies exploring the repertoires of transient killer whales, this study was only able to compare to Madrigal *et al* (2021) due to the type of frequency parameters extracted. Sautilus *et al* (2005) examined the vocal repertoire of the AT1 transient population using duration (ms), whistle component frequency (Hz) and frequency intervals between sidebands (Hz). Sharpe *et al* (2017) described the vocal repertoire of three subpopulations of transients within the Gulf of Alaska stock: Pribolif Island, Western Aleutian Island, and Eastern and Central Aleutian Islands. However, frequency parameters for described call types were not reported, and therefore there was a limited possibility to draw meaningful comparisons. Similarly, Deecke (2003) described a repertoire for West Coast transients, but frequency parameters were not definitively reported. This lack of standardized methodology raises the question as to whether some of these subpopulations actually have different repertoires or do these studies define repertoire differently. The lack of standardized methodology in defining Cetacea repertoires makes it difficult to both compare results from previous studies and add to existing data. Having a consistent methodology is of particular importance for this study to identify the population of transients travelling through the Bering Strait. It is difficult to discern both the origins and relevant differences of these transient killer whales without standardised methodology.

4.4.Conclusion

The current study examined transient killer whale call occurrence in the Bering and the southern Chukchi Sea to further understand the expected change in the spatiotemporal distribution of these animals. In addition, this study was the first to describe an acoustic repertoire for transients in the Bering Strait and the Chukchi Sea in an attempt to begin to understand their population structure. While the findings from this study do provide a solid

baseline, there are still many unknown elements. Despite an increase in survey effort in the Bering and Chukchi Seas regarding the northerly expansion of transient killer whales, the population structure of transients in this area is still not well described. The most straightforward way to begin to understand the population structure in this region is to develop a sound methodology for defining a vocal repertoire in this region. This methodology does not need but be novel but instead can adapt previously successful methods used in defining bird repertoires and apply similar principles to killer whale repertoires. For example, a study examining the effectiveness of the 'Coupon Collector' method as a way to define killer whale repertoires would allow for studies to take full advantage of the effective nature of passive acoustic monitoring. The 'Coupon Collector' method is a model of signal occurrence which has proven successful in providing an accurate indication of true repertoire size in certain bird species such as the northern mockingbird (*Mimus polyglottos*) (Kershenbaum et al., 2015). Once a standardized methodology is implemented, analyses conducted on passive acoustic recordings can be compared effectively and combined to yield more significant results. In addition, since subpopulations of killer whales also tend to vary genetically and morphologically, it is necessary to conduct intensive genetic analysis in photoID better to understand the population structure of transients in this area. With the Arctic warming rapidly, understanding the population structure of transients is necessary to understand the potential ecological implications in this region.

Contents

Executive Summary

The well-being of Arctic communities is a vital part of U.S. Arctic policy. Understanding the relationships between coastal residents and the marine environment is an essential contribution to the effective management of Arctic marine resources and activities that affect those communities and resources. In the context of the Arctic Integrated Ecosystem Research Program (Arctic IERP), the Chukchi Coastal Communities component focused on Arctic Indigenous community understanding of and response to ecosystem changes being studied by other components of the Arctic IERP. We examined how ecosystem changes affect communities, and we made available to other Arctic IERP researchers an annotated bibliography of information that had already been documented from Arctic Indigenous coastal communities about ecosystem change in their region. Together, these efforts helped connect the overall work of the Arctic IERP with the interests and concerns of coastal communities in the region.

Our project explored the nature of human-environment relationships in the region by compiling what has already been documented about local, Traditional, and Indigenous knowledges of the Chukchi Sea ecosystem and the changes it is undergoing, and by examining collaboratively with a team of experienced coastal residents the responses of coastal communities to variability and change. Our findings illuminate how and why a changing ecosystem matters to coastal communities, and provide insights into the ways communities can respond effectively to changes that are beyond their control. The compilation of information and knowledge in the annotated bibliography provided information relevant to the overarching questions of the Arctic IERP and many of the specific questions that were addressed by the other projects that were funded. Our project addressed four specific questions:

- What are local people's perceptions of the natural physical and ecological drivers of changes in the availability of animals for subsistence harvest?
- What are the primary drivers (natural, social, cultural, economic) of shifts in subsistence use patterns?
- Have shifts in harvest patterns affected food security and, if so, how?
- How resilient are human communities to variability, anomalies, and shifts in the marine environment?

Our project's activities centered on meetings of the research team, including members of eight coastal communities. The communities involved were Savoonga, Diomede, Buckland, Kotzebue, Kivalina, Point Hope, Point Lay, and Utqiaġvik.

The Chukchi Coastal Communities component produced one scientific paper on its own, reporting the results of its research. This paper was published in the *Arctic* in June 2021. The main message of this paper is that traditional values and Indigenous leadership are essential for addressing the intertwined effects of social and environmental change in the region.

The PI of the Chukchi Coastal Communities component also led a group effort across the Arctic IERP that resulted in a paper published in *Nature Climate Change* in February 2020. The main message of this paper is that the northern Bering Sea-Chukchi Sea ecosystem is rapidly transforming.

Rapid environmental change, such as that found by the studies in the Arctic IERP, poses considerable challenges to resource management and to coastal community well-being. In terms of resource management, our findings show also that regional human activity causes environmental change in addition to larger processes such as a warming global climate. Resource management needs to take into account the combined effects of various forms of change and disturbance. Still, more work is needed to understand the complex interactions that create outcomes, especially in a time when widespread environmental change is happening even more rapidly than was expected when the Arctic IERP began.

For coastal communities, our findings reflect much of what their residents have already experienced. Sharing of information among the eight communities involved in our project was valuable in helping team members see the extent and type of change occurring throughout the region. Societal change cannot be separated from environmental change when it comes to community-level effects and responses. Key conclusions of the Chukchi Coastal Communities component are that traditional values remain essential to community well-being and that Indigenous leadership is necessary for responding to change in ways that will sustain overall community well-being (as defined by communities). An additional point is that equitable partnerships with scientists can help provide valuable information to communities as they determine how best to respond to change, and provide important information to the broader science community.

Preamble

The Arctic Integrated Ecosystem Research Program

The Arctic Integrated Ecosystem Research Program (Arctic IERP, 2016-2021) was motivated by the rapid changes occurring in the waters of the northern Bering and Chukchi Seas. While much research has been done in the region, many important questions remain. As a cohesive research endeavor, the Arctic IERP was designed to address a single, overarching question:

How will reductions in Arctic sea ice and the associated changes in the physical environmental influence the flow of energy through the ecosystem in the Chukchi Sea?

The report you are reading now is one of five final reports from the fieldwork phase of the Arctic IERP (a synthesis phase was initiated in 2022 after the completion of the Arctic IERP field-based projects). This preamble provides a brief overview of the Arctic IERP, both to place each final report in the broader context of the whole program, and to encourage readers to examine the other final reports to learn more about the research that was done. More detailed information about the Arctic IERP can be found at https://www.nprb.org/arctic-program.

The spatial domain of interest for the Arctic IERP extended across the Chukchi Sea Large Marine Ecosystem (LME) as redefined by the Arctic Council's Protection of the Arctic Marine Environment (PAME) working group, and the northern Bering Sea (above 61.5° N) as it strongly influences dynamics in the Chukchi Sea from the upstream direction. The main focus has been on the greater Bering Strait region and the Chukchi Sea. The program included the Arctic Basin and Beaufort Sea insofar as processes in the Chukchi Sea are influenced by these adjacent areas.

Development of the Arctic IERP

Before any Arctic IERP research proposals were written, the NPRB administered an assessment program, the Pacific Marine Arctic Regional Synthesis (PACMARS; https://www.nprb.org/assets/uploads/files/Arctic/PacMARS_Final_Report_forweb.pdf), that applied $1.5M provided by Shell and ConocoPhillips to compile and synthesize existing information about the ecosystem and inform research priorities. This assessment included community meetings in 2013 in Savoonga, Gambell, Kotzebue, Nome, and Barrow (now Utqiaġvik), in which representatives from 17 communities between St. Lawrence Island in the Bering Sea and Barter Island in the Beaufort Sea participated. One major area of emphasis that emerged from these community meetings was concern about food security for the region's residents in light of the rapid environmental changes taking place. Results from the scientific assessment and input provided via the community meetings informed the creation of the Arctic IERP. The PACMARS report informed both the IERP Request for Proposals (https://www.nprb.org/arctic-program/request-for-proposals/) and the submitted proposals.

Following a proposal review process, the Arctic IERP formally began in 2016 with funding from the North Pacific Research Board (NPRB), the Collaborative Alaskan Arctic Studies Program (formerly the North Slope Borough/Shell Baseline Studies Program), the Bureau of Ocean Energy Management (BOEM), and the Office of Naval Research (ONR) Marine Mammals and Biology Program. Generous in-kind support was contributed by the National Oceanic and Atmospheric Administration (NOAA), the University of Alaska Fairbanks (UAF), the U.S. Fish & Wildlife Service (USFWS), and the National

Science Foundation (NSF). This coordinated program was developed in cooperation with the Interagency Arctic Research Policy Committee (IARPC) and the U.S. Arctic Research Commission.

The Research

The Arctic Integrated Ecosystem Research Program (IERP) invested approximately $18.6 million in studying marine processes in the northern Bering and Chukchi Seas in 2017-2021, beginning in the summer of 2017. The research was divided into three main, complementary projects. The Arctic Shelf Growth, Advection, Respiration, and Deposition Rate Experiments (ASGARD) project carried out research in late spring and early summer of 2017 and 2018 aboard R/V *Sikuliaq*. The Arctic Integrated Ecosystem Survey (Arctic IES) conducted fieldwork aboard R/V *Ocean Starr* in late summer and early fall 2017 and 2019. In addition to the vessel-based surveys, sub-surface moored sensors were deployed to gather biophysical information continuously from June 2017 to September 2019 and autonomous platforms were brought to bear (e.g., gliders, saildrones, air-deployed profilers).

In addition to the vessel-based work, a team of Arctic residents and social scientists, including members from eight communities in the North Slope and Northwest Arctic Boroughs and the Bering Strait region, met several times during the project to assess and analyze Indigenous observations and experiences with various types of change occurring in the region from Savoonga to Utqiaġvik. This group also compiled an annotated bibliography of Traditional Knowledge or Indigenous Knowledge (available through the data portal described below), to help researchers from other components of the Arctic IERP find information relevant to their studies.

Prior to the commencement of fieldwork, meetings were held in the three hub communities of Nome, Kotzebue, and Utqiaġvik. Scientists from the Arctic IERP and NPRB staff met with community members from each region to discuss the research purpose and plans. Research plans were also shared and discussed at meetings of the Alaska Eskimo Whaling Commission (AEWC), the Indigenous Peoples Council for Marine Mammals (IPCoMM), and with the Tribal Councils of Gambell and Savoonga on St. Lawrence Island. One result of these meetings was a shift in timing of the ASGARD cruises from May until June as well as a shift in timing and survey regions for the Arctic IES cruises, to avoid conflicts with subsistence hunting activities during what is traditionally the time for walrus hunting. Another result was the creation of communication protocols to avoid conflicts by alerting coastal communities to the presence of research vessels and adjusting the ships' routes to avoid areas where hunting was taking place. These communication protocols included regular radio broadcasts and daily emails to community members throughout the research area.

Results from the research are published in a growing list of peer-review journal articles, as well as cruise reports that provide contemporary accounts of the cruises, and many social media postings that are available through the NPRB website. Data are publicly available as described below.

Collaborations

The NPRB collaborated and coordinated with several other U.S. agencies and organizations that fund Arctic marine research. NPRB staff worked closely with the U.S. Interagency Arctic Research Policy Committee (IARPC) and the U.S. Arctic Research Commission. As the Arctic IERP was developed, the

NPRB secured commitments for collaboration from 22 existing research projects that were detailed in Appendix A of the request for proposals, and made connections with new projects as they were funded.

International researchers also collaborated with the Arctic IERP via the Pacific Arctic Group (PAG), the North Pacific Marine Science Organization (PICES), and the Intergovernmental Consultative Committee (US/Russia - bilateral) as well as collaborations developed by individual investigators. PAG participants, including researchers from Canada, China, Japan, Korea, Russia, and the United States, have coordinated their cruise plans to sample standard stations in the Chukchi and Beaufort Seas termed the Distributed Biological Observatory (DBO). The Arctic IERP contributed to this effort. US-Russian data sharing initiatives were hosted in San Diego in 2016 and Vladivostok in 2017 to promote collaboration and exchange and to facilitate collaboration and synthesis of data and trends of patterns observed in the US and Russian waters in the northern Bering and Chukchi seas (PICES Press, Volume 26, Issue 1). ICC collaborations and other connections also brought scientists from the Russian Federal Research Institute of Fisheries and Oceanography (VNIRO), the Russian Pacific Scientific Fisheries Research Center (TINRO), and Hokkaido University to the US to participate in the Arctic IES cruises and co-author results. This collaboration is expected to connect research interests within respective EEZs (Russia/US) of the Chukchi Sea.

COVID-19

While the fieldwork of the Arctic IERP was completed before the outbreak of COVID-19, the final meeting of researchers in November 2020 was changed from an in-person event to an online format. Other plans for in-person events, such as meetings in hub communities within the US Arctic region (Nome, Kotzebue, and Utqiaġvik), were cancelled. Laboratory work and some collaborations were postponed or cancelled due to COVID-related restrictions and concerns. The NPRB made supplemental funds available to assist researchers with unanticipated expenses due to the pandemic. The overall productivity of the Arctic IERP was likely not greatly reduced, due both to good fortune in the fieldwork being completed and to the collaborative relationships that had been built or strengthened during the program.

Data Portal

Axiom Data Science, Inc. provided data management support to the Arctic IERP throughout the field program. Axiom staff assisted the scientists in authoring metadata and publishing the datasets to public archives. The data collected by the Arctic IERP are publicly accessible at https://arctic-ierp.dataportal.nprb.org/.

General Introduction

The well-being of Arctic communities is a vital part of U.S. Arctic policy (e.g., Obama 2013). Understanding the relationships between coastal residents and the marine environment is an essential contribution to the effective management of Arctic marine resources and activities that affect those communities and resources (e.g., BOEM 2014). In the context of the Arctic Integrated Ecosystem Research Program (Arctic IERP), the Chukchi Coastal Communities component focused on Arctic Indigenous community understanding of and response to ecosystem changes being studied by other components of the Arctic IERP. The intent was two-fold. First, we examined how ecosystem changes affect communities, especially in the context of other forms of change that they are experiencing at the same time, such as economic, cultural, and social changes. Second, we compiled and made available to other Arctic IERP researchers an annotated bibliography of information that had already been documented from Arctic Indigenous coastal communities about ecosystem change in their region, to make sure that information was considered along with instrumental and other scientific data. Together, these efforts helped connect the overall work of the Arctic IERP with the interests and concerns of coastal communities in the region.

Our project explored the nature of human-environment relationships in the region by compiling what has already been documented about local, Traditional, and Indigenous knowledges (LTK; NPRB 2005) of the Chukchi Sea ecosystem and the changes it is undergoing, and by examining collaboratively with a team of experienced coastal residents the responses of coastal communities to variability and change. Our findings illuminate how and why a changing ecosystem matters to coastal communities, and provide insights into the ways communities can respond effectively to changes that are beyond their control. The compilation of information and knowledge in the annotated bibliography provided information relevant to the overarching questions of the Arctic IERP and many of the specific questions that were addressed by the other projects that were funded. Our project addressed specific questions as follows:

What are local people's perceptions of the natural physical and ecological drivers of changes in the availability of animals for subsistence harvest?
We examined what has been documented already (e.g., ADF&G, N.D., Huntington et al. 1999, 2016, George et al. 2004, Braund 2013. Oceana and Kawerak 2014. B. Raymond-Yakoubian et al. 2014. J. Raymond-Yakoubian et al. 2014, Gadamus and Raymond-Yakoubian 2015a,b, Gadamus et al. 2015, the Northwest Arctic Borough subsistence mapping project, unpublished NSB work, Kawerak archives, UAF's Project Jukebox), emphasizing the region from St. Lawrence Island to Utqiaġvik. (The inclusion of St. Lawrence Island, in accordance with the Arctic RFP's scope, created an overlap with the five communities that were involved in the LTK component of the Bering Sea Project, of which Savoonga was the northernmost (Huntington et al. 2013a, b, c).) We additionally addressed specific questions or topics identified in collaboration with and via a survey of other Arctic Program PIs to better provide relevant information and create a foundation for collaborative analysis.

What are the primary drivers (natural, social, cultural, economic) of shifts in subsistence use patterns?
Have shifts in harvest patterns affected food security and, if so, how?
The review of existing information allowed us to address these questions. Of particular interest was a comparison with Bering Sea Project findings that indicated strong connections between communities and the ecosystem, in the sense of high subsistence production and powerful spiritual significance of the human-ecosystem relationship, but weak coupling in the sense that human activities and outcomes do not appear to respond rapidly and directly to environmental changes (Haynie and Huntington

2016). It is important to understand both the social system (culture, economics, policies, technology, regulations) and the ecosystem so as to understand how environmental change is moderated by the social system to produce effects and responses in coastal communities. While there was no doubt that environmental change affects coastal communities, the exact nature of the mechanisms of such change were not well understood. The concept of food security (Council of Canadian Academies 2014, ICC-Alaska 2014a, b, 2015) provided a useful framework for seeing the interplay of these factors.

How resilient are human communities to variability, anomalies, and shifts in the marine environment?
If coastal communities were unable to cope with variability, they could not have persisted as they have for decades, centuries, and millennia (e.g., Rainey 1947). Most research to date has examined the nature of changes in the environment (e.g., Cochran et al. 2013), rather than also considering the social system in which those environmental changes act (Haynie and Huntington 2016). We examined more carefully the mechanisms by which communities take advantage of favorable conditions and adjust to unfavorable ones. It is important to note in this context that change is not necessarily disadvantageous, although most assessments of change emphasize negative outcomes rather than new opportunities (cf. Noongwook et al. 2007, Huntington et al. 2017).

Our project's activities centered on meetings of the research team, including members of eight coastal communities. The communities involved were Savoonga, Diomede, Buckland, Kotzebue, Kivalina, Point Hope, Point Lay, and Utqiaġvik. The meetings were held in conjunction with the Arctic IERP's Principal Investigator (PI) meetings, in March 2017, March 2018, and January 2020. All of these were in Anchorage, Alaska. Project staff from Kawerak Inc. in Nome, Alaska, compiled an annotated bibliography of sources of LTK from the region, which was shared with all participants in the Arctic IERP.

The Chukchi Coastal Communities component produced one scientific paper on its own, reporting the results of its research. This paper was published in the *Arctic* in June 2021. The main message of this paper is that practicing traditional values and Indigenous leadership are essential for addressing the intertwined effects of social and environmental change in the region. This paper addresses all three of our research questions.

The PI of the Chukchi Coastal Communities component also led a group effort across the Arctic IERP that resulted in a paper published in *Nature Climate Change* in February 2020. The main message of this paper is that the northern Bering Sea-Chukchi Sea ecosystem is rapidly transforming. This paper went beyond the research questions addressed by our component of the Arctic IERP.

The accepted manuscripts are included as chapters of this final report. Publication details are provided in the appropriate section of this report.

Results of the Chukchi Coastal Communities component

This chapter presents the findings of the Chukchi Coastal Communities component, as reported in a paper published in Arctic *in June 2021. This chapter consists of the accepted manuscript for the paper. Note that the published manuscript was subject to copy editing and other changes. Full details of the publication can be found in the appropriate section of this report, below.*

"We never get stuck": a collaborative analysis of change and coastal community subsistence practices in the northern Bering and Chukchi Seas, Alaska

Abstract
The Indigenous communities of the northern Bering and Chukchi Sea are experiencing extensive social, economic, and technological change. The region's marine ecosystem is also characterized by a high degree of variability and by rapid change. Residents of eight coastal communities from Savoonga to Utqiaġvik were involved in the Chukchi Coastal Communities Project, which used the results of a literature review together with the experiences of the community participants to co-analyze what is known about societal and environmental change in the region and what the communities' experiences have been in responding to those changes. Some of the observed changes are transient in duration and effect, such as the passage of an individual ship, whereas others, such as the creation of the Red Dog Mine Port Site, persist and may force lasting changes by coastal residents. Some responses can use existing knowledge, for example hunting bowhead whales in fall as well as spring, whereas others may require learning and experimentation, such as harvesting new species such as the Hanasaki crab. Our findings show that the results of a change are more important than the source of the change. They also emphasize the continuing importance of traditional values and practices as well as attitudes conducive to persistence and innovation. Indigenous leadership is an essential component of continued resilience as the ecosystem continues to change. The resilient characteristics of coastal communities, and their ability to determine their own responses to change, need greater attention, to match the research effort directed at understanding the ecosystem.

Key Words:
Chukchi Sea, Bering Sea, Iñupiaq, St. Lawrence Island Yupik, subsistence, response

Introduction

Subsistence activities, which include traditional hunting, fishing, and gathering practices, provide vital cultural, nutritional, economic, social, and spiritual benefits to Indigenous residents of the northern Bering Sea and Chukchi Sea coast of western and northern Alaska (ICC-Alaska, 2015; Raymond-Yakoubian, 2019). In recent years, much attention has been given to the effects of climate change on subsistence and other aspects of Indigenous community life in Alaska and elsewhere (e.g., Fall et al., 2013; Gadamus, 2013; Pearce et al., 2015). At the same time, community members and researchers both recognize that subsistence practitioners have long dealt with considerable environmental variability on time scales from hours to decades (Kapsch et al., 2010; Huntington et al., 2013a). In addition to environmental considerations, subsistence practices have been affected by social, economic, regulatory, technological, and other forms of change (Kersey, 2011; Raymond-Yakoubian, 2013; Moerlein and Carothers, 2012; Huntington and Eerkes-Medrano, 2017). These societal shifts have affected both the demand for subsistence foods and the ability to procure those foods (Fall et al., 2013). For example, modern hunting equipment facilitates access but requires money for purchase, maintenance, and operation, which can limit participation for those with limited access to cash. While negative effects on subsistence get much attention and for good reason, the various changes communities have experienced have also had positive effects (e.g., Noongwook et al., 2007; Huntington et al., 2017a), in part due to the ability of communities to adjust where possible and to take advantage of opportunities.

That ability to adjust and to find and create opportunities is an essential attitude in an environment characterized by variability, as is the case for the northern Bering and Chukchi Sea marine ecosystem (e.g., Moore et al., 2018; Huntington et al., 2020). Weather and sea ice conditions can change within hours and can vary greatly from year to year. The harvest of marine mammals, seabirds, and fish in coastal communities also varies from year to year (e.g., Fall et al., 2013). If the Iñupiat and St. Lawrence Island Yupik of Alaska's western and northern coasts were unable to cope with that variability, their communities could not have persisted (e.g., Hovelsrud and Smit, 2010). This is not to say that such strategies are always effective. In both oral history and the archeological record, there is abundant evidence of the abandonment of settlements and shifts in subsistence patterns and technology (e.g., Mason and Gerlach, 1995). Nonetheless, the application of knowledge and skills to changing conditions, also described as adaptations to change, have been described in a number of papers. Thornton and Manasfi (2010), for example, define eight modes of adaptation, such as mobility and diversification. In addition, Walker and Salt (2012) describe societal characteristics or attitudes that promote adaptive responses, such as openness and diversity. Huntington et al. (2017a) examine how communities are able to respond to change, autonomously or in collaboration with others outside the community. Amid current concerns about the effects of climate change on the Arctic and its residents (e.g., Brinkman et al., 2016), the question of how coastal residents respond to change is ever more pertinent, deserving of detailed attention at the community level.

Our study started from the premise that much has already been documented about Indigenous observations of, experiences with, and responses to variability and change in this region. Rather than engage in another effort to interview community residents, we elected to engage community-identified experts in a co-analysis of the existing information. This approach is part of a shift in the role of community participants from providers of information to interpreters of information, and part of a wider movement towards meaningful collaborations, Indigenous leadership in research, and the co-production of knowledge, a paradigm emphasizing the need to work together from start to finish in research projects (Lemos and Morehouse, 2005; Bartlett et al., 2012; Meadow et al., 2015; Whyte, 2017; David-Chaves and Gavin, 2018; Peltier, 2018; Kirby et al., 2019). The aim of the study and of this paper therefore is not to generate or report new observations and basic information, but to take a new look at what is already on record, to better understand the meanings and implications of that existing information from the perspective of Indigenous communities.

Our project had two questions in mind. First, do different types of change manifest themselves in different ways, for example in the time scale on which they operate, and do they have demonstrable effects on subsistence outcomes? Climate change and other modes of change such as the effects of industrialization or commercial fishing are often regarded as a major influence on subsistence practices (e.g., Cochran et al., 2013; Brinkman et al., 2016). We seek evidence to support that oft-repeated assertion.

Second, what strategies are used by Iñupiaq and St. Lawrence Island Yupik residents of Alaska's northern Bering and Chukchi Sea coasts? If the strategies being used are likely to be effective in light of continued change to the ecosystem, it will be important to support the use of those strategies. If the strategies are unlikely to continue to be effective, it will be important to recognize their shortcomings and for coastal communities to develop alternatives. We conclude by considering the context in which environmental change affects the region's communities and its implications for the future well-being of those communities.

Figure 1: Map of the region showing the communities with experts on the project team.

The study area for this project extends from St. Lawrence Island in the northern Bering Sea to Utqiaġvik at the edge of the Chukchi and Beaufort Seas (Figure 1). There are over a dozen Alaska Native communities along the coast or close enough to the coast to use the marine environment for subsistence. Of these, we selected nine communities to be invited to join the project, based on their connections to the sea, their participation in previous collaborative research efforts of this type, and their willingness to take part. Eight were able to accept: Savoonga (2019 population est. 735; Alaska Department of Labor, 2020), Diomede (97), Buckland (509), Kotzebue (3,112), Kivalina (427), Point Hope (670), Point Lay (236), and Utqiaġvik (4,536; formerly known as Barrow). The participant chosen by the ninth community was unable to attend due to schedule conflicts and no substitute could be arranged. The communities are Iñupiaq and St. Lawrence Island Yupik, referred to collectively here as the "Chukchi coastal communities."

Methods

Our work (the Chukchi Coastal Communities Project) is part of the North Pacific Research Board's Arctic Integrated Ecosystem Research Program (Arctic IERP; http://www.nprb.org/arctic-program/about-the-program/). The Arctic IERP includes several projects spanning physical oceanography to social

science, in an effort to consider the Chukchi Sea ecosystem and the implications of the environmental changes taking place in the region. The scope of the Arctic IERP was shaped in part by previous efforts to engage coastal communities in the planning and conduct of Arctic research (Grebmeier, 2014). The Chukchi Coastal Communities Project examines the ways environmental changes affect the Iñupiaq and St. Lawrence Island Yupik communities along the Chukchi Sea coast of Alaska, and also seeks to make available their observations of change in order to contribute to the program's collective understanding of what is happening in the region's marine environment.

Recognizing that Alaska Native communities have been the subject of extensive research concerning subsistence and environmental change (among many other topics; see for example Cochran et al., 2013 and references therein; Raymond-Yakoubian and Raymond-Yakoubian 2017), the Chukchi Coastal Communities Project does not include primary research, such as interviews, in the communities. We instead conducted a literature review of publications relevant to Chukchi coastal communities and their role in the marine ecosystem. We found 248 publications, including articles in scientific journals, books, reports, and other materials. The review began with papers known to the project team and reviewing the reference lists of the publications already in the collection. We expanded through internet searches using keywords such as "Bering, Chukchi, Bering Strait, North Slope, Northwest Arctic, subsistence, indigenous, Alaska Native, hunting, climate change, adaptation, resilience," and other terms and combinations found in the works already in our collection. The bibliographic details of the publications and a short list of key points or topics for each one were compiled into a document which was archived in the Arctic IERP data collection. This material is summarized below and constitutes the starting point for our co-analysis discussions.

In parallel to the literature review, members of the eight participating communities along the coast were identified as experts and selected by the project leads in cooperation with Tribal and community leaders to take part in meetings to review and co-analyze what is known about societal and environmental change in the region and what these data tell us concerning the communities' experiences and well-being. By "co-analysis," we mean an effort to work together, not simply for academically trained researchers to ask questions of community experts and take notes, but for all involved to discuss observations and implications of changes, effects, and responses, based on each person's experiences and understanding.

The meeting discussions were organized around the topics mentioned in the Introduction. In March 2017, the project team met in Anchorage, Alaska, with 12 residents of the coastal communities (including two of the project leads) and two project leaders who live in the greater Anchorage area. In March 2018, the project team met again in Anchorage, this time with 11 residents of coastal communities (including two project leads and one project staff person) and the two project leaders from the Anchorage area. In both years, notes were taken of the discussions, circulated to participants for review and corrections, and archived as part of the Arctic IERP data collection.

The authors of this paper include the project leads as well as community experts who were interested in contributing to the paper, beyond the meeting discussions. The overall project lead (HPH) is a non-Indigenous scholar living near Anchorage, Alaska. Project co-leads include a non-Indigenous scholar living in the Anchorage area (JRY) and working for Kawerak, Inc., a regional non-profit based in Nome; an Iñupiaq from Kotzebue who at the time of the research was the planning and science director for the Northwest Arctic Borough (NN); and an Iñupiaq from Utqiaġvik who at the time of the research was a subsistence research specialist with the North Slope Borough Department of Wildlife Management (QH). The three remaining co-authors are a St. Lawrence Island Yupik whaling captain and local leader from Savoonga (GN), an Iñupiaq provider of social services in Kotzebue who grew up on the land away from the community (CH), and an Iñupiaq employee of the North Slope Borough Department of Wildlife Management from Utqiaġvik (BA). All six of the Indigenous co-authors are active and experienced subsistence practitioners with additional extensive experience as members of formal scientific research efforts.

Examples of Causes of Change, Effects on Subsistence Practices, and Responses to Change

The literature review provided numerous examples of changes that have occurred in Chukchi coastal communities and their surroundings over the past years and decades, as well as resulting effects on subsistence practices and outcomes, and a range of ways that individuals and communities have responded. These documented examples were complemented by observations of project team members during the co-analysis meetings. The list is not exhaustive. Instead, we have selected examples that community experts identified as representative of common experiences and trends, and that illustrate a range of factors driving those changes.

We found dozens of examples of effects on subsistence practices. Fewer studies documented clear changes in outcomes, such as reduced (or increased) harvest levels. The causes of effects on subsistence can be divided first into societal and environmental categories, and then further into subcategories. Environmental changes include changing weather, changing sea ice, changing abundance or distribution of harvested species, and the availability of new species to harvest. Societal changes include industrial activity such as shipping or offshore oil and gas activity, technological change, social or cultural change, economic change, and regulatory change. We considered both the short-term effects, lasting a season or less, and long-term effects, lasting for years or decades. A summary of examples of changes and effects is presented in Table 1.

In Table 2, we present examples of several categories of response and potential limits to the effectiveness of a given strategy. Broadly, the strategies fall into two categories: specific actions that can be taken, such as hunting bowhead whales in fall as well as spring, and general approaches that promote problem-solving and innovation, such as persistence and a willingness to experiment.

As noted earlier, the information in both tables was the foundation for our co-analysis discussions. The literature survey also provided an annotated bibliography for the use of Arctic IERP researchers and others interested in Chukchi coastal communities' observations of an experiences with change. This information could be used, for example, to compare findings from research cruises or remote sensing with local observations and understanding. Such efforts are separate from the purpose of this paper.

Table 1. Examples of changes experienced by Chukchi coastal communities and their short- and long-term effects on subsistence. These examples were documented in the literature included in our project bibliography and complemented by additional observations shared in our project meetings.

Examples of change	*Short-term (days to seasons) effects on subsistence*	*Long-term (years to decades) effects on subsistence*	*References*
More strong winds and storms Rapid break-up of ice leading to short duration of good hunting conditions Marine mammals migrating farther from some communities	Temporary poor hunting season	Reduced hunting opportunities	Ashjian et al., 2010; Hanson et al., 2013; Huntington et al., 1999, 2013a, 2017a; Oceana and Kawerak 2014; March 2017, 2018 discussions
Earlier break-up and later freeze up of sea ice	Earlier and later access for hunting from boats	More hunting opportunities from boats in Buckland, Utqiaġvik Fall whaling season in Savoonga	March 2017 discussions; Noongwook et al., 2007; Oceana and Kawerak 2014
Less reliable shorefast ice	Harder to find places to haul whales out for butchering	No bowhead whales taken in Kivalina since 1994	Huntington et al., 2017a; Slats et al., 2019
More rain in summer	Spoilage of drying meat and fish	Need to switch to other methods of preservation	Raymond-Yakoubian, 2013; Raymond-Yakoubian and Raymond-Yakoubian, 2015
Warmer weather	Flooding of ice cellars and loss of stored food	Thawing ice cellars and need to find other methods of preservation	Christie et al. 2018
Hanasaki crabs arriving near St. Lawrence Island Increased salmon near Utqiaġvik	Need to learn new skills, tastes	New source of food	Huntington et al., 2017b; Carothers et al., 2013
Increased commercial ship traffic	Marine mammals temporarily become wary and hard to approach	Change in marine mammal distribution and local abundance, e.g., near the Red Dog Mine Port Site, reduced hunting opportunities	Huntington et al., 1999, 2017a; Kawerak, 2013a
Shift from sled dogs to	In Emmonak, single-day hunting	Reduced harvests of ringed seals	Hall, 1971; Burch, 1985;

snowmachines for winter transport	trips become possible, resulting in a smaller use area	(*Pusa hispida*) and fish	Raymond-Yakoubian, 2013; Raymond-Yakoubian and Raymond-Yakoubian, 2015; Fienup-Riordan et al., 2013
Larger boats, more reliable motors, GPS navigation	Able to travel in worse conditions	Expansion of overall use areas	Raymond-Yakoubian et al., 2014; Huntington et al., 2017a
Arrests of Diomede residents for illegal trade in walrus ivory	Loss of hunters due to incarceration	Loss of hunting and skin boat making traditions as hunters avoid walrus hunting and skills are not passed on	March 2017 discussions
Imposition of bowhead quota by IWC	Changes in hunting patterns	Restriction on harvest, need to spend time lobbying for continued quota	Huntington, 1992; Noongwook, 2018
Schooling requirements	Loss of opportunities to participate in subsistence	Reduced transmission of subsistence skills and knowledge	Napoleon, 1996; March 2017, 2018 discussions; Raymond-Yakoubian, 2019
Greater participation in the wage economy	Shift to weekend hunting patterns to accommodate work schedule	Higher subsistence production in Utqiaġvik due to greater access to boats, snowmachines, etc	Kruse, 1991; Galginaitis, 2013
Reduced income, purchasing power	Embarrassment at lack of equipment, avoidance of subsistence activities	Reduced participation in subsistence activities	March 2017 discussions; Raymond-Yakoubian, 2019

Table 2: Response categories, examples, and what might constrain the effectiveness of the responses. These examples were documented in the literature included in our project bibliography and supplemented by additional observations shared in our project meetings.

Response	*Example*	*Limits on effectiveness*	*References*
Using different areas	Variation in use areas over time	If species remain available somewhere in range and the areas are available for use Added travel cost if new areas are farther away	Braund, 2010; Gadamus and Raymond-Yakoubian 2015a
	Moving from Diomede to Nome	If moving is an option, if hunting remains good in new area, if newcomers are allowed to hunt there	March 2017 discussions
Using different times	Fall whaling in Savoonga	If species remain available and conditions are suitable	Noongwook et al., 2007
Using different species	Variation in harvest composition from year to year	If at least some species remain abundant	Braund, 2010; Fall et al., 2013; Raymond-Yakoubian, 2013
Being prepared	Continual observation, readiness to take action when opportunity presents itself	If there are opportunities to seize	March 2017 discussions; Raymond-Yakoubian et al., 2014; Kawerak, 2013a, b; Huntington et al., 2017a

Results of the Co-Analysis

Types and effects of change

Chukchi coastal communities face many types of change and disturbance, as illustrated in Table 1. Separating these by type—e.g., environmental vs. societal, or local vs. global—is less important than understanding the characteristics of each disturbance. For example, the duration of the disturbance marks the difference between a temporary problem, a seasonal problem, or a long-term problem. The passage of a single ship can disrupt marine mammal behavior for a day or two. The operation of the Red Dog Mine Port Site over many decades has caused a long-term shift in marine mammal distributions in the area. Similarly, a storm can keep hunters on shore for a few days. Poor spring weather or ice conditions can reduce harvests for a season. Declines in the reliability of shorefast ice has contributed to Kivalina not landing a bowhead whale (*Balaena mysticetus*) since the mid-1990s. Changes in ice break-up patterns have reduced the duration of good seal hunting conditions from weeks to days or even less.

The duration of a disturbance or alteration distinguishes variability from change. The Arctic environment has always been variable and hunters have had to adjust from day to day, season to season, and year to year. This is considered normal. The annual Pacific walrus (*Odobenus rosmarus divergens*) harvest on St. Lawrence Island varies greatly, due to weather and ice conditions as well as societal factors. The quote in the title of this paper—"We never get stuck"—is indicative of the expectation that community residents will have to find ways to make do, and that attitude is as important as skill in doing so.

More recently, the environment has also undergone persistent changes. Sea ice forms later and breaks up earlier and more rapidly, affecting marine mammal hunting patterns as well as fishing and crabbing through the ice. The loss of suitable hunting and fishing days has reduced opportunities. On the other hand, earlier break-up can create earlier access, as is the case for Buckland seal hunters, and a late freeze-up has created a new fall bowhead whaling season in Savoonga. More rain in summer makes it harder to dry fish and meat, complicating the task of preserving foods in traditional ways. Ice cellars, dug into permafrost to provide sub-freezing storage at no cost, are themselves threatened by thawing permafrost caused by warmer weather and other changes to soil conditions. Stronger and more frequent winds reduce the number of days suitable for boat travel, and larger boats cannot completely overcome this problem.

Shifts in the distribution and abundance of different species have also affected subsistence practices. The increased availability of salmon (*Oncorhyncus* spp.) in Utqiaġvik has created a new fishery and led people there to learn how to smoke salmon. The Hanasaki crab (*Paralithodes brevipes*) is a relatively new arrival in the waters off Savoonga, providing a new and valued source of food. In both cases, it appears that these changes are likely to persist.

As with environmental variability, short-term societal matters such as family health or a major construction project employing many local residents for a season are typically viewed as normal variability. Of greater note for the communities are long-term changes. Schooling requirements take up considerable time for children, reducing opportunities to participate in subsistence activities and learn the necessary skills and knowledge. Few schools make allowance for subsistence or provide in-school ways of learning from Elders. Replacing dog teams with snowmachines starting in the late 1960s reduced the demand and thus the harvest of seals and fish that were formerly used as dog food. Faster snowmachines

have had the counterintuitive effect of reducing the seal hunting area in some communities, because hunters can go out and back in a day rather than making extended camping trips to more distant locations.

The decades-long shift towards greater participation in the wage economy has raised incomes and thus the ability of some people to purchase equipment used for subsistence. Even those without jobs may benefit from relatives willing to share their gear. On the other hand, having a job can reduce the time available for hunting or the flexibility to go when conditions are good. Some employers in the region provide subsistence leave, above and beyond vacation days, but not all work can be put off in this way. The other side of this phenomenon is that people without the means to go hunting or fishing may be left out of subsistence activities. Their situation may be compounded by embarrassment that they have to walk to a harvesting area or use old equipment, so some individuals avoid potential social discomfort by staying home instead of trying to participate in subsistence.

Another persistent shift has been in the regulatory environment. The quota imposed since 1978 by the International Whaling Commission (IWC) for the bowhead whale hunt has, among other things, meant that leaders of the whaling community have had to spend considerable time traveling to meetings and other venues to defend their practices, taking them away from hunting and other responsibilities in the community. A major enforcement action in the early 1990s against illegal harvests of Pacific walrus tusks led to several hunters from the Bering Strait area being charged with this crime. One result was that the walrus harvest on Little Diomede declined sharply and has not recovered because some prominent hunters were jailed and as a consequence others were reluctant to hunt. The transmission of skills and knowledge to younger hunters was thus interrupted, creating an even more lasting effect.

Response strategies

Environmental changes in the Arctic attract a lot of scientific and media attention. Addressing the root causes of these changes, however, is a challenge. The causes are dispersed globally and include powerful economic interests as well as established patterns of energy-intensive human behavior. Some Arctic activists have taken up this cause, but it remains a major challenge.

Some societal influences on subsistence, on the other hand, are closer to home or have a clearer focal point. The effects of commercial shipping to Red Dog Mine or the North Slope oil fields can be raised with the companies involved. In the case of North Slope oil activities, one result has been a cooperative agreement between whalers and companies to improve communication and reduce or avoid ship traffic that interferes with whaling. Even the IWC quota for bowhead whales is at least set by a single international body that meets on a regular basis, so whalers know when and where to go to advocate for their way of life. Changing the schedules of local schools and employers has in general proved hard to do, but at least community members have access to the relevant decision makers. Adoption of new technology is up to the individual, subject to such considerations as affordability.

Whether the ultimate causes of change can be addressed or not, individual hunters can and do adjust in many ways to respond to change. Communities can pool their talents and resources to do so to an even greater extent. Hunting areas may shift and expand, both because animal distributions change and also because new technologies such as larger boats, more reliable engines, and GPS navigation allow for more efficient and safer travel, though going farther will take more time and fuel. Subsistence activities may also take place at different times, ranging from a shift of a few days or weeks if sea ice breaks up earlier, to Savoonga's creation of a fall whaling season. Harvest composition varies year to year (e.g., Bacon et al. 2009), and can also shift over time, in response to access, species availability, and other factors. Some changes, however, will require more than an individual or community can do alone. Collaboration and cooperation with those outside the community will be necessary, too. Such efforts can be as simple as Utqiaġvik harvesters learning from friends and relatives farther south how to smoke salmon, or as

complicated and difficult as persuading the U.S. government and the IWC to permit the harvest of other species of large whales. All of these strategies depend on having animals to harvest at some time and place within reach of the community.

In addition to changing activities, Chukchi coastal residents also recognize the importance of attitudes in creating effective responses to change. These characteristics do not simply exist, but are developed and encouraged within the communities of this study (and undoubtedly far beyond) as distinct skills to be practiced and refined. Harvesters have always been prepared for variable conditions, whether in recognizing signs of danger or being ready to act when opportunities arise. Being ready is not so much a response in itself as the foundation for any other response, from making use of the now-briefer seal hunting period after shorefast ice breaks up to using social media to share information from one community to the next about animal migrations. Persistence is similarly a necessary virtue, again as illustrated in the adage that "We never get stuck." Using new species, such as the Hanasaki crab, new tools, such as drones or satellite imagery for scouting sea ice conditions, or learning new ways to prepare and store foods are all part of a ceaseless search for what will work best at any given time. Here, too, there are ultimately limits to what can be accomplished, but not for lack of trying.

For all the attention to changes in the Chukchi marine ecosystem, widespread changes in subsistence outcomes are hard to identify. There are many relatively modest effects, as shown in the examples in Table 1, but the reduction of seal and fish harvests due to the replacement of dog teams with snowmachines is so far a much larger change than has been forced by environmental change in the region. One reason for the lack of apparent effects is range of responses used by subsistence harvesters, as shown in the examples in Table 2.

This is not to say that further changes will have similarly modest effects or that responses will continue to be effective. Coastal residents will remain innovative and committed to providing food for their communities. Modern technology will help in many ways, and remoteness and minimal competition for most of the marine resources of the region leaves the coastal communities considerable flexibility in what, when, and where to hunt. On the other hand, increased commercial shipping (AMSA, 2009) and industrial activities such as offshore oil and gas activity (Gautier et al., 2009; Holland-Bartels and Pierce, 2011) create another type of competition, not for species per se but for access to an undisturbed sea, even as they may provide more local income. Those lacking cash or equipment will have less ability to participate in subsistence, regardless of the abundance or accessibility of animals and plants. Regulatory restrictions could limit the ability of harvesters to adjust by not allowing the take of animals outside regulatory seasons even though the timing of animal presence and/or abundance have changed, taking species they have not harvested before, or by preventing them from making up for poor harvests of one species (e.g., bowhead whales) by increasing their take of another (e.g., caribou). Furthermore, the fixed infrastructure of today's communities limit hunters' and fishers' ability to always move to where the fish and animals are abundant or accessible.

Cataloguing the range of factors that influence Chukchi coastal communities and communities elsewhere is in itself of limited value in fostering resilience and adaptation to change. Community well-being will depend on many factors as well as the interplay among those factors, limiting the ability to predict or even to recognize which influences matter most. What is likely more important is the ability of communities to develop their own responses to change, on their own terms, and with support from and in cooperation with others when necessary and desired. The effects of environmental change on Chukchi coastal communities are not negligible but demonstrable, and play out under the influences of societal and other changes that mediate both the effects of those changes and the responses to them.

Discussion

Co-analysis and community perspectives

The movement towards collaborative research and the co-production of knowledge is in part a recognition of the rights of community residents to be more than study subjects (Smith 1999; Wilson 2008; Kovach 2009; Strega and Brown 2015). Involving Arctic peoples in all phases of a research project is worthwhile on its own merits, recognizing the full intellectual contributions made by everyone involved in such projects, and sharing the rewards of credit and income from the work of research. Scientifically, it is also reasonable to ask what is gained from a collaborative or co-productive approach as compared with other methods. In our study, the answer lies less in dramatic insights and more in the steady accumulation of additional ideas and perspectives.

The co-analysis emphasizes the importance of the results of change rather than the sources of change, when it comes to their effects on communities and the strategies used to address those changes. Whether marine mammal distribution has shifted because of vessel traffic or reduced sea ice, hunters still have to find ways to adjust. The ability to adjust is useful no matter the cause of change. Addressing the source of the change, by negotiating with a shipping company or advocating for one's community at the IWC, is also a form of adjustment, and doing so can give a sense of agency that reinforces the idea that one can affect the outcomes that matter. At the same time, changes that stem directly from a specific and identifiable human action, such as industrial activity or an oil spill, are also likely to produce a different reaction among those affected than would an event with unknown or natural causes, such as fluctuation in some animal populations. In the former case, stress is likely to be higher as individuals seek to blame those they see as responsible and realize the problem may have been preventable (e.g. Cunsolo Willox et al., 2013, 2015), whereas in the latter case, people may be better able to get on with adjusting to cope with what has changed (e.g., Himes-Cornell et al., 2018).

The co-analysis discussions emphasized the importance of attitude (e.g., Walker and Salt, 2012) as well as skill and knowledge, and the crucial role that traditional values and practices continue to play in successful subsistence outcomes. These are not new ideas in the literature on Arctic communities and change (e.g., Hovelsrud and Smit, 2010; Cochran et al., 2013; Ford et al., 2015; Huntington et al., 2017a), but they often receive less attention and emphasis than what is changing. The abilities, both learned and taught, to be ready and to carry on deserve more attention as effective elements of individual as well as collective (i.e., cultural) response to change, and greater recognition as traits essential to the well-being of remote communities in variable, changing, and challenging environments.

Together, these insights suggest a broader scope of inquiry and discussion, not limited to ecosystem studies or societal studies, but taking the community perspective as starting point, to address community needs and concerns (e.g., Huntington et al., 2019). Further documentation of how much is changing and how fast is useful only up to a point. Greater understanding of how people have already adapted to change and how those strategies can be fostered and supported in response to future change is a more useful contribution to supporting the well-being of region's coastal communities. More important still is a leading role for Tribal and community voices and leadership in deciding how they want to shape their own future (Raymond-Yakoubian and Daniel, 2018). Doing so is an opportunity for true collaboration between scientists and coastal residents and, ultimately, the local, regional, and national policy makers whose decisions will have a large influence on what happens next.

Theories of change and response

From an academic point of view, we can also consider the outcomes of the co-analysis discussions in light of existing theories of change and response, drawing for example from ecology and business management. The emphasis on the characteristics of disturbance, especially the role of duration, aligns with the ecological and social-ecological idea of pulse-press dynamics (e.g., Collins et al., 2011;

Ratajczak et al., 2017). Pulses are short-term disturbances that cause disruption but from which the system recovers to something close to its original state. Presses are long-term disturbances that led to long-term alterations in a system's structure and functioning. One poor hunting season may cause hardship and even loss, but communities and cultures have recovered from such events in the past. A change in sea ice conditions, however, may force marine mammal hunters to alter their practices, to the point of abandoning previous modes of hunting, as with Kivalina and bowhead whaling, or creating new modes of hunting, as for Savoonga and fall whaling.

Responses to change can be considered technical or adaptive, a concept taken from business management (e.g., Heifetz et al., 2009). Technical changes are those which apply a known solution to a problem, whereas adaptive changes are those that require developing a new solution, typically because the problem is of a nature not previously encountered. Technical changes may often be sufficient for pulse problems, since the basic nature of the system does not change, and in a system with high variability, subsistence harvesters have a number of alternatives to use if their primary methods are not sufficient in a given season. Under press-like changes, however, the system itself is likely to change, in turn sometimes—but not always—requiring the development of new knowledge, skills, and methods to achieve similar outcomes. Harvesting the Hanasaki crab may not be a major challenge, but it is still a new skill to learn. Using new tools such as drones, satellite imagery, and GPS require experimenting and the generation of new knowledge and skills. On the other hand, being ready to harvest when conditions are right has always been important, even if good conditions for some activities no longer last as long.

When discussing change and response to change, it is important not to overlook what should stay the same (Huntington et al., 2017a), as reflected in some entries in Table 2, such as being prepared, being persistent, and being willing to experiment. Sharing remains an essential component of social life in Indigenous communities and their hunting, fishing, and gathering practices (Raymond-Yakoubian, 2013). Hunters need to be mentally and physically prepared (Kawerak, 2013b). Respect for the animals is critical to the long-term well-being of hunter and hunted alike (Kawerak, 2013a; Raymond-Yakoubian and Raymond-Yakoubian, 2015; Gadamus and Raymond-Yakoubian, 2015b). Humility and cooperation are necessary for social cohesion. Effective response strategies exist not in isolation, but in a context of healthy interpersonal and human-animal and human-environment relationships (Hovelsrud and Smit, 2010). If that foundation is not solid, then dealing with change may become extremely difficult or impossible, no matter how extensive the resources one has available. With a solid foundation, by contrast, a great deal can be done even in the face of major environmental change. The ability of Savoonga's whalers to create a fall whaling season in the northern Bering Sea is but one example of what is possible through the synergy of Indigenous skill, knowledge, determination, and collaboration.

Our examples and findings are consistent with other studies of responses to change (e.g., Emery and Flora, 2006; Thornton and Manasfi, 2010; Walker and Salt, 2012), that humans draw on a wide range available resources to support an equally wide range of strategies of response. Our findings are also broadly consistent with other Arctic studies which have found that environmental and societal factors both have a large influence on community well-being, including subsistence practices (e.g., Hoveslrud and Smit, 2010; Pearce et al., 2010, 2015; Ford et al., 2015; Rasmussen et al., 2015; Hastrup, 2018; ICC Alaska, 2015), and that identifying demonstrable changes in community well-being (e.g., population trends) is difficult (Hamilton et al., 2016), perhaps due to the range of responses that provide a buffer against deleterious effects (Huntington et al., 2018).

Understanding the nature of changes, for example as pulse-press dynamics, and the types of responses those changes will require, such as technical and adaptive solutions, can help communities and their allies to focus their efforts and perhaps to make a more persuasive case when needed to convince others to change, too. Our co-analysis approach has emphasized the continuing importance of traditional values and practices, such as the attitude of never getting stuck, as well as the need for attention to the conditions within and outside communities that foster effective responses to change. Movement towards approaches

that use co-production of knowledge and are highly collaborative is a welcome step in this regard, especially if it can also lead towards collective action.

Acknowledgments

Our research was part of the North Pacific Research Board's Arctic Integrated Ecosystem Research Program. We are grateful to the NPRB for funding and to our colleagues in the Arctic IERP for their ideas and support. We thank the participants in the Chukchi Coastal Communities Project, our fellow team members, who contributed ideas and insights to this paper, including Lucinda Wieler and Niviaaluk Brandt, former project Research Assistants at Kawerak; Orville Ahkinga, Dora Ahkinga, Opik Ahkinga, and Frances Sistuq Ozenna from Diomede; Raymond Lee Jr. from Buckland; Millie Hawley from Kivalina; Steve Oomituk from Point Hope; Willard Neakok Jr. from Point Lay; and Michael Donovan from Utqiaġvik. We also thank the communities and researchers whose work is presented in the publications we reviewed, and for several colleagues who reviewed portions of this manuscript. Finally, we are grateful to Jeremy Davies for preparing the map in Figure 1, and to the reviewers for their constructive comments that led to a much better paper. This paper is Arctic IERP Publication #39.

Results of the Arctic IERP Group Effort

This chapter presents the findings of the Arctic IERP group effort (so named in order to distinguish it from the synthesis phase of the Arctic IERP, which is a separately funded part of the overall program to take place after the main research phase), as reported in a paper published in Nature Climate Change *in February 2020. This chapter consists of the accepted manuscript for the paper. Note that the published manuscript was subject to copy editing and other changes. Full details of the publication can be found in the appropriate section of this report, below.*

Evidence suggests potential transformation of the Pacific Arctic Ecosystem is underway

Abstract

The highly productive northern Bering and Chukchi marine shelf ecosystem has long been dominated by strong seasonality in sea ice and water temperatures. Extremely warm conditions from 2017 into 2019 - including loss of ice cover across portions of the region in all three winters - were a marked change even from other recent warm years. Biological indicators suggest this state change could alter ecosystem structure and function. Here we report observations of key physical drivers, biological responses, and consequences for humans, including subsistence hunting, commercial fishing, and industrial shipping. We consider whether observed state changes are indicative of future norms, whether an ecosystem transformation is already underway, and if so, whether shifts are synchronously functional and system-wide, or reveal a slower cascade of changes from the physical environment through the food web to human society. Understanding of this observed process of ecosystem reorganization may shed light on transformations occurring elsewhere.

[Main text]

The Pacific Arctic, composed of the Chukchi and northern Bering seas (Figure 1), is one of the world's most productive ocean ecosystems (1), characterized by high benthic biomass resulting from persistent, nutrient rich flow through the Bering Strait (2) that fuels high primary production (3). In summer and fall, the region is home to millions of nesting and migratory seabirds, with hotspots of foraging activity shared with marine mammals (4), supporting coastal Indigenous communities. The delivery of nutrients together with the extent and timing of sea ice (5) are dominant environmental factors structuring this ecosystem. Freeze-up in fall and winter eliminates large expanses of open water, causing whales, Pacific walrus (*Odobenus rosmarus divergens*), many seals, and seabirds to migrate southwards into the Bering Sea and beyond (6).

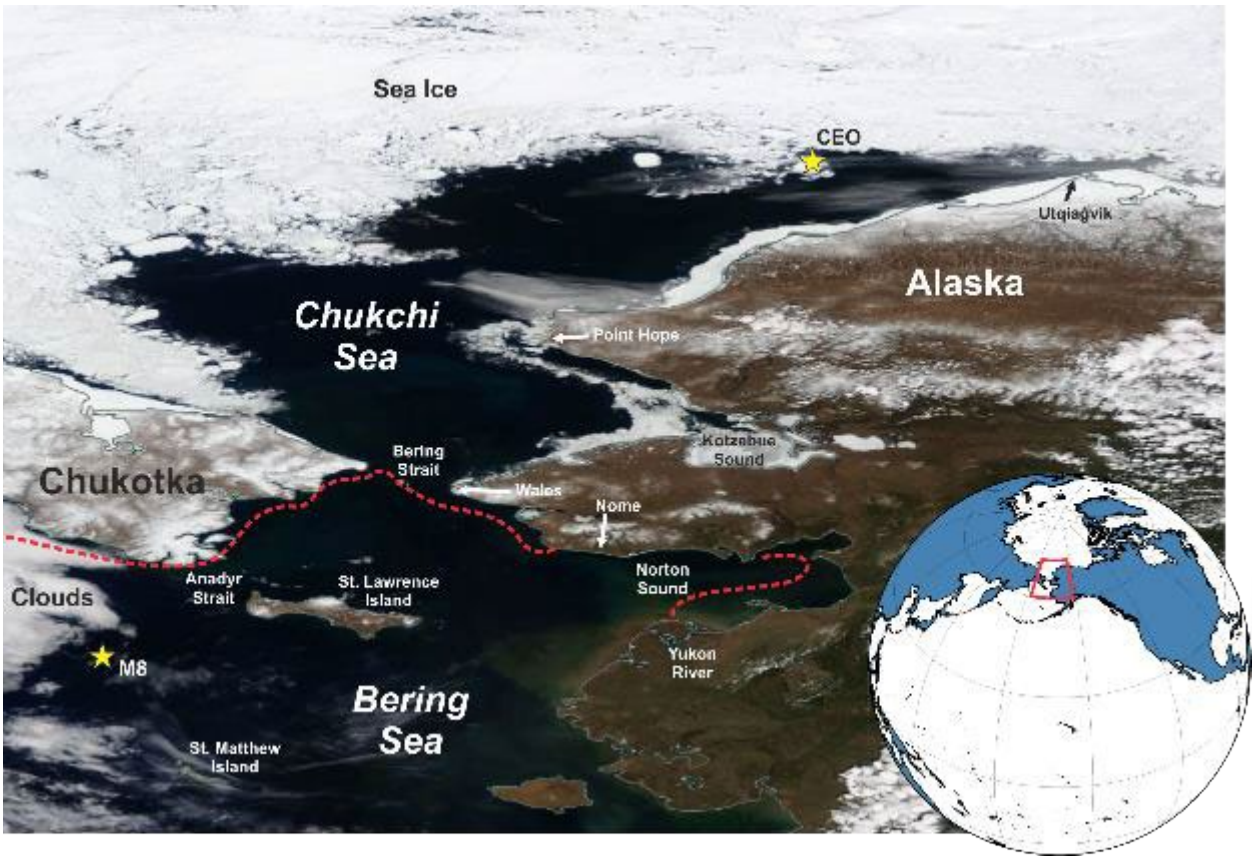

Figure 1. Sea ice changes in recent years. True-color MODIS satellite image showing northern Bering and Chukchi sea ice conditions on 2 June 2017. Red dotted lines denote the 1980-2010 ice edge climatology for June 2nd. Yellow stars denote locations of oceanographic moorings M8 and CEO. Inset locates the study region. Image from NASA Worldview.

In spring, the return of sunlight heralds snow melt, growth of sea ice algae, and a phytoplankton bloom that typically exceeds the consumption capabilities of pelagic consumers, resulting in carbon falling to the seabed, fueling rich benthic communities (7,8). Solar radiation and melting sea ice help stratify the upper water column, impeding the ability of winds to mix surface and subsurface waters. In summer, low-salinity surface waters near the pack ice remain cool relative to the shelf waters warmed by insolation. The Bering Sea cold pool, near-bottom shelf waters cooler than 2°C south of Bering Strait, has long served as a thermal barrier to northward migration of subarctic groundfish (9), which are major stocks for the southeastern Bering Sea's $2 billion fishery and account for about half the seafood landings in the United States (10,11).

Recent Changes in the Pacific Arctic Marine Ecosystem

Declining sea ice in this century has reduced surface albedo in spring and summer, accelerating oceanic heat uptake and causing earlier and more rapid sea ice melt (12). The pack ice and marginal ice zone has retreated north beyond the Chukchi shelf in recent summers, while warmer shelf waters delay sea ice formation in fall. Simultaneously, the northward flow of water through Bering Strait has increased, as has its temperature (2), so that it now delivers more heat, freshwater, nutrients, and biota northwards into the Arctic (13). Near-bottom water temperatures exceed 0°C for a larger portion of the year (Figure 2).

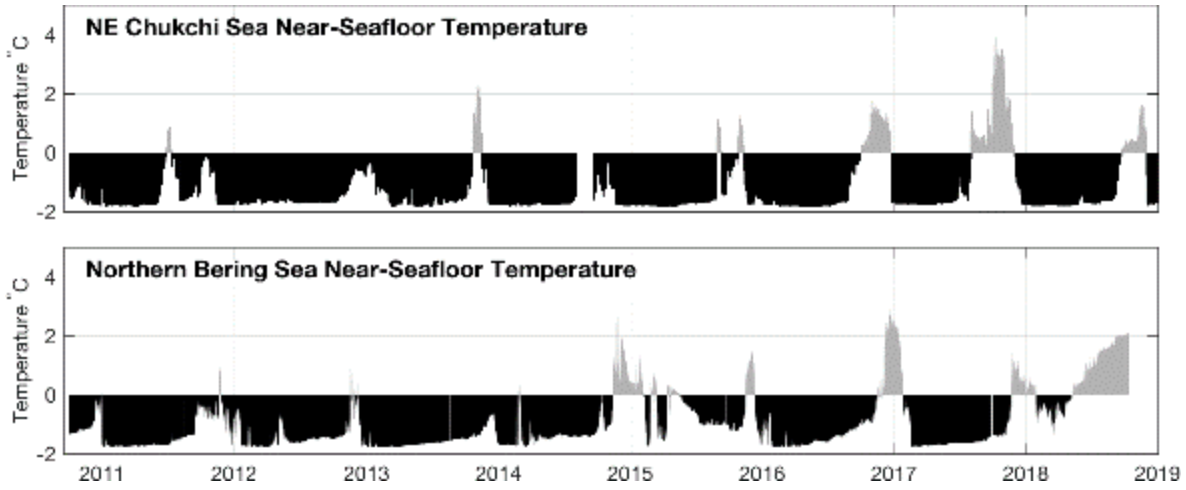

Figure 2. Near-bottom water temperatures. Previously, temperatures in important seafloor habitats remained below 0℃ for most of the year. In recent years, an increasing number of months exhibited temperatures well above 0℃. Mooring locations are indicated on Figure 1.

Ramifications of these physical changes have included more salmon in the Chukchi and Beaufort seas (14,15), walrus hauling out on shore in northwestern Alaska in late summer instead of on sea ice (16), an increase in the frequency and seasonal duration of killer whale (*Orcinus orca*) presence in the Chukchi Sea (17), an increase in planktivorous seabirds in the Chukchi Sea (18), and a northward shift in

the distribution of other seabird species (19,20). For the Indigenous peoples of the region, spring marine mammal hunting opportunities dependent on the presence of sea ice have decreased and shifted in time (21), although the lack of sea ice has allowed additional whaling to occur in fall and early winter in the northern Bering Sea (22).

And Then Came 2017

In 2017, physical conditions in the Pacific Arctic marine shelf ecosystem of the Chukchi and northern Bering seas described above showed signs of a sudden and dramatic shift relative to historical means and even to other recent unusually warm years. In turn, these physical changes seemingly precipitated several significant ecological shifts, with consequences for the region's residents. Based on published and unpublished data from the authors, many changes persisted in 2018 and even into 2019, suggesting that 2017 was not a passing oddity of brief consequence to social-ecological systems, but a sign of what is to come.

In early January 2017, the sea ice edge had barely progressed south of Bering Strait and for the entire winter its extent remained at least $2x10^5$ km^2 below the long-term average. In June, ship-based observations found near-bottom ocean temperatures in Bering Strait of nearly 4 °C, over 3°C and four standard deviations warmer than the 1991-2016 June mean (2). Indeed, by June, the eastern Chukchi shelf was already mostly sea ice-free (Figure 1). In early December 2017, the ice edge was over 1000 km north of its climatological mean position near St. Lawrence Island. There was no sea ice in the Bering Strait in February 2018 and southerly winds forced a large ice retreat again in February 2019 (23). Waters in Norton Sound exceeded 10°C before the end of June 2018 and the cold pool was again minimal by late summer.

Reduced ice cover and warmer seas likely impacted primary production by influencing thermal, light, and stratification conditions. In spring of 2018, in the southern Bering Sea, the bloom was delayed due to a lack of freshwater input from melting sea ice, and chlorophyll concentrations were an order of magnitude lower than usual; however in the northern Bering Sea the ice-associated bloom was early and extensive (24). In addition, the detection of domoic acid in shipboard water samples (Figure 3) and saxitoxin in a few stranded and harvested walruses from Bering Strait villages led to concern about harmful algal blooms and food safety from Indigenous residents, though analytical challenges make the impact difficult to determine (25).

Changes in species distributions had already been observed this century, but not to the extent observed in 2017. The copepods *Calanus glacialis/marshallae* in 2017 were found to be remarkably low in abundance relative to 2012-2015 (Figure 4). Multispecies epibenthic biomass in the southern Chukchi Sea also exhibited a pronounced decline relative to comparable collections in 2004, 2009, 2012, and 2015 (Figure 4). In contrast, acoustic-trawl surveys indicate that age-0 Arctic cod abundance was dramatically higher in the Chukchi Sea in 2017 compared with previous surveys: backscatter in the northern Chukchi Sea (67 N to 71.5 N) was 5.6 times greater than in 2013, and 16.3 times greater than in 2012 (Figure 5), but the fish had low energy content. Juvenile pink salmon (*Oncorhyncus gorbuscha*) catch per unit effort in surface trawl surveys in the northern Bering Sea was two times greater during 2017 than previous years (Figure 4). Juvenile pink salmon return as adults the following year, and the adult pink salmon return to Norton Sound was much stronger than expected during 2018 (27). Adult walleye pollock (*Gadus chalcogramma*), Pacific cod (*Gadus macrocephalus*), and northern rock sole (*Lepidopsetta polyxystra*) biomass in bottom trawl surveys increased in the northeastern Bering Sea during 2017, likely due to northward movement of these fishes in the absence of the Bering Sea cold pool (28).

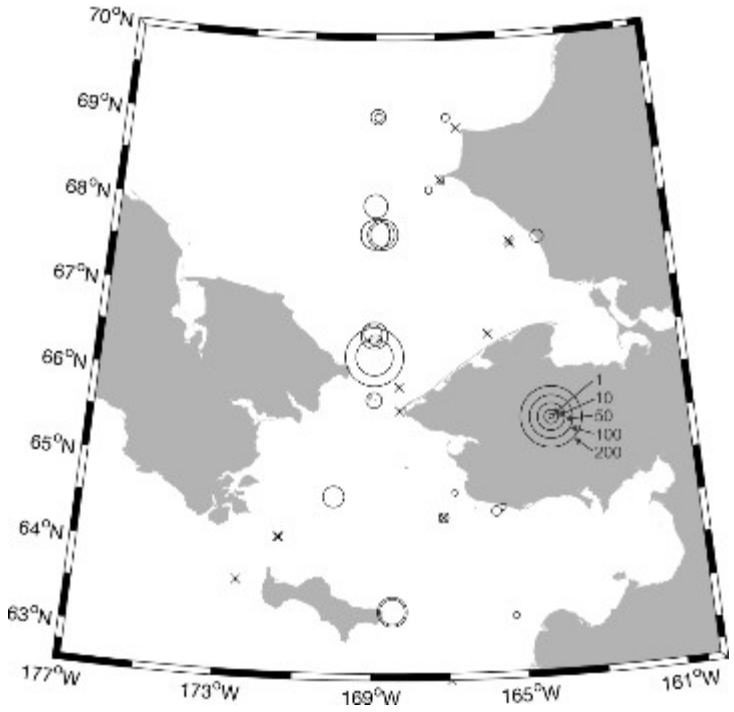

Figure 3. Seawater concentrations of domoic acid, June 2017. NTD = no toxin detected.

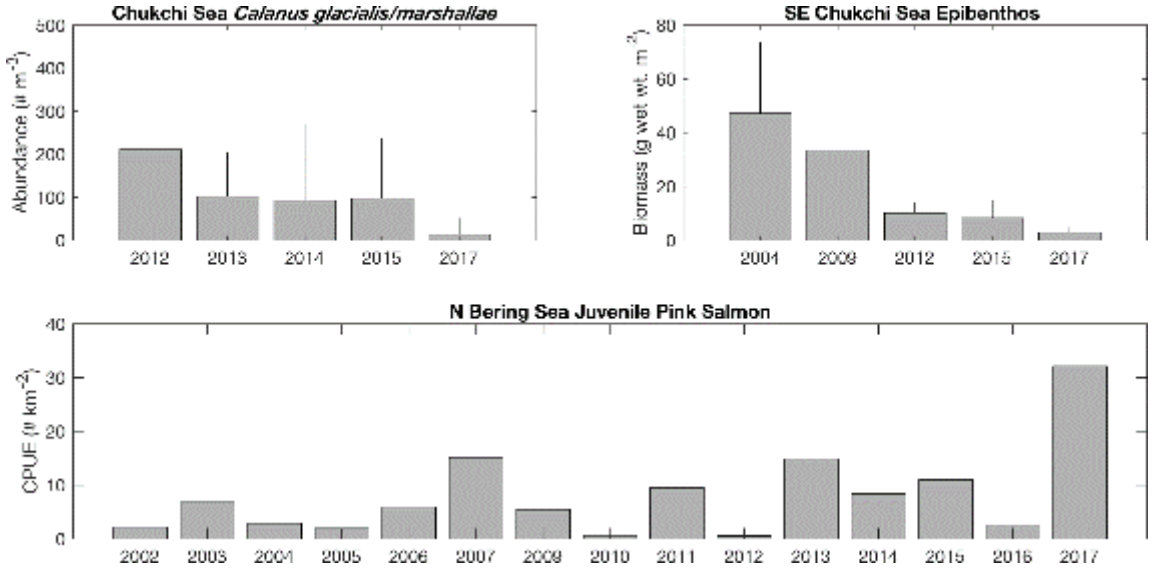

Figure 4. Biological changes in recent years. Observations show declines of Calanus glacialis/marshallae *abundance (upper left) and epibenthic biomass (upper right) in 2017 relative to prior years, and an*

increase in juvenile pink salmon catch per unit effort (CPUE) (bottom). The graphs in upper left and upper right show simple means and standard deviation error bars.

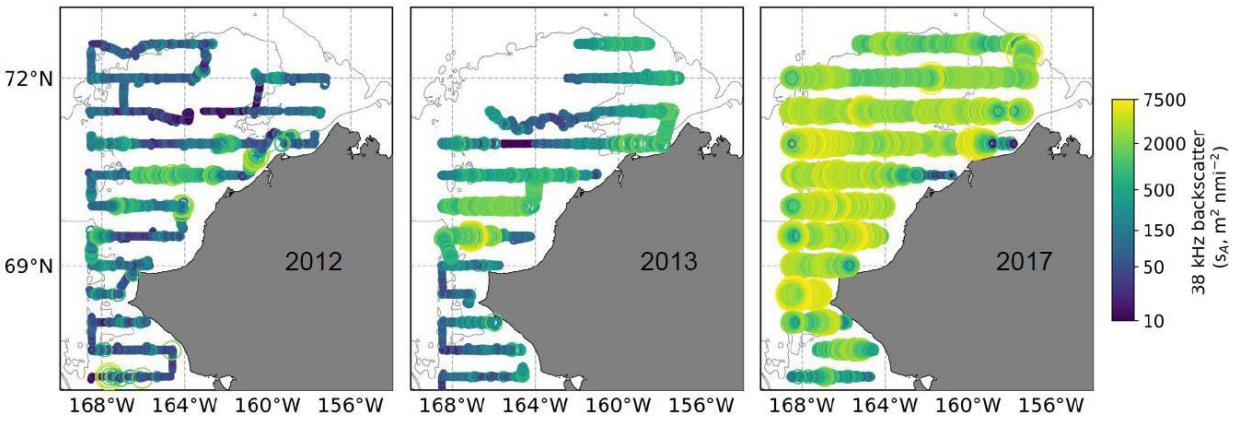

Figure 5. Arctic cod abundance change. Acoustic surveys indicate that the abundance of age-0 Arctic cod increased substantially in 2017 relative to 2012 and 2013. Trawl sampling indicated that Arctic cod dominated acoustic backscatter in this area in 2012 and 2013 (26). This was also the case in 2017: Arctic cod accounted for 95.4% of fish captured in 33 midwater trawl hauls.

In offshore waters, total seabirds declined from 2012-2017 in the southern and northern Bering Sea, but densities were above the long term mean in the Chukchi Sea during most of that period. The increase in the Chukchi Sea in 2015-2017 was primarily due to short-tailed shearwaters (*Ardenna tenuirostris*), which feed primarily on euphausiids, and less pronounced increases in piscivorous black-legged kittiwakes (*Rissa tridactyla*) and murres (*Uria* spp). In contrast, planktivorous auklets (*Aethia* sp.) had low densities in the Chukchi Sea in 2017 and 2018 but increased in the northern Bering Sea those years (24). Reproductive success was low for seabirds in the Bering Sea in 2017-2018, and there were mixed-species die offs there and in the Chukchi Sea (24,29;), with dead birds emaciated. Notably, numbers of murres and kittiwakes attending the large Chukchi Sea colony continued to increase (30) at a rate suggesting immigration of piscivorous nesting birds.

In the spring of 2017, bowhead whales, including females with calves, were seen near Utqiaġvik, Alaska, a month earlier than usual and the Utqiaġvik whale hunt recorded the earliest known landing, on 13 April. Four bowhead whales equipped with satellite transmitters all wintered (2017/18) in the Chukchi instead of their usual wintering area south of Anadyr Strait in the Bering Sea (31) and a bowhead was recorded singing near Utqiaġvik on 11 January 2018, something never recorded before at that time of year. In 2018/19, the bowheads were again north of Anadyr Strait in winter. Spotted seal (*Phoca largha*) pups in the spring of 2018 were found in poorer condition (less fat and lower mass/length) than in recent years, and almost no ribbon seals (*Histriophoca fasciata*) were seen during those same surveys, raising the specter of a failure in the 2018 year class. In the spring and summer of 2018 and 2019, more than 280 bearded (*Erignathus barbatus*), ringed (*Pusa hispida*), spotted, and unidentified seal carcasses, primarily young and many emaciated, were reported from beaches mostly of the northern Bering and southern Chukchi seas, nearly five times the annual average from 2014-2017, prompting the National Oceanic and Atmospheric Administration to declare an “unusual mortality event” (32).

Anomaly or Transformation?

Changes in sea ice extent, water temperature, currents, zooplankton abundance, animal distribution and health, hunting success, and other aspects of the ecosystem are noteworthy in themselves, but such large-scale changes could conceivably occur without altering basic relationships among ecosystem components. The investigation of specific mechanisms underlying these changes were not part of the cited studies, however it is known from other areas, including the southern Bering Sea, that the spring sea-ice break-up spurs a productive phytoplankton bloom, and its timing together with ocean temperatures determines phytoplankton species composition, carbon export to the benthos, and food quality for zooplankton (24). Changes towards lower-lipid zooplankton reduces over-winter survival of fishes such as salmon and Arctic cod (33), even if they increase numerically in summer due to favorable thermal and oceanographic conditions. Lower zooplankton food quality and increased competition from predatory fish moving north from the Bering Sea might explain seabird and seal mortality.

The ecosystem-wide changes seen in 2017-2019 have the potential to fundamentally reconfigure the Pacific Arctic marine food web. An altered physical environment characterized by warmer waters and a longer open-water season is allowing subarctic species to establish themselves in the Chukchi Sea; seasonally for now, but possibly year-round in the future. Subarctic invaders such as walleye pollock and Pacific cod could fundamentally transform interactions among pelagic species, benthic invertebrates, groundfish, seabirds, and marine mammals by exerting strong predation pressure on forage fishes and benthic crab, worm, and shrimp communities (10). Predation pressure from these fishes adds top-down stresses to the bottom-up changes associated with altered temperature and primary and secondary productivity. Indigenous hunters may begin to find familiar species of fishes and marine mammals at unusual times of year or unfamiliar species during customary hunting and fishing periods (21).

An interdisciplinary look at the Pacific Arctic marine ecosystem as it changes may provide a rare opportunity to track ecosystem transformation in detail as it unfolds, rather than reconstructing details after the fact. The transformation of an ecosystem may reflect a cascade of sequential changes that take place over multiple years rather than a single shift or tipping point (e.g., 34), though changes to individual ecosystem components may be sudden and dramatic. For example, because of positive feedbacks in the climate system (e.g., 12) it is possible that 2017 marked the crossing of a threshold that precludes return to the system state common just a decade ago. We find that a closely coupled synergy between bottom-up and top-down factors (e.g., 35) appear to best characterize this system's transition, and the interactions among these multiple stressors have important implications for understanding any subsequent reorganization.

The result would be the transformation of an Arctic marine ecosystem into one characterized by subarctic conditions, subarctic species, and subarctic interactions (Figure 6). The Chukchi Sea may soon resemble the east-central Bering Sea shelf in condition, structure, and function, with annual sea ice, warmer bottom water temperatures, and ecosystem productivity derived from forage fishes and pelagic zooplankton rather than the benthos. Changes in the historically strong benthic-pelagic coupling have already been observed in the southeastern Chukchi Sea, where overall epibenthic biomass declined by an order of magnitude from 2004 to 2017; the fact that the most abundant taxa were consistent over time may hint at overall changes in ecosystem productivity or pathways rather than specific habitat changes (36,37). Yet this transformation is more complex than an ecosystem migrating north. For example, the Chukchi Sea would likely retain some characteristics distinguishing it from the Bering Sea shelf, due to higher latitude and downstream location relative to the Bering Strait nutrient supply. How these competing features will combine to create a new state of the Pacific Arctic ecosystem remains to be seen.

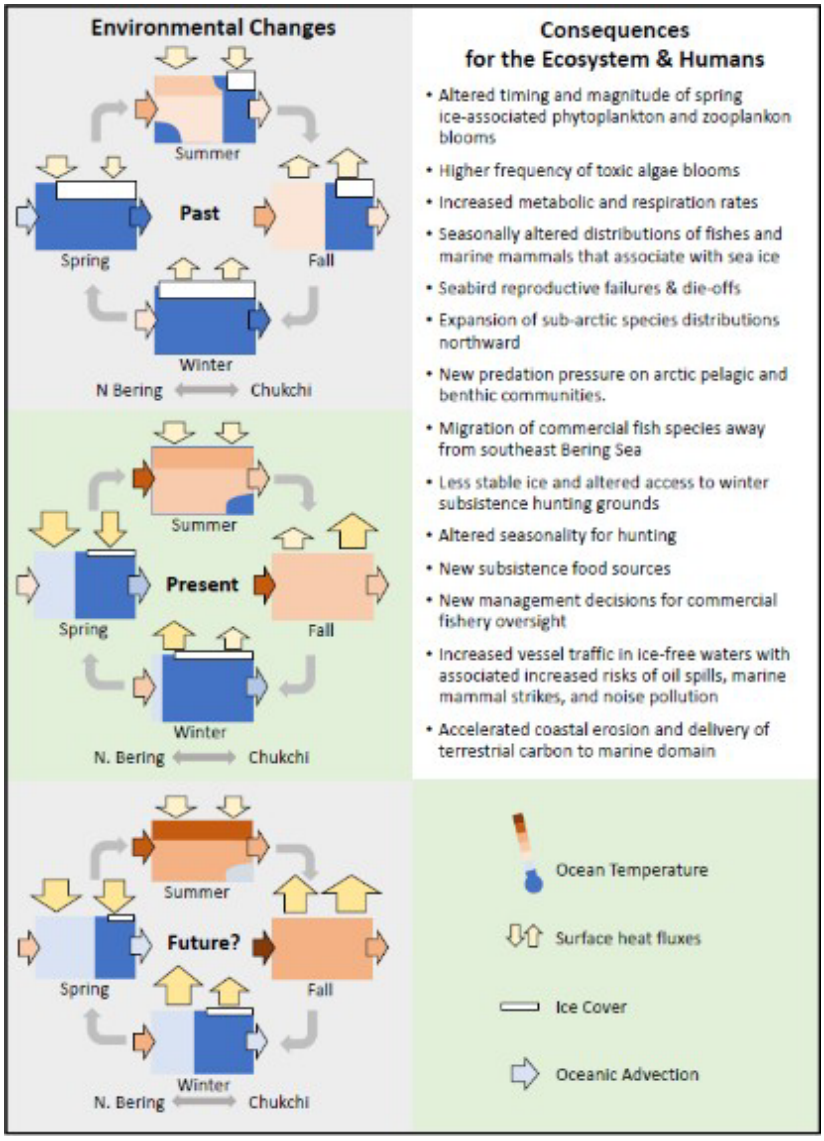

Figure 6. Environmental changes and related consequences. Observed and potential future changes in the physical environment (left panels) in the Northern Bering and Chukchi shelf systems (i.e., bottom-up forcing), along with observed and anticipated consequences for the biological and human components of the ecosystem (right panel).

In addition to its regional significance, the pattern of change underway in the Pacific Arctic may eventually shed light on the progression of ecosystem transformation more generally (38), which manifests as large-scale alterations in the connections and interactions among species and among physical and biological processes. Overpeck et al. (39) suggested the possibility of such a transformation resulting from the removal of perennial ice in the Arctic, though they focused on "before" and "after" states of the system without describing the transformation in between. The pioneering work of Gunderson and Holling (40) recognized that transformation and reorganization are less predictable and less well understood than a simple shift from stability to instability.

What To Expect Next?

The expectation is for the sea ice season to further shorten and sea ice coverage to diminish (41). Waters will become warmer and stay warm longer into fall and winter. How quickly these changes propagate through and persist in the system, and what additional sudden shifts may occur, are hard to predict. It is likely, however, that there will be differences in the temporal and spatial scales over which physics and biology change (42). Physical conditions that were once anomalous may become normal. The biological response will follow but may not carry over across years until species and behaviors that thrive in the new conditions are able to persist. Hunters and fishers will adjust to some degree but may find it necessary to switch the timing or targets of their efforts (43).

Specific trajectories of these changes and their implications for the Pacific Arctic ecosystem, including Indigenous coastal communities, are still unclear. To stay with or ahead of these system transformations rather than reacting to a new state some years from now, some critical unknowns, especially regarding ecosystem relationships, require further attention and continued monitoring at multiple scales. As sea ice retreats earlier, will some species cling to existing fixed habitats (e.g., depositional zones) and remain largely in place, while others follow shifting habitats (such as the ice edge)? Will subarctic species be able to flourish and persist in the Chukchi Sea year-round, transforming the ecosystem into a locus of groundfish or pelagic predator abundance? Will increased industrial activity such as shipping combine with climate-driven ecosystem changes in ways that amplify the consequences of either alone (44)? How can coastal communities adjust and adapt quickly enough to retain cultural and nutritional security (45)?

Even in this age of information overload, it is how remarkable how scarce (and thus how valuable) the available data are for making statistically robust comparisons of today's conditions versus yesterday's. For example, quantifying changes in primary and secondary productivity cannot immediately follow the spring retreat of sea ice because previously the ice itself precluded ship-based measurements at locations and times now ice-free. Across the study region, even 15 years of annually collected data is an unusually long time series, and for biological parameters most of these data are confined to summer months. Hence, it is important to learn to distinguish surprises from completely new observations.

A cascade of effects through an ecosystem may include tipping points governed by positive feedbacks for individual components, making recovery to the previous structure and function ever less likely (e.g., 34,46). Top-down changes such as increased predation may result from bottom-up changes such as the removal of thermal barriers to range expansion of predators. The experience to date in the Pacific Arctic by itself will not resolve these questions, but it does suggest that, with regard to cascades versus tipping points or top-down versus bottom-up controls (e.g., 47), ecosystem transformation may be a complex matter of "both and" rather than a simple dichotomy of "either/or."

These questions are more than a curiosity (48). The well-being of coastal communities and the management of human activities in the region, including potential commercial fisheries, depend on reliable information and insight into what is likely to happen next. In Alaska waters, industrial and research activities are planned in ways to reduce interference with Alaska Native subsistence harvests, and conscientious vessel operators communicate with communities and adjust their plans to avoid areas where hunters are active (e.g., 49). Growing uncertainty about the timing of animal migrations and optimal harvest conditions increases the likelihood of conflict and concerns about food security. Coastal communities are likely to face difficult choices between capitalizing on increased economic opportunity and limiting industrial interference with subsistence activities.

The profound shift in ecosystem state and conditions suggest a new framework is needed to replace the paradigm that served well in recent decades. The Pacific Arctic marine ecosystem

transformation is not an isolated case. Social-ecological systems worldwide are facing similar pressures from changing physical conditions, with implications that are increasingly uncertain as transformation propagates through the food web and to human outcomes (50). Long-term and multi-scale data are necessary to detect, examine, and respond to such changes. A better understanding of the nature of system transformation will help humans detect transformations earlier, perhaps in time for more effective response or adaptation, even if prevention may no longer be possible.

Data Availability

All data collected as a part of the North Pacific Research Board's Arctic Integrated Ecosystem Research Program (Arctic IERP) are being curated and preserved. Because the research is actively ongoing, the data are under program embargo through July 2021. At that time, all Arctic IERP data will be publicly released with a CC-0 license from the Research Workspace DataONE Member Node, and this paper will be cited in the DOI for those data, to create a formal link. In the interim, please contact the authors for access to Arctic IERP data.

In Figure 1, we acknowledge the use of imagery from the NASA Worldview application (https://worldview.earthdata.nasa.gov/), part of the NASA Earth Observing System Data and Information System (EOSDIS). Ice-edge marking is from Maslanik, J. and J. Stroeve. 1999. Near-Real-Time DMSP SSMIS Daily Polar Gridded Sea Ice Concentrations, Version 1, F17. Boulder, Colorado USA. NASA National Snow and Ice Data Center Distributed Active Archive Center. doi: https://doi.org/10.5067/U8C09DWVX9LM. Accessed 12-December-2018.

2015 epifauna data are available at https://doi.org/10.25921/b2g4-bs86.

Other data are available on request, pending curation and archiving as part of ongoing studies.

Acknowledgments

- Much of the research reported here and preparation of the manuscript was conducted under the Arctic Integrated Ecosystem Research Program (Arctic IERP; http://www.nprb.org/arctic-program/). This manuscript is Publication Arctic IERP-014. Funding for the program was provided by North Pacific Research Board, the U.S. Bureau of Ocean Energy Management, the Collaborative Alaskan Arctic Studies Program (formerly the North Slope Borough/Shell Baseline Studies Program), and the U.S. Office of Naval Research Marine Mammals and Biology Program. Generous in-kind support was provided by the U.S. National Oceanic and Atmospheric Administration (NOAA; Alaska Fisheries Science Center and Pacific Marine Environmental Laboratory), University of Alaska Fairbanks, U.S. Fish & Wildlife Service, and the U.S. National Science Foundation. The findings and conclusions of this paper are those of the authors and not necessarily those of the agencies and organizations with which the authors are affiliated or which provided support.
- This manuscript is a contribution to the U.S. Marine Biodiversity Observation Network (MBON), the U.S. Integrated Ocean Observing System, and the Group on Earth Observations Biodiversity Observation Network (GEO BON). The work and publication were partially funded under the U.S. National Oceanographic Partnership Program (NOPP) through NOAA award # UAF NA14NOS0120158 Arctic Marine Biodiversity Observing Network (AMBON), with contributions from NOAA, the U.S. Bureau of Ocean Management (BOEM), Shell Exploration & Production under management of the Integrated Ocean Observing System (IOOS), as well as contributions of U.S. National Science Foundation (NSF) grant #1204082.

- We are grateful for the contributions of many colleagues to the research and writing of this paper, including Gay Sheffield.
- This paper is PMEL contribution # 4917.
- Collections of fish specimens were made under the auspices and terms of Scientific Research Permit numbers 2012-11, 2013-8, 2017-2 and 2019-7 issued by the NOAA's Alaska Regional Office and permit numbers CF-12-005, CF-13-016, CF-17-023, and CF-19-018 from Alaska's Department of Fish and Game.

Author Contribution Statement

HPH, SLD, FKW, EF, CL, and KS developed the idea and contributed to writing and editing the paper. MB, PB, JJC, ADR, DD, JCG, KI, DGK, KK, RL, LQ, PS, DS, and CW wrote sections of the paper and contributed to editing of the manuscript. All authors provided data and reviewed the final manuscript and approved it for submission and publication.

Competing Interests

The authors declare no competing interests.

General Discussion

The main results of the Chukchi Coastal Communities component of the Arctic IERP have been presented in the chapter that consists of our manuscript accepted by *Arctic*. That chapter also includes a discussion of the results of our work, which we will not repeat here. Instead, this section will discuss the role of the Chukchi Coastal Communities component with regard to the Arctic IERP overall.

The Arctic IERP focused on changes to the marine ecosystem of the northern Bering and Chukchi Seas, Alaska. These changes were studied in various ways, from physical changes (sea ice, water temperature, etc.) to biological and ecological ones (energy flow through trophic levels, distribution and abundance of various species, occurrence of harmful algal blooms, etc.). Much of this research was carried out from research vessels operating in the region, with additional data gathered from instruments moored or deployed during the cruises and recovered later. Partly in the interest of avoiding interference with subsistence activities, much of the oceanographic work was conducted beyond core hunting and fishing areas of the coastal communities.

Basic patterns of change were evident and consistent throughout the region, as described by coastal residents. Ice formed later and melted earlier. Waters were warmer in summer than they had been in previous times. Fishes, seabirds, and marine mammals shifted their distribution, the timing of their migrations and movements, their behaviors, and their abundance. The meetings of the Chukchi Coastal Communities component team helped connect experiences and observations among the participating communities, again illustrating how widespread the changes were and how they affected all aspects of the ecosystem. The details documented by the ship-based research helped show how such changes extended throughout the study region. The convergence of information from different sources, as we saw in the Arctic IERP, has shown that changes are as extensive.

The main opportunities to share information between the ship-based teams and the coastal communities team came during the Arctic IERP PI meetings. The agendas for the meetings provided time for interactions between the two groups. Additional informal interactions occurred during breaks and outside the formal meeting. These interactions were effective in creating shared understanding. In addition, the Chukchi Coastal Communities team created an annotated bibliography of sources of LTK for the study region, which was made available to all other PIs. The Coastal Communities team also surveyed other PIs about their specific interests in what might be available from LTK. We are not aware, however, of how much these resources were used by the other PIs.

The Chukchi Coastal Communities component plan was designed based on experiences in the Bering Sea Project (2008-2013) and in light of a comparatively modest budget for community-based research within the Arctic IERP. Specifically, we decided not to pursue original research in coastal communities for two reasons. First, much research of this kind has already been done, and there is resistance from Alaska Native Tribes and communities to additional projects that appear to repeat what has already been done and which place additional demands on community residents to take part in gathering information. Second, the funds available to the Chukchi Coastal Communities component did not allow for extensive research in multiple communities, which would have limited the breadth of coastal community participation.

Accordingly, we decided instead to engage coastal community residents in analyzing the available information. This innovation served two purposes. First, we could involve several communities along the coast from Savoonga to Utqiaġvik. We had planned on nine communities, and in the end eight were able to participate. Second, the coastal residents would participate not simply as sources of information, but

also as analysts of that information. The movement towards co-production of knowledge, in which western-science trained researchers and community members work as partners throughout a project, involves among other things emphasizing equity among knowledge systems and team members to, in part, divest ourselves of hierarchical roles in research. Our approach attempted to provide for the full engagement of all participants in all aspects of the work.

Our initial results were promising. Team meetings in March 2017 and March 2018 generated a great deal of information and insight as well as enthusiasm among the participants. Both meetings were held in conjunction with PI meetings, helping to create a sense of belonging with the larger group. After that, unfortunately, other events intervened in our plans. The federal government shutdown in early 2019 forced us to cancel our plans for another team meeting that winter. The missed meeting robbed us of both momentum and continuity. Also during this period, some of the participating organizations in our project underwent personnel changes. In some cases, the individuals who took over the positions were willing to engage enthusiastically with the project. In other cases, less so. In January 2020, we held another team meeting, with a high degree of turnover from the previous ones, but still considerable enthusiasm for the effort overall.

Then COVID came, along with further personnel changes. COVID prevented additional in-person meetings for the duration of the project. While we were able to complete our major research paper, which addressed our hypotheses and fulfilled our commitments to the Arctic IERP, we were unable to take on additional work that we had hoped to do. For example, we had begun discussions with the larger PI group about a comparative analysis of the hazards that a changing environment poses for coastal communities. Without deep engagement and collaboration with coastal community members, however, such an undertaking was not possible. We tried virtual meetings, but found them unsatisfactory for this purpose. Additional personnel changes at one of the participating institutions, combined with the fact that the project was wrapping up, led to that region effectively dropping out of the project in mid-2020, though individuals continued to participate, including being co-authors of our *Arctic* paper.

We provide this history as context. The Chukchi Coastal Communities component of the Arctic IERP fulfilled its primary purpose. Engaging community members in analysis and interpretation of observations proved to be a valuable technique. The information already documented from coastal communities was a sufficient foundation for our work. What we missed, due in large part to the unexpected events noted in the previous two paragraphs, was further opportunity to interact with researchers from other components of the Arctic IERP. It is possible that those interactions may have led to additional collaborations. We are frustrated that circumstances prevented us from finding out where things may have gone.

Our experiences suggest a few considerations for future IERPs and also the synthesis phase of the Arctic IERP. First, as we also experienced on the Bering Sea Project, there is no substitute for repeatedly getting together when it comes to building relationships. Annual meetings were sufficient, but longer intervals made things more difficult. Making time during the meetings for a variety of interactions was also important. Time is always at a premium in PI meetings. Cross-cultural and cross-disciplinary relationships, on the other hand, need unstructured time to see where conversations and ideas will go. It is to the Arctic IERP's credit that the PI meetings included some time for exploratory conversations. Unfortunately, there was often insufficient time to see where those conversations would lead, especially in cases of challenging cross-cultural communications, and the inability to meet during the COVID era meant that conversations that had begun could not be continued. We are not sure what the solution is, but we do believe that the external disruptions to the PI meeting schedule exacerbated any communication problems during the Arctic IERP.

Second, collaboration needs to be an active process throughout a group effort. We provided the annotated bibliography of LTK sources, but this was insufficient on its own. It may be the case that the information from those sources simply was not pertinent to the interests and needs of the PIs from other components of the program. It is likely, however, that more intensive collaboration was required to develop specific research questions, identify relevant sources of information, interpret that information in light of the research questions, and present the findings of the joint effort. Because such collaborations often develop after the overall program is underway, it is difficult to budget for them at the start of a project. The synthesis phase of the Arctic IERP presents one option for pursuing such ideas, but it requires waiting for that phase to begin and also writing a separate proposal for the resources needed, both of which can sap momentum from a budding collaboration. Building time into the initial budget is another option, if the PIs are willing to forgo other tasks to leave the resources available and if program managers are willing to allow a portion of the budget to be flexible for these types of relationship building and collaboration.

Third, research and outreach are different activities. The Chukchi Coastal Communities component involved community members, but their time was committed to the role of researchers not community liaisons. The conflation of community-based research and community outreach is unfortunately widespread in the scientific world. Social science research is often conflated with community outreach as well. We appreciate that all researchers in the Arctic IERP had an obligation to contribute to outreach efforts, but such expectations need to be clearly communicated from the outset and budgeted accordingly. Strong community outreach takes as much time, effort, and preparation as other elements of the overall research enterprise. Expecting community members who participate in a program such as the Arctic IERP to take on this extra duty is unfair and also a poor substitute for properly supported outreach carried out by those with the appropriate connections, expertise, and experience.

Fourth, the benefits of participating in a program such as the Arctic IERP need to be made clear to communities from the beginning. In this case, ‘from the beginning’ means when conceptualizing and planning an IERP effort. This should involve including Tribal representatives and community members from the IERP area in the actual IERP planning efforts. It is not possible to create an IERP that meets the needs of multiple groups/communities/stakeholders without them being involved in the development of that IERP. It is also not possible to foster true and meaningful co-production of knowledge (if that is one of NPRB’s goals) without this early and ongoing involvement in questions such as: Is an IERP in X area needed? What are the topics or themes the IERP should focus on? Who will be involved in soliciting proposals (i.e., will there be, and what kind of, outreach to organizations that don’t conventionally submit proposals? What are the criteria for proposal review and who will be involved in reviewing proposals? etc., etc.). Contributing to the scientific enterprise is undoubtedly valuable, but may not be fully satisfactory to those concerned first and foremost with the well-being of their communities, and may not be sufficient motivation to engage fully and enthusiastically with a research program or project that communities have not been meaningfully involved in developing. Doing so will not happen as the result of a single community meeting, but will require extensive interaction, learning from experience, and a willingness to invest fully in community engagement and co-production.

Application to Resource Management and Alaska Communities

Rapid environmental change, such as that found by the studies in the Arctic IERP, poses considerable challenges to resource management and to coastal community well-being. In terms of resource management, our findings show also that regional human activity causes environmental change in addition to larger processes such as a warming global climate. For example, a regional increase in vessel traffic can affect the distribution of marine mammals on short and long time scales, depending on the duration of the disturbance. Although large-scale commercial fishing does not occur north of the Bering Strait at present, increased activity in the northern Bering Sea and experiences elsewhere have made many coastal community members wary of additional ecological and social changes if fisheries continue to move northwards. Resource management needs to take into account the combined effects of various forms of change and disturbance. At present, different forms of human activity tend to be managed separately. Fishing, shipping, and offshore petroleum development are managed in different ways by different agencies, albeit with efforts to consider cumulative effects. Still, more work is needed to understand the complex interactions that create outcomes, especially in a time when widespread environmental change is happening even more rapidly than was expected when the Arctic IERP began.

For coastal communities, our findings reflect and document much of what their residents have already experienced. Sharing of information among the eight communities involved in our project (in a way that is different from how information is typically shared) was valuable in contributing to team members' overall understanding of the extent and type of change occurring throughout the region. Thinking about the various forms of environmental change also helped illustrate how much is occurring in the region, a perspective that may not be apparent when focusing on one form of change or human activity at a time. Furthermore, societal change cannot be separated from environmental change when it comes to community-level effects and responses. Community leaders must pay attention to all the challenges facing their communities and must understand how those challenges interact with one another. Key conclusions of the Chukchi Coastal Communities component are that the practice of traditional values remains essential to community well-being and that Indigenous leadership is necessary for responding to change in ways that will sustain overall community well-being. An additional point is that equitable partnerships between communities and scientists can facilitate valuable two-way information exchange, including information that can be used by communities as they determine how best to respond to change.

Directions for Future Research

Our research has shown that more research is needed to understand the details of how coastal communities respond to change. Much work has been done to document the changes that are taking place, but far less has been done to understand the actions communities take in response and the degree to which those actions contribute to sustaining community well-being. Our paper in *Arctic* shows that there are a range of responses that communities are making, consistent with prior research. Still, understanding *what* is being done is not the same as understanding *how* and *why*. Such information can be valuable for other communities experiencing change, and also for those making decisions that affect community, region, and ecosystem well-being. Participation in research and management activities is time consuming and demanding, and those burdens are only increasing for coastal communities. Making the most of the effort expended will be important for sustaining their involvement and their ways of life.

As mentioned earlier, one potential research effort to consider is an appraisal of the various hazards coastal communities face from a changing environment. From greater storm exposure due to loss of sea ice to harmful algal blooms to shifting distributions of species harvested for subsistence, communities must weigh many demands on their time and attention. The various hazards also create different forms of risk, from loss of life and limb to infrastructure damage to changing harvests and diets. Comparing these hazards in terms of severity, urgency, and other factors is not a trivial undertaking. The comparison is also one that cannot be done by others on a community's behalf, but must fully involve the community from start to finish, from conceiving of the project and its scope to sharing the results in ways that do not cause additional harm through misunderstanding or stigmatization. Done well, such an effort could be valuable to community leaders as well as others whose work affects community well-being.

In addition to topics for future research, our project suggests an approach to be continued in future work. That is, the engagement of coastal community members in analysis and interpretation of information. This happened to some extent and largely incidentally in the Bering Sea Project, and by design to a far greater extent in the Chukchi Coastal Communities component of the Arctic IERP. We recommend using approaches like this to an even greater extent, extending also to sharing results in formats that are effective in reaching coastal community audiences and beyond. By this we do not mean outreach on behalf of the entire program, but specifically conceiving and generating products that present the findings of the project or projects for which community members have served as researchers. In other words, we recommend further progress towards the full and equitable engagement of community members in research that involves them, their communities, and their environment (i.e., their traditional lands and waters, as well as contemporary use areas, if those differ).

Synopsis

"We never get stuck": How Chukchi Coastal Residents Are Dealing with Change

Why We Did It

Rapid changes are happening in the Arctic, including in Alaska's Indigenous coastal communities. The climate is warming, ecosystems are shifting, and cultures and societies are facing new and increasing stresses. At the same time, traditional values remain strong and vital. Our question is how coastal communities can remain resilient in the face of all that is happening.

Arctic communities have always had to respond to environmental variability. In contemporary times, they have also faced the long-term effects of colonization. The continued effects of colonization can be seen through the dominant society's policies and practices surrounding, for example, governance, education, and 'resource' management and access. These effects intersect with rapid warming of the ocean, air, and land. Community well-being depends on connection to and understanding of the environment and having the ability and authority to respond effectively to change. Our team of coastal community residents and researchers sought to understand more about these experiences and how communities can act to sustain their communities, cultures, and livelihoods.

What We Did

We formed a team of academically trained researchers and coastal community residents to analyze information together. We met several times during the course of the project to review what has already been documented, record additional observations, and look for patterns and lessons. Our approach fostered discussions among people from different coastal communities, leading to new insights and connections.

The study region and the communities that were involved in the Chukchi Coastal Communities component of the Arctic IERP. Map from our 2021 paper in Arctic.

What We Learned

For coastal community residents, the nature of the changes they are seeing and experiencing is more important than classifying them into different sources of disturbance. What matters is the effect of those changes on people's activities. Not surprisingly, long-term changes have long-term effects, and short-term changes have short-term effects. Coastal residents have responded to those changes in many ways, from shifting the timing and location of some food harvesting activities to harvesting new species. In addition to sovereignty in decision-making, coastal community team members emphasized the importance of one's attitudes toward change, especially a willingness to be flexible and innovative. The more power that Tribes and communities have to respond as they see fit, the more resilient they will be.

Why It Matters

Coastal communities are seeing many types of change in their waters, from loss of sea ice to harmful algal blooms. Understanding how those various changes may pose risks, and how those changes affect each other is important, as is determining how to respond effectively. Environmental changes are occurring along with extensive societal changes, too. None of these changes can be treated in isolation. Further research partnerships should consider best practices for equitable collaborations with communities, how best to share scientific information with partner communities, and how to assess and respond to the risks that are identified.

Acknowledgments

We thank the North Pacific Research Board for funding and support of the Chukchi Coastal Communities component of the Arctic Integrated Ecosystem Research Program. We thank the North Slope Borough for additional funding to support the participation of North Slope Borough and Northwest Arctic Borough team members throughout the project. We thank all who took part in our team meetings, including Lucinda Wieler and Niviaaluk Brandt, former project Research Assistants at Kawerak; Orville Ahkinga, Dora Ahkinga, Opik Ahkinga, and Frances Sistuq Ozenna from Diomede; Raymond Lee Jr. from Buckland; Noah Naylor, Cyrus Harris, Siikauraq Whiting, and John Chase from Kotzebue; Billy Lee from Shungnak; Millie Hawley and Alexis Hawley from Kivalina; Steve Oomituk from Point Hope; Willard Neakok Jr. from Point Lay; and Qaiyaan Harcharek, Billy Adams, Michael Donovan, Brower Frantz, Nicole Kanayurak, and Robert Suydam from Utqiaġvik. We also thank all participants in the Arctic IERP for engaging with the Chukchi Coastal Communities team to create a collaborative atmosphere for the program.
